Where—we are tempted to enquire—where did this modest, truthful, honourable, gentlemanly exemplification of the want of worth—this Fellow of the College he abused—where did he learn his peculiar, his *very* peculiar manners and morals? The confidential medical adviser of the discharged footman, the journeyman joiner, and the broken-down clerk, who formed the respectable Direction of the West Middlesex Insurance Company—the consulting physician to this low-lived gang of obvious swindlers—was he a master or a scholar in their promising school? Did he learn, or teach, there, those elevated practices which give him, in a profession marked by all kinds of anomalies, a circle of distinction so peculiarly his own? We should have concluded in asking, if no amount of newspaper exposure—no magnitude of general snubbing—no extent of enforced isolation —no severity of repeated horsewhipping—could shame or terrify the "Fellow" into common decency, common sense, common honesty; but remembering that at once atoning and explanatory cause—his useful monomania of the Reflex Functions—we exclaim,—Alas! poor man! would that he had some friend left—some strangers' charity yet unalienated—that, now, that he has told what he has picked up on the Nervous System, he might be shrouded from public view, and protected from himself, in some friendly asylum, where, enjoying the novelty of innocuous repose, he might feel the benefit of that moral restraint, the object of so many of his prescient laudations, and the highest fortune that can now await him.

CORRESPONDENCE WITH MR. WAKLEY.

In reference to the reply sent, as before mentioned to the *Lancet*, we have had the following correspondence with Mr. Wakley.

(No. 1.)

Mr. Wakley has to-day received a communication, without date or address, signed "the Editor of the MEDICAL TIMES," and accompanied by two notes, signed T. Piers Healey, and H. Gregory. If the author of the communication will append his name and address to it, Mr. Wakley will insert the letter and notes in the next number of the *Lancet*, to the editor of which journal the communication is addressed.

35, Bedford Square, Dec. 19, 1842.

(No. 2.)

Medical Times Office, Dec. 19, 1842.

The editor of the MEDICAL TIMES, happy to find that nothing but proof of the genuineness of his letter delivered this morning to Mr. Wakley is required, to insure its insertion "in the next number of the *Lancet*," hastens to enclose a document which will remove every doubt on that subject. The absent date should be Dec. 17, the address Medical Times office.

ENCLOSURE.

Sir,—I beg to give you my personal assurance that the letter delivered to you this day, and referred to in your note of the same date, is the genuine letter of the editor of the MEDICAL TIMES, and further, that the letter signed H. Gregory is a copy of one written by the reporter of the MEDICAL TIMES, as that signed T. Piers Healey is a veritable copy of one written by myself. I moreover offer myself as personally responsible for the truth of every statement in the said letter of the editor of the MEDICAL TIMES.

I have the honour to be Sir,
Your obedient servant,
(Signed) T. PIERS HEALEY.

Essex Street, Dec. 19th.

(No. 3.)

"The editor of the MEDICAL TIMES" cannot fail to perceive that he has not complied with the request contained in the note of the editor of the *Lancet*, dated yesterday, namely, that he would authenticate with his name the communication to which reference was made by the editor of the *Lancet*.

35, Bedford Square, Dec. 20, 1842.

(No. 4.)

The editor of the MEDICAL TIMES is at a loss to know *why* he should confide his name to Mr. Wakley's keeping, when that "authenticity" Mr Wakley seems anxious for, has been placed beyond all doubt by Messrs. Healey and Gregory's attesting the accuracy of the communication with their names; and by the former gentleman's honoring Mr. Wakley with the assurance, that he took upon himself the responsibility of all the statements and opinions expressed therein by the editor of the MEDICAL TIMES.

The communication being evidently from Mr. Wakley's offer of insertion, not unsuited for publication in the *Lancet*, there being—as may be presumed from the same offer— and

which indeed is clear on the face of the communication, a claim in justice, and "honest English fair play" for its insertion—"the authenticity, also, which was asked, being" furnished, backed moreover, by what was masked, the personal responsibility for every statement, of a highly respectable member of a learned profession; the editor of the MEDICAL TIMES cannot explain why anything else—save under a misunderstanding—*can* be asked except in the supposition, that Mr. Wakley has been *diplomatizing* to escape with some grace an act of common justice and 'honest English fair play," by demanding as a preliminary what he felt was unnecessary, and knew would not be conceded

If not favoured with a satisfactory reply in the course of to-morrow, the editor of the MEDICAL TIMES will feel it necessary to insert this correspondence in the next number of that Journal.

Medical Times Office,
December 20th, 1842.

SPASMODIC STRICTURE OF URETHRA, RETENTION OF URINE, AND PUNCTURE OF THE BLADDER ABOVE THE PUBES.

By W. SMITH, Surgeon.

(For the 'MEDICAL TIMES.')

PRIVATE ROBERT MITCHELL, hospital corps, British auxiliary legion, at St. Sebastian, after indulging a little too freely with liquor on the forenoon of the 5th of May 1837, was seized with symptoms of retention of urine in the evening. These at first, however, gave him little trouble, as he had been subject during these last few years, on occasional and similar debauches, to similar attacks. During these attacks, he stated that it had been frequently attempted to pass the catheter, but uniformly without success; and under these circumstances, the effects of the spasm had always been subdued, and a discharge of urine produced by fomentation or the warm bath. As these means had not even always been necessary—the bladder having not unfrequently after considerable distention evacuated its contents with more or less difficulty at a longer or shorter period—the patient, who was himself at this time an orderly in the hospital of St. Telmo, made no application to the orderly medical officer during the night, nor until the visiting hour next morning, when he was seen by Surgeon Docker and myself, as he was attached to the same department of hospital in which we were engaged.

Fomentations were now assiduously applied to the abdomen, from nine till half-past ten a. m. without any relief. The pain from distention of the bladder was becoming more and more severe, and the anxiety and restlessness of the patient increased in the most remarkable manner; whilst the tension of the abdomen and swelling of the pubic region continued to augment more and more. He was now bled to the extent of ℔ii., which produced partial syncope, but even after the lapse of half an hour was followed with no beneficial effect whatever upon the stricture. At half-past eleven three grains of opium were administered, and at midday, warm fomentations to the pubic region were reapplied, and continued for two hours, with similar ineffectual results as before. I now reported the case to Mr. Alcock, the deputy inspector general of hospitals. During the progress of the above treatment, I had frequently attempted to pass both metallic and elastic gum catheters of various sizes, without being able to reach the bladder; and Mr. Alcock, on examining the case, tried the introduction of the smallest sized bougie unsuccessfully. Surgeon Wilkinson was now ordered to superintend the treatment of the case, and we jointly agreed to place the patient immediately in the warm bath. Before placing him into the bath, we administered—antim. potassio-tart. gr. ii., solut. murph. acetatis, ℞ xxx. He remained in the bath one full hour, and was taken out at the end of that time in a complete state of insensibility. Every muscle of the body was apparently in a state of passive relaxation; yet the patient, either by nature or art, had hitherto been unable to pass a single drop of urine. The flaccid state of the muscular system, and the enlarged size of the abdomen, now equally distended from the ensiform cartilage to the pubes, caused the patient much more to resemble a woman in the ninth month of utero gestation, than a man afflicted with simple retention of urine, arising from spasmodic stricture of the urethra. The swelling of the abdomen had apparently increased a hundred per cent., during his stay in the warm bath; but the apparent enlargement was, no doubt, owing more to the passive state of the muscular system than to the augmentation of the quantity of urine, which the kidneys would be able to have secreted in one short hour. The pulse when taken out of the bath was small, wirey, and trembling, and it numbered, on examination, one hundred and thirty in a minute. In this state of matters, all chance of saving the patient by medical means now seemed at an end; and as the necessity of puncturing the bladder at one point or other seemed inevitable, it again became our duty to re-report the case as it now presented itself, to Mr. Alcock, who was still upon the premises. On relating the facts as above, Mr. Alcock re-visited the ward, and immediately determined on puncturing the bladder above the pubes.

The patient was still lying on his bed in a state of insensibility, and as it was now about four p. m., he had passed no urine for a period of about twenty-eight hours. Mr. Alcock, with a small sized trocar, pierced the parietes of the abdomen in the centre of the linea alba, immediately above the pubes, and penetrated the bladder. On withdrawing the trocar, five pints of urine were drawn off by means of the cannula, of a clear aqueous appearance and the distention of the abdomen soon receded to its normal state. After thus evacuating the contents of the bladder, the cannula was immediately withdrawn, and the wound closed with adhesive plaister; neither was it deemed necessary to try to pass a catheter through the urethra into the bladder.

During the operation, which Mr. Alcock performed in the most dexterous manner, the patient was as insensible to pain and the influence of external objects as if he had been under the influence of mesmerism. Ten minutes after the bladder was emptied, he began to talk incoherently and toss his extremities in the most frantic manner in all directions. In a few minutes more he became completely convulsed; his countenance assuming the most daring and furious appearance, whilst he swore most heartily. The ferocity of the countenance, however, after twelve or fifteen minutes, gradually relaxed into a mild sympathetic appearance; and the *convulsions terminated in involuntary discharge of fæces.* It has been truly said that pleasure and pain are relative terms, and that without the occasional visitations of the one, we should be ill able to appreciate the transcendent felicities of the other. In the full period of my professional life I have never seen the truth of this more completely exemplified than I did in this case. No sooner had consciousness returned, than the patient expressed himself as then enjoying the happiest period of his existence, stating his feelings to be equal to all the enjoyments of heaven, at the same time that he thanked us a thousand times with genuine sincerity, and said we had relieved him from the cruelest torments of hell. This felicity, however, at the maximum, became less and less appreciable, and gradually subsided into what may be termed the truly comfortable, until about seven in the evening, when he fell asleep.

Having given the necessary directions, he was left to the enjoyment of repose, and I saw him again at ten o'clock. I was then informed that he had slept calmly for three hours. He awoke whilst I was standing by his bed, and I found him perfectly collected, without pain on pressing the abdomen, with moist skin, pulse weak and wirey, numbering one hundred a minute. He had had no passage, from a laxative glyster, exhibited before seven o'clock, and I administered immediately, for the purpose of acting on the intestinal canal, ol. recini ℥iss. I now left him, and ordered,—℞. antim. potassio-tart. gr. 10; mag. sulph. ℥ii.; aqua tent. ℥viii.; misce et solve, sumat æger cochlea. mag. quaque hora per noctem.

May 7th, 1 A.M.—Has had since I saw him last one copious stool.

7 A.M.—Has had another copious stool; and about one hour ago had made water per urethram to the quantity of ℥xii., felt during the passage of the urine a little scalding in the course of the urethra, and slight pain over the pubic region, which gradually became inappreciable, after a lapse of fifteen minutes. Skin moist, tongue clean, no pain on pressure of the abdomen, pulse one hundred and ten, hard and small, but has passed on the whole a good night, and slept well. I now performed venesection to the quantity of ℥xii., and during the operation the pulse fell to ninety, becoming at the same time more soft and natural. The same saline solution I ordered to be continued, notwithstanding that he had a little retching once or twice during the night from the effects of the medicine.

6 P.M.—Has had two stools during the day, tongue clean, abdomen free from pain, pulse one hundred, but soft.

May 8, 10 A. M.—Pulse eighty, of healthy character, tongue clean, skin moist, makes water naturally when required, but the scalding of the urethra continues on passing urine.—Continue as before.

May 9th, 10 A.M.—Symptoms favourable, pulse seventy-five, continue saline medicine every fourth hour

May 10th, 10 A.M.—Pulse sixty, functions natural. Remit medicine altogether.

May 13th.—Mitchell is now able to work today in the hospital square with the other convalescents.

May 16th.—Continues doing well, the wound in the abdomen not yet cicatrized, but has no inconvenience from it, never passed any urine by it

May 20th.—Wound of the abdomen healed, and the patient fully recovered.

INJURIOUS DYE FOR THE HAIR.—Dr. A. Th. Bruck, of Osnabruck, thinks that a violent ophthalmia, under which a lady of 40 was labouring, might be attributed to a dye which she had used during several years for her hair. It is sold at Cologne under the name of *Poudre d' Italie*, and has been shown, by chemical analysis, to consist of lead and lime.

EXTRACTS FROM FOREIGN JOURNALS.

(From the Berlin, Medicinische Zeitung, for the 'Medical Times.')

GERMAN.—*Epidemic Scarlatina, in the Circle of Pillkallen, in the years* 1841-42.—(DR. ASMUS.)—From July, 1841, until the middle of the winter of 1842, scarlet fever reigned in the above circle in a very strange manner. It was mild on its first commencement—children ran the streets with sore throats and eruptions, without being aware of the fearful disease which had visited them: the disease was often confined to a slight sore throat of an hour's continuance, and no one had perceived its nature, had it not been followed by dropsy or furfuraceous exfoliations. After having observed with attention many hundred cases in several epidemics, I agree with most physicians, that the scarlet eruption is an essential symptom of scarlatina in the greater number of cases, but I cannot entirely allow that it is always so. Some very anxious patients, who considered a trifling and almost momentary difficulty of swallowing of sufficient importance to consult a physician, being advised carefully to observe their skins, they perceived as well as myself only the slightest redness and the conception that scarlet eruption was present, only for an hour, appears to me too arbitrary. In such cases, if an abundant diuresis did not occur as a means of prevention, dropsy as a rule used to follow; and one might, with the highest probability, foretell that leucophlegmatic affections would follow where the eruption appeared but lightly, when otherwise the fever was of any significance.

These mild symptoms in a large number of sick maintained themselves only a short time, and even during this not throughout: here and there, swelling of the tonsils occurred so violently, that it was necessary, in pressing cases, even almost daily, to make deep incisions in the swollen velum and posterior wall of the throat, to prevent suffocation. Now, also, slight symptoms of encephalitis showed themselves, and very young children died after parotitis had devolped itself. This appears to have taken the place of scarlatina in children, for a few weeks or even months; for where a whole family suffered from scarlet fever, the youngest children, as a rule, fell victims to it.

After four weeks, scarlatina continued no longer to disguise its proper symptoms. The eruptive fever became more lively, and symptoms of encephalitis occurred more frequently. Gastric mixed affections were seldom remarked, and in any very apparent gastritic devolopment if any one thought it right to administer an emetic to allay any gastritic symptom, he quickly regretted it, on account of its effects on the brain; so that after an unfavourable experience of the employment of vomits, I abstained from their use during the whole course of the epidemic. This disposition to inflammatory affection of the brain, in the course of this disease, was so great, and all that produced congestion in the head so injurious, that I must deplore having given an emetic in a case of membraneous cynanche. It was a child three years old, which, in my morning visit, after having left it the evening before in a very satisfactory situation, a very cold north-east wind had blown and I found a membraneous cynanche developed. The cough had, according to his parents, commenced about midnight. An emetic now administered did not operate—great anxiety came on—the child became delirious—his reddened eyes almost started from his head—strabismus and convulsions supervened—and the child did not survive the emetic four hours.

After eight weeks the occurring cases were in part newly distinguished by the angina, and these were the most favorable, or the first symptom of scarlatina was sickness, with the perfect possession of the intellect; pain of the head was not long absent, and quickly accompanied with delirium; for the most part (with reddened eyes, outward strabismus, and very contracted pupil) the eruption effloresced; that in very bad cases appeared equally in the first hours of the disease; and with the formation of the scarlet eruption on the skin, to the most intense and extensive scarlet redness, the inflammation of the brain rapidly increased. As the sudden disappearance of the eruption was of great importance, so could one not rejoice upon its continuance: it often remained completely developed until death.—Where medicine did not affect any good, the children died during the height of inflammation, before the symptoms caused by effusion on the brain had made their appearance; I saw effusions only twice in the course of the epidemic.

After a few weeks, although the disease was less frequent, yet it showed itself the more malignant. A sore throat was now a wished-for symptom; every case commenced with cephalitic irritation, which quickly increased to delirium. Should help not be quickly given in this space of time, the persons attacked died immediately. Dropsy after scarlatina, appeared throughout the country. This infectious disease was spread more by the clergy and teachers than from natural causes, in spite of me. Dropsy of the cavities of the brain frequently occurred, and I must most determinately distinguish these from exudation arising during inflammation of the brain. This disease which till now was new to me, appeared in the following manner:—Those individuals affected with irritation of the brain, recovered apparently, got up, felt themselves well, and took their food with appetite; they frequently took cold which, in some cases observed by me, they had anxiously avoided. After five, six, fourteen, or more days, the eyelids first began to swell; they (the sick) had a swollen appearance—slight delirium occurred, but at intervals, and the sickness which had been so long overcome again showed itself. The patients yet went about, did not totter, but felt themselves only very faint; after some time the swelling at length spread itself over the limbs. Delirium and sickness then increased much, and the patients were anxious to remain in bed, because they could not keep up from weakness. Some of the senses were wanting, more especially the sight, with the intellect undisturbed, if the intercurrent phantasies are not considered. If the patient were asked any question, he answered sensibly, but looked in another direction than that from which the question came: one of my patients, a boy of about twelve years of age, answered to my question, "I see nothing at all, but I hear." The patient died with epileptic or eklamptic fits, after the thread-like pulse had long before become imperceptible. One of these cases presented to me an interesting example of the aura epileptica, and epileptic fits with complete possession of the faculties, although the cause of the spasms lay manifestly in the brain (I will not pronounce the spinal marrow at the same time free from effusion). He had epileptic attacks twelve or sixteen times in the twenty-four hours. Its commencement was announced by a creeping in the points of the fingers, which spread by degrees, and terminated in convulsions, from which followed convulsions in other parts of the body, and at length of the whole body, including the muscles of the face; no one who saw the spasms could distinguish them from ordinary epileptic spasms. The patient, a boy of fourteen, had his perfect recollection, and suffered fearfully; he regularly bellowed, and described the spasmodic pain of the muscles as unbearable, so that an unspeakable anguish came on with the aura, before the spasmodic sufferings again returned. I waited for another attack, and as the aura began to appear, I squeezed the wrists powerfully; the convulsions propagated themselves no farther, and the joy to have found the means of preventing such painful spasms was indescribable, not only in the sufferer, but in the bystanders. Epileptic spasms with perfect recollection without the aura, were lately very frequently observed by me. This was a very evil consequence of scarlet fever; for external remedies even blisters applied to the scalp were fruitless. I am unspeakably sorry that I had not employed opium earlier, of which as restraining the secretion of urine, I had ungrounded fear; as many young lives were preserved by it, which must have died in a lamentable manner. Later I employed diuretic remedies—calomel, digitalis, squills, &c; the combination agreed with the stomach, and was always beneficial; at least no more of my patients died.

The elder patients who were attacked, fluctuated to about forty years of age. New born children and those of a few weeks old, were seldom attacked; when they were, they frequently died with swollen parotids, without marked eruptions. However, the eruption was not without examples in new born children. One case occurred to me, which furnished a proof that scarlatina, like small pox, can attack the fœtus in utero. A woman who had already brought forth four children, lost two of her children when she believed she was near her fifth pregnancy. The delivery followed six weeks after the legitimate term, as fixed by her, and she bore a very deformed, badly-nourished child, which showed no signs of (*partus serotinus*) protracted birth; the entire epidermis from head to foot, came off in great patches—that of the hands might have been drawn off like a glove. It was many weeks before the skin, afterwards sown over with pustules, became normal, the child grew moderately, and became quite sound. The mother, æt. 36, had neither sore throat, nor otherwise any symptom of scarlatina, but immediately after delivery, she became hydropic, and recovered by the use of carbonate of ammonia.

As regards the general treatment, leaches, calomel, cold applications to the head, and effusions over the whole body, were the chief means used, and as I have nothing new to communicate, I therefore confine myself to this sketch. I lament that I cannot, from the circle of this year's epidemic, and my collected experience on it, say a word for the carbonate of ammonia, after all the praise which has been bestowed on it by the German, North American, and English physicians. So much as it has been recommended in brain irritation it rendered me no good service, and where it appeared to have been of some benefit, it remains doubtful whether the same end would not have been obtained even without the employment of every medical means. Even in considerable febrile condition, where local considerations did not require any other medicament, as long as the brain remained free, I resolved to the use of cool treatment, without any other medicament. But in one affection, consequent to scarlet fever, and which hitherto has been the terror of the physician, and where only to my knowledge the ammonia can be praised, I can unconditionally, and without fear of contradiction,

recommend it, namely, in the dropsy following scarlet fever, with exception of that of the brain. Neither calomel nor digitalis, squills, or cream of tartar, or the host of other diuretics, can here render that service which the carbonate of ammonia is able to perform, as two drachms to six ounces of water. The carb. of ammonia operates specifically in the dropsy from scarlat na, and in the most desperate cases, where effusion into the chest is not to be mistaken, it even causes recovery, whilst it, like no other medicine, produces activity in the urinary secretion, and thus in a few days causes a decrease of the effusion. Therefore all thanks to the recommender of this distinguished remedy, and I finally remark that I am not inclined to contradict its good effects in the first stages, when any other epidemic is less disposed to inflammation of the brain than this, which now for months has offered itself to my observation.

MEDICAL EDUCATION.

To the Editor of the 'Medical Times.'

Sir.—I perceive, from your journal of the 10th instant, that the subject of medical education has been occupying the attention of the government, and that it is about to be introduced to the notice of the public in the Medical Times.

If Sir J. Graham really does desire to improve the condition of the profession in this country, the means are simple enough. He has only to adopt the same system as that adopted on the continent,—namely, the "concours." This is the only system which can award to industry and talent its just recompense.

Supposing some great work, which required the individuals occupied in it to be possessed of no other qualification than their superior corporeal force, was necessary to be accomplished, and that many more persons than were necessary, presented themselves as candidates for the employment,—what would common sense dictate as the only effectual means of determining upon the most eligible candidates? The answer to this question would be, that the strength of each person must be proved, and that they who possess most ought to be chosen. Any other means than this would not only be considered ineffectual, but unjust. Now, as knowledge is power, ought not precisely the same plan to be employed in the selection of individuals to fill those situations in the profession which require the best abilities and the greatest quantity? Certainly Sir J. Graham, and every other disinterested man would answer in the affirmative. Another question is, are such means employed in choosing dressers, professors, &c.&c.? On the Continent they are, but in England they are not; and hence we are so much behind our Continental brethren, and justly the subject of their ridicule.

As I have not time to enter into this subject fully, I will make only one comparison between the Continental and English method of election. Those young men who perform some of the minor operations in the hospitals, and execute the orders of the surgeons, are called dressers in the English hospitals, and interns in the French ones.

The interns are chosen from the pupils by public examination, which are so conducted that none but the most intelligent and best informed young men can possibly obtain such situations; they are afterwards, I believe, allowed a small gratuity whilst they remain in the hospital and have their education free of expense. Every year they are re-examined, and receive a preferment according to their superiority. Every Englishman who has visited the Continent knows how much these interns are esteemed in their profession, and after they quit the hospitals, their position of intern entitles them to general respect. Now for the dressers; they obtain their situation merely by paying for it. No account is taken of their anatomical or surgical qualification; so that, if any one should be deficient in this respect, so much more is received by the surgeon for introducing a young man into the hospital, to torture and ill-treat the patients,—or, in other words, the charitable object of the institution is sacrificed to the private gain of the surgeon. This young man, in order to have some equivalent for the additic sum of money which his father has paid for him, receives from the surgeon a certificate of his position as dresser; and hence the same irrational means of gaining admission to sick people, which commenced its cruel operation upon the inmates of the hospital, will afterwards extend its baneful influence to all those who are imposed upon by a certificate which has been obtained merely by money.

The same evil exists in the selection of all medical officers, and it is evident that the bad effects of this evil will be increased in proportion to the elevation of the individual who has been thus recommended to the world.

The object of this letter is merely to excite enquiry, for I prefer that those who are employed in legislation for the profession would doubt the truth of my statements and examine and compare for themselves. As in the exact sciences, so in the science of legislation; we can have no truth without searching for it, and that person will generally obtain most, whose search is most diligent and unfettered by partiality, interest or prejudice.

Veritas.

PERISCOPE OF THE WEEK.

Test for the Adulteration of Æthereal Oils with Alcohol.—The best method of testing, according to Borsarelli, is with chloride of calcium Perfectly dry chloride of calcium dissolves in oils containing alcohol, and forms a liquid stratum at the bottom of the vessel; when but little alcohol has been mixed with them, the pieces change, at least their form, but in pure oils the chloride of calcium remains perfectly unaltered. This has been confirmed by Brande on oil of lemons.—

Quesneville's Ferruginous Effervescing Powders.—Under the name of "*poudre pour eau gazeuse ferrée*," Quesneville sells a powder, of which 16 grammes are placed in a vessel full of water, which is then well corked until the whole has dissolved It may be taken as a chalybeate. Quesneville states the powder to consist of 4 drachms sugar, 1 dr. bicitrate of soda, 18 grs. bicarbonate of soda, and 18 grs. double citrate of iron and soda. Breton found it impossible to obtain thealt ter double salt in a fit state for pulverization, and therefore submitted the powder to a more careful examination. He attempted to separate the constituents mechanically, and in this way obtained colourless acid grains, which proved to be tartaric acid, particles of bicarbonate of soda, and a small quantity of transparent pale green granules, which proved to be the protosulphate of iron. In a quantitative analysis, in which the tartaric acid was determined as a lead salt, the iron as oxide, the soda as sulphate, and the loss accounted for as sugar, Breton found Quesneville's powder to consist of 20 parts bicarbonate of soda, 22½ tart. acid, 1 part green vitriol, and 56½ sugar; there is, therefore, an excess of tartaric acid. Water prepared with the powder made according to the above prescription, had quite the taste of Quesneville's. The bicarbonate of soda and the tartaric acid must not be powdered finely, otherwise they act on each other even in the state of powder.

The Microscope's use in Animal and Vegetable Physiology.—By selecting says Mr. Grainger, some of the more simple or cellular plants, where the typical structure is displayed unobscured by the addition of parts which, in the higher classes, renders the task of investigation so much more difficult, the botanist is enabled, with the assistance of the microscope, to demonstrate that tendency to the spiral disposition of the component parts, which so strongly pervades the vegetable kingdom. If, for example, we examine the different species of confervæ, it will be seen that the organic corpuscles are deposited in spirals —A process evidently of the same kind was noticed by Schleiden, and has since been pointed out by Mr. E. Quekett, in the development of the vascular tissue of the higher plants. The latter observer has ascertained that the membranous tube which precedes the vascular tissue becomes charged with innumerable granules, which, after a short time, begin to adhere to the inner surface of the tube, assuming a spiral direction or form, and thus lay the foundation, as it were, for the vascular tissue. Again, if we watch the circulation of the chara, which, as a microscopic object, almost rivals in interest the circulation of the blood, something of the same kind is noticeable; that is to say, the little globules which indicate the currents going on in each cell of this plant, follow in the larger cells a definite spiral direction, so that while the globules describe curved currents, there are intervals, called by Dutrochet lines of repose, where no motion takes place. In these instances we have an opportunity of perceiving, in its simplest but most evident manifestation, that spiral form which is so eminently displayed in the whole vegetable kingdom.—And here I would remark, that one of the most important principles established by modern research is, that the anatomist, in determining the fundamental character of any organ, must seek for it in the lower forms of organic beings, where the typical structure is displayed in all its simplicity.—Another important addition to vegetable anatomy was the discovery, by Schultz, of the vessels by which the circulation of the elaborated sap, or latex, is accomplished. Previous to these researches nothing could be more unsatisfactory than our knowledge respecting the channel by which that fluid which is to the plant what the arterial blood is to the animal, was carried to the organs which it is designed to nourish. The existence and action of these vital vessels, as they were called by Schultz, have been almost universally admitted; there are, however, some careful microscopic observers who have not been able to satisfy themselves that a true circulation does, in reality, go on in the vessels we are describing. One gentleman possessing a very superior instrument, has repeatedly sought for the currents described, but so long as his observation was confined to the living plant in an unmutilated condition, no motion could be seen; but on making an incision, movements, which were attributed to the escape of the fluids, were observed. Without dwelling further on this point, I would only remark, what is familiar to many who are present, that motions are occasionally seen in fluids which have been mistaken for vital phenomena, although they, in reality depend on physical causes, such as those seen in the red particles when a drop of blood is placed in the field of the microscope, on in the capillary vessels of the frog's foot when severed from the body. —I have now to allude to a series of investigations which have thrown anew and unexpected light on some of the most important laws which regulate the growth or fomation of organized structures. I refer to the natomy and physiology of cells. Although so much has been written upon this subject, brief notice of the discoveries of Schleiden nd Schwann may, perhaps, be permitted on his occasion. The first great truth which tese investigations

have revealed is, that although nature displays infinite variety in the secondary formations of animals and vegetables, yet that in the primary development of the several organs, one form alone, that of a nucleated cell, is observed. The mode of origin of this primordial cell appears to be as follows: the minute granules existing in the primitive plastic, but as yet unformed substance, aggregate together, and so form a small and usually disc-shaped body, which, being the rudiment or origin of the future cell, was called by Schleiden the *cytoblast* or cell-germ, though the term of nucleus, first given to this body by our distinguished countryman, Dr. Robert Brown, is still very generally retained. According to Schleiden, it is doubtful if the cytoblast is in reality the true germ of the cell; for he remarks, that in the cytoblast itself a minute sharply-defined object, presenting the appearance of a thick ring, or thick-walled hollow globule, is observed, which, forming even earlier than the nucleus is called the *nucleolus*. From the surface of the cytoblast there rises subsequently a thin transparent vesicle; and this it is which constitutes the walls of the cell. The celebrated German anatomist, Schwann, has demonstrated that the same identical phenomena which thus occur in the vegetable are also exhibited in the animal kingdom; and thus we learn, that whether a corpuscle of blood, a fibre of muscle, a filament of nerve, or a vessel, is destined to be formed, the foundation of each is a cell containing a nucleus, which, undergoing a series of transformations, may be ultimately converted first into a tube and then into a fibre. This is a brief account of one of the most brilliant discoveries which, perhaps, has ever been made in connexion with the science of organization. The great principles it establishes respecting the formation of animal and vegetable tissues have been universally adopted, although some modifications, and those not unimportant ones, have been introduced by other observers into the theory as originally announced by Schleiden and Schwann. Those physiologists supposed that the nucleus or cytoblast, having performed what they conceived to be its specific office—the formation, namely, of the cell—was cast off as useless, and absorbed. Further inquiries, both in Germany and England, have shown, however, that the nucleus is a much more important organ than was originally imagined. Thus Rosenthal contends that the nuclei serve to the reproduction of the organ tissues, by becoming elongated into fibres; and Reichert, although he condemns this theory as hypothetical, conceives that Rosenthal's inquiries have shown that the nucleus does not disappear in the manner stated by Schwann. It is, however, in this country especially, that the importance of the cytoblast has been shown by Dr. Martin Barry. This distinguished observer contends, that instead of being removed after having formed the parent cell, the nucleus becomes the source of new cells; and as it is capable of dividing or multiplying itself, and of thus giving origin to objects endowed with the same properties as itself, the nucleus possesses in this kind of vegetative growth an almost illimitable power of increase. Without entering into the merits of this question, I may be allowed to point out, that although the power possessed by the primary cells, and by the tubes proceeding from them, of absorbing new matter and depositing this in their interior, was known to Schleiden and Schwann, as, for instance, in the formation of the spiral vessel of the plant, and of the muscular fibre in the animal; yet to Dr. Barry belongs the great merit of fixing the attention of physiologists on one of the most important points connected with the history of cells, the independent power, namely, in virtue of which they may increase almost *ad infinitum*. It is this endowment which is more particularly interesting to the physiologist, and to the pathologist, as it is calculated to explain many of the phenomena connected with nutrition and secretion, as well as the growth of carcinomatous and other tumours. Strange as it may appear, the new being or embryo, like all its individual parts, springs from a cell, or, more correctly, from its nucleus, called the germinal vesicle, or, from its discoverer, the vesicle of Purkinje. The admirable investigations of Dr. Barry, have established, among so many other valuable results, the fact that by a process precisely the same as that described as taking place in the nucleus of the cell, the minute object discovered by Wagner, and called the germinal spot, gives origin to incipient cells, which fill the whole of the interior of the germinal vesicles. Ultimately two of these cells enlarging constitute the true germ, and then each giving origin to two other cells, the number becomes 4, 8, and so on, increasing in the ratio of geometrical progression.

Rubeola.—The cause of rubeola, says Mr. Wilson, is a special contagion, probably originating in the association of a number of individuals under hygienic conditions unfavorable to health, and propagated to the present hour by generation of the morbid poison in the system of those affected by the disease. Like other contagions it is neutralized, or rendered active, by states of the atmosphere, being increased by cold and dampness of the atmosphere, and diminished by the opposite conditions, heat and dryness. Measles prevail consequently during the autumnal, winter, and spring months of the year, and principally in the former and latter, the dryness of the atmosphere which accompanies the sharp frosts of winter being unfavourable to its transmission. Certain states of the system are favourable to the diffusion of rubeola, as, for example, the presence of inflammation of the mucous membrane of the air-passages; indeed, catarrh or cough may be regarded as indicating a morbillous constitution.—The infection of rubeola is a fact too well known to need any instances in proof, and the infecting distance would appear to be considerable. The period during which infection is possible is difficult to determine, but for the sake of security it is necessary to secude the patient for at least three or four weeks. It may be as well to remember also, that subjection to an attack of this fever affords only partial security against its subsequent invasion: persons have suffered from measles as many as three or four times, and have still remained liable to its attack. The infectious nature of the fever is also exhibited in its epidemic prevalence. The contagion of rubeola has been put to experimental proof by inoculating a sound person with the blood or fluids of the diseased. Dr. Home, Cullen, Speranza, and others, succeeded in producing an attack of measles in this manner, by inoculating with blood: Dr. Monro effected the same object by means of the tears and saliva; and Willan remarks that the inoculation of the fluid of some accidental vesicles developed on the skin during rubeola communicated the disease, and was the means of transmitting it, subsequently, by infection to several other children. After inoculation the symptoms of the fever make their appearence in the course of a few days. At one time it was thought that the symptoms of the inoculated disease were milder than the sporadic form, and it was proposed to employ inoculation, as in small-pox, for the purpose of inducing a mitigated affection. The results of the experiments in the above cases were not, however, favourable to this opinion, and all expectation of benefit from such a mode of procedure has been relinquished.

On Mattico as a Styptic.—The mattico (says Dr. W. Munro,) has been very often used by me in the Dundee Infirmary, as an external styptic; but I have not as yet used it internally. It has been very often used to stop the bleeding from leech-bites, and uniformly with the most decided success. Leeches were applied, by his own desire, inside the nostrils, to our house surgeon, a stout florid young man, with head symptoms in fever. The bleeding, which was profuse, could not be stopped by cold applications to the head, plugging, &c.; but the mastico, in leaf, applied over the bites, and pressed on with the point of the finger, proved immediately successful. The application of the leaf caused increased heat and throbbing for five minutes, when all unpleasant symptoms went off. The mattico was applied to a man with a wound of the right temple, in whom a considerable branch of the temporal artery had been divided; the wound was dressed, and a compress and bandage applied, but still the blood burst out. Cold water was several times had recourse to, still the bleeding returned after a while; at last the mattico was used. I stuffed the wound with the powder, but found that it was washed away from the wound in the vessel; I then pressed in several pieces of the leaves, holding them firmly for some time with the point of the finger; and the result was, that we had no more hæmorrhage. We had a somewhat similar case of a man with a wound of a branch of the palmer artery, which resisted graduated compression and bandages, and in which the mattico was used with the best success.

Internal Employment of Nitrate of Silver.—Dr. Fisher, of Tambach, found fused nitrate of silver efficacious in cases of grastralgia aring from purely dynamic affections of the nerves of the stomach, especially in females.—He gives this salt in the dose of four or five milligrammes, either in pills or draught. He prescribed it without any advantage in the cases of gastralgia caused by hemorrhoidal diathesis, and become independent of the latter.

Injections of Infusion of Cubebs Vaginitis.—A woman, aged 28 years, was admitted to the *Hopital de la Pitie*, on the 5th of April, 1842, to be treated for intense urethro-vaginitis, which had lasted nine months, accompanied by violent pain and abundant flooding. This woman had been subjected to several modes of treatment, without success. From the time of her admission, she was submitted to injections, repeated six times a day, of 30 grammes of cubebs in a quart of water. At the end of two days, the flooding had diminished, but the inflammation of the urethra remaining, cubebs were administered in the dose of 3 grammes every hour. On the 17th of April, the patient was completely cured; there was no longer either pain or flooding. Thus, in twelve days, one of the most rebellious of diseases, of nine months' standing, was cured. M. Piorry states, that he has, in numerous instances, very successfully employed cubebs in inflammation of the canal of the ureter, or of the vagina. Setting out with the principle that cubebs act only when put in contact with the diseased mucus membrane, by means of the urine, when the uretur is affected

or by means of injections, for the vagina, M. Piorry administers this medicine internally, or by way of injection, at very short intervals.

ADULTERATION OF TOBACCO.—"Bengal safflower is preferred," says Mr. C. Watt in the Chemist, "at the price of twenty-eight shillings per cwt. It is infused in a weak solution of potassa or ammonia, the former giving a dark brown color resembling 'Shag,' and the latter a light brown, approaching in appearance to 'Returns.' Considerable loss, however, having occurred from the vegetable matter dissolved out, an improvement has lately been introduced; the safflower, having been moistened, is placed in trays in a cask, into which the ammoniacal gas is allowed to pass. By this process, the weight is increased, whereas, after the earlier methods of preparing it, a loss of one half was sustained. Having thus explained to Mr. Bremner the particulars of a process which, doubtless, he well knew before, I will add the price at which it has been sold, viz., 1s. per lb., and I beg to enclose (in confidence) the name of the firm by whom the tobacconists have been supplied with this adulteration, one of whom, when the new Act was introduced, pathetically exclaimed, 'Behold another fortune lost!' I am in possession of samples, and I know that orders for a ton were obtained in the course of a month, by a travel'er on his journey. In the case of the ammoniacal preparation, a ton would afford a profit of about £84.—Perhaps this will explain the ticketting of tobacco at 2s. 6d. per lb, the duty alone being above 3s. It may not be amiss to inform the public, that the substitutes for tobacco are always in shorter threads than genuine tobacco. The vegetable used for the adulteration of tobacco, are far too numerous to be mentioned here."

CHILBLAINS IN CHILDREN.—Dr. Stober, Professor to the Faculty of Medicine at Strasburg, employs when the chilblain is recent, of a deep red, and not ulcerated, cataplasms of linseed meal, or bread and water, surrounded with sugar of lead. The cataplasm is kept on all night; in the morning it is removed, bathing the foot in warm water. Under the influence of this very simple treatment, chilblains are often cured in three or four nights.—Where chilblains are old, and where ulceration is threatened, Dr. Stober bathes the affected parts with tincture of iodine once in every twenty-four hours, and that for several days in succession; or a similar unction may be made with a mixture of equal parts of dilute nitric acid, and distilled cinnamon water, applied once a day with a feather.—

As regards ulcerated chilblains, Dr. Stobler, to hasten cicatrization, has recourse to stimulants, and, in preference to binoxide of mercury (red precipitate) incorporated with lead.

POMMADE FOR ATONIC ULCERS OF THE LEGS.—℞ Dry Tannate of Lead, 30 gram.; Lard, 8 ditto—M. The pommade is spread on pledgets of cotton wadding, and is applied to the ulcers with them.—This medicine has succeeded where others have failed.

TESTIMONIAL.—A meeting was held by the students of the Charing Cross Medical College, on Saturday, the 17th inst., for the purpose of presenting to Edwin Canton, Esq., an elegant snuff box bearing the following inscription:—"Presented by the Students of Charing Cross Medical College to Edwin Canton, Esq., M. R. C. S., Demonstrator of Anatomy, as a testimony of their grateful sense of his unwearied exertions in the promotion of their studies."

ROYAL COLLEGE OF SURGEONS IN LONDON.

List of gentlemen admitted members on Friday, December 16th, 1842:—

M. Ward, F. J. Osborne, C. P. Daniell, W. T. Edwards, W. S. Watson, A. Stephens, J. Hancock, P. Wallis, R. Baker, W. Miner, P. Benson, A. King, H. R. Daniell, T. W. Fothergill, F. Hawthorn.

Admitted Monday, Dec. 19th:—

H. Hadlow, G. Newstead, H. Carless, J. Lugg, T. Howell, J. C. Blanshard, T. Holman, J. P. Oates, H. W. Best, G. Pink, T. Lyle, F. B. Hunt, T. Good, R. Cammack.

ADVERTISEMENTS.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 19, Essex Street Strand, in the Parish of St. Clement's Danes, Westminster, in the County of Middlesex.—December 24th, 1842.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 171. Vol. VII. LONDON, SATURDAY, DECEMBER 31, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times' Office, Hate Lancet Office, London.

SUMMARY.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College

GENTLEMEN.—Another class of agents, useful in slight inflammation are *Derivatives*, which act as we have before noticed by draining the blood from the vessels affected to other vessels at a distance from them. Thus in slight affections of the head, pediluvia are frequently beneficial—they cause determination to the feet, and thus relieve the head. The application of warm poultices is also of service, because the heat which they maintain increases the passage of blood through the obstructed vessels. On the same principle fomentations are useful in some internal complaints, as peritonitis, —hot applications relieve the tension of the parts, and thus diminish the irritation. *Evacuants* act by drawing off the blood to other parts, by causing the actual removal of some of the fluids. Where nervous irritation is a leading feature, another series of remedies may be called into our assistance, viz., counter-irritants, which differ from derivants, inasmuch as the latter seem to act upon the vessels only, whereas the former act upon the *nerves* also; thus strong heat operates as a counter-irritant—sinapisms, blisters, turpentine, &c., act in a similar way. These are chiefly for cases where there is great pain and little vascular excitement, viz., spasms, colic, nausea, inflammatory dyspepsia, &c. These remedies, however, must not be applied too early if much inflammation is present; nor yet much counter-irritation be applied too *near* to an inflamed part, or the mischief will only be increased. If they are adopted when there is great vascular excitement, inflammatory fever is very likely to be induced—blisters applied for two or three hours have an evacuant as well as rubefacient effect. Opium is sometimes effectual in putting a stop to inflammation by paralysing nervous agency, and thus destroying the influence it has in the production of the inflammatory process, and cuts off the connection between the local inflammation and the system. Narcotics, of which you know opium is the representative, should always be preceded by some degree of depletion, because this class of agents at first *excites* the action of the heart, and also tends to arrest the secretions. They should be combined with mercury, antimony, or ipecacuanha, because the tendency of these is to *increase* the secretions: opium is often useful in putting a stop to slight catarrhal inflammations; henbane, camphor, &c., are in most cases decidedly inferior to opium. When, in addition to local mischief there is inflammatory *fever* present, we have to treat the whole vascular system, and through it all the secretions. It is clear that mere local treatment can be of little avail, so long as the powerful vis a tergo is in operation. We must regard all the parts as in a state of high pressure, and the remedies to which I have been alluding would tend only to aggravate the symptoms, while the fever continues; for the local applications would act as irritants. Derivants can do little good—counter-irritants are hurtful, and narcotics also, because they cannot control the action of the heart, but rather increase it. The first measure, then, in this case, must be to withdraw the stimulus of the blood, because it is the blood itself that stimulates; we must, therefore, bleed, and give such medicines as shall further relieve the vessels by augmenting the secretions, and by diminishing their tonicity: for these two purposes,—mercury and antimony appear to be eminently adapted. All these measures must be employed in proportion to the importance of the part affected, and in proportion to the amount of vascular fulness present. In some inflammations, such as parotitis and tonsillitis, &c., resolution may be effected generally without the necessity of much depletion. Below the age of four years, the only way in which we can abstract blood safely is by leeches. Bloodletting is sure to produce an influence, if it is carried far enough. It is much more difficult to cause syncope in violent inflammatory fever than in persons who are in possession of full health. There is, consequently, said to be a great "*tolerance*" of bloodletting in fever accompanying inflammation; the heart and arteries are able to lose a large quantity of blood, and yet continue to act as before. For example—a strong male, in good health may be able to bear, without fainting, the loss of about sixteen ounces, while in cases of acute pleurisy or arachnitis, a patient may require the abstraction of from *thirty* to *forty* ounces, to induce syncope; in pneumonia about thirty ounces may be borne; in bronchitis, erysipelas, &c., from sixteen upward; and in congestive apoplexy upwards of *forty* ounces have been drawn; in cases of continued fever and anæmia, the tolerance of bloodletting is considerably diminished. Our object in bleeding is to produce a *lasting* impression upon the inflammation, with the loss of as little blood as possible; in the early stage the vessels may regain their healthy state without any reaction occurring. In cases where we wish to produce a strong and decided effect, we must act upon the brain at the same time as the heart, and should, therefore, place the patient in the erect position, and bleed from a large orifice, or even from an orifice in each arm at once. We must continue the bleeding either until the pulse is softened or until some of the leading symptoms are relieved. If the disease is recent, the sudden removal of the tension will probably be successful, and effect a cure. In mere nervous syncope the pulse speedily regains its strength. We may ask how general bleeding acts upon local inflammation? We reduce the action of the heart and also alter the character of the blood; it diminishes the fibrin and red particles more than the serum. Haller observed, that as the blood was drawn from the whole system, the blood in the inflamed part began to flow more rapidly, and sometimes in an opposite direction. The alteration effected will be in proportion to the recent existence of the inflammation. The pressure is removed from the oppressed vessels, and the evil thereby reduced. If, however, the local inflammation is extensive, and has involved the structure of the vessels, so that they will not easily recontract; it is not desirable to produce so rapid an impression, but a more slow and permanent one is to be attempted: for when inflammation has existed for some hours, or where the habit of the patient is very plethoric, we must obtain *more* blood; and to effect this, we must bleed from a *small* orifice, and keep the body in an easy posture, so that no immediate impression may be produced upon the brain. In nervous subjects, the influence produced upon the heart by the brain is very rapid, so that if there is so much sthenic inflammation present as to require the abstraction of a considerable quantity of blood, it is obvious that we must take all possible precautions to avoid the supervention of syncope; for I presume you are all aware that, when syncope occurs, the blood ceases to flow: we must, therefore, place the patient in the horizontal position, and allow the blood to escape as gradually as we are able. Suppose, for a moment, that violent inflammation has existed for several hours, and you proceed to bleed the patient from a large opening and in the erect posture, and fainting is instantly produced; what will be the consequence? It will be this—the very small amount of blood obtained will not remove, in any degree, the local inflammation; but as soon as the patient has rested for a short time, reaction will be effected, and the whole inflammatory process will proceed with all its previous energy. You see, therefore, the importance of bearing these distinctions carefully in your minds. But you will find that bloodletting *alone*, however discreetly it may be managed, will not be a sufficient remedy in cases of inflammation, and will require to be followed up by other means; for after even ample venesection there may remain enough nervous irritation to induce inflammatory fever, although the local inflammation may have been at first diminished; then this fever, reacting upon the *little* local inflammation left behind, may speedily re-excite it, and matters soon return just to the place in which they were at the commencement; so that, after venesection, it becomes our duty to adopt measures that shall allay the nervous irritation, and perhaps the very best agent we can employ for this purpose immediately after bloodletting, is *opium*. But supposing that the nervous irritation is of slight extent, so as not to demand special attention, and we find in it still considerable *vascular* excitement remaining, we must have recourse to *local* bloodletting as well as general. This local depletion produces a much greater influence upon the *heart* than on the *brain*, and therefore is particularly adapted to the circumstances we are supposing, viz., cases where inflammation has existed for a considerable period. It is especially indicated, also, in inflammation affecting membranes, and more decidedly so if the membranes are near to the *surface* of the body as in pleurisy, peritonitis, pericarditis, and the like. Local depletion has some beneficial effect in cases of bronchitis, also in inflammation of the mucous membrane of the intestines. I need scarcely tell you, that the ordinary mode of local depletion is the application of leeches in numbers regulated by circumstances; another method is cupping, which, in many instances, is invaluable, and far superior to leeches. Local bleeding has much less effect on inflammation seated in the parenchyma of organs, because the vessels of the organ are less connected with the external surface to which leeches or cupping would be applied. For example—in a case of deep seated pneumonia,—or, indeed, in any pneumonia whatever,—the application of leeches is, I believe, of little or no use. Again, in inflammation existing within the head, I think leeches are of comparatively little benefit. In old age, leeches are particularly useful because the vessels having lost their elasticity are not so easily affected by *general* bloodletting. We have next to consider more particularly some of the principal *internal remedies* in inflammation—for we have other means of evacuating besides bloodletting, and none are so effectual for this purpose as *purgatives*, except in cases where violent inflammation is seated in the mucous membrane of the alimentary canal, in which case you can readily perceive much caution is requisite. The influence that can be produced upon the system by means of purgatives is very great; it is no difficult matter even to cause *syncope* by their administration, although such a result is rarely advisable. The brisk purgatives are the most useful, such as calomel and jalap; the neutral salts are also serviceable; these remedies are, of course, not to be depended upon alone; when there is much inflam-

mation, it is better to repeat bloodletting, if it can be done. In some inflammatory affections in children, *purging* is the *best* remedy. Diuretics (which are also, to a certain extent, evacuants) are of little or no use in cases of active inflammation: to depend upon them would be like blowing gently upon a red hot iron.

One of the great antiphlogistic agents, and one that perhaps most nearly resembles bloodletting, is *antimony*. It must not, however, supersede bloodletting, but it is of the greatest service either with or after it. It has a decided tendency to maintain the reduction of the arterial action which venesection has produced; it diminishes most perceptibly the *hardness* of the pulse. In *slight* cases of inflammation, James' Powder will answer every purpose; but in more active cases the *tartar emetic* (or potassio-tartrate of antimony) is preferable; sometimes it produces purging, and generally vomiting at first, if given in anything like full doses. It is found most beneficial as an antiphlogistic, when it does *not* produce discharges of any kind. It seems to be of special efficacy in *pulmonary* inflammations; its mode of operation has been much disputed. Some talk about it absorbing the power of inflammation, and say, that its emetic action takes place when the inflammation is reduced; but then patients will continue to take it when inflammation is diminished with less sickness than when the inflammation was *commencing*. Laennec thought it acted as a counter-irritant, by setting up an amount of irritation in the stomach; he also thought that it operated as a sorbefacient. It acts both as a counter-irritant and absorbent. Small doses are diaphoretic, without *increasing* the action of the *heart*. How then is it diaphoretic? It has some property of *relaxing* the vessels, it diminishes the tonicity of the vessels. Antimony is of most service in the early stages of inflammation, when the arterial tension is greatest; it is of no use when solid effusion has taken place. It is less useful in inflammation of simple or serous membranes—its efficacy may be said to be in proportion to the greater vascularity of the inflamed part. It is very beneficial in inflammation of the testicles, lungs, &c. It is certainly useful in slight cases of inflammation of the mucous membrane of the alimentary canal. The dose, as an antiphlogistic, is in most cases from the quarter of a grain to two grains. But some employ it in very much larger quantities: for instance, the Italians recommend doses of ten grains two or three times a day.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM.

[illegible]

[illegible]

GENTLEMEN.—I have now to bring before you the diseases of the cerebral system; the first part of the subject of the nervous diseases in relation to actual diseases. The two former lectures were confined to what may be considered preliminary to that which ought to form the chief subject of my observations, viz., the physiology of the nervous system. I now introduce to you the subject of the diseases of that system themselves; but before I do this, I must call your attention to one or two points of some importance. It is quite obvious to us all that the nervous system is nothing without the circulating system. Now I shall say two words, first of all, with regard to the circulating system, and then two words more respecting that circulation with the nervous system. I need hardly explain to you the organs of circulation, which you must be all well acquainted with, but I do wish to make one observation or two in the first place: you hear of the veins, the heart, and the arteries. Now I take the heart and the arteries to be merely machinery; the object of which machinery is to produce the circulation through the capillary vessels. The chief part, in fact I might almost say the only part, of an effective circulation is the circulation of the capillary system. The blood is received from the capillary system by the veins. The veins may be considered as so many ducts leading the blood back from the part that had been supplied, to the heart. The heart is the organ of the motion of the blood, and it may be regarded simply as the instrument of motion, and the arteries must be considered as merely tubes carrying the blood to the parts required to be nourished. Now, the observation I have to make is this:—that all these are mere machinery; that the veins are tubes and the heart is the instrument of propulsion, and that the arteries are mere tubes. I am not aware of any change in the blood produced either in the veins, in the heart, or in the arteries. If, then, no change is produced in the blood, in this part of the vascular system, it is quite plain that all that is really circulation, all that is really function, with regard to the blood itself, is performed in the capillary system. The arteries divide, and divide again, into minuter and minuter branches. These minute branches divide into other vessels, which I have ventured to call channels, rather than vessels, because I extremely doubt whether they possess any vascular coat at all; indeed, when I investigate this subject, I am the more inclined to believe that they are mere channels formed into the interstices of the substance of the lungs, rather than that they possess any coats, as in the larger division of the arteries. I think I said this ten years ago—and the subject is still, a matter of doubt and a matter of uncertainty. But, as far as my opinion is concerned, I say that it is much more probable that the capillary vessels are mere channels, than that they are actual tubes. As to these channels, they are various in form; but, generally speaking, they consist of channels which unite and then divide, and then unite and then divide, and then unite and divide again through the whole substance, and of this the body is nourished. They are uniform in size, and what is important to observe is, when the arteries become smaller and smaller, and the veins become larger and larger. The arteries subdivide continually, and the veins unite continually. The arteries subdivide, and become smaller; the veins unite and become larger; the capillary vessels unite, and divide again and again, forming, as it were, a net-work of channels, rather than vessels; they maintain the same diameter. What is the object of all this? I believe that the simple object is—what I would venture to call one of irrigation; the blood runs through all the organs of the body; and they derive from it, thereby, that nutriment they require to enable them to undergo changes, and to be nourished. Now, with regard to the capillary vessels in the lungs, I need hardly tell you that their object is to expose the blood to the atmospheric air, in order that certain portions may be taken up, and that other portions may be given out, in the process of respiration. We see, therefore, that the object of this irrigation—this true circulation—is to nourish all parts of the body, to give increased strength to the parts, by healthy secretions, and to do everything that is required for the nourishment of the system. This, then, is the first word I wanted to say on the subject of circulation. I believe the veins, heart, and arteries, to be mere machinery—the whole and sole object of which is, to irrigate the different organs of the body, which is done through the medium of the capillary vessels. But, there is another view of the subject; it is quite plain that things are carried into the blood and out of the blood. Now the blood may be viewed as situated between the organs of digestion—that is to say, the stomach and the small intestines, and the organs of excretion. From the stomach and small intestines, the particles are taken up to form chyme, and then to form blood, the blood is thus formed. But there are organs that, like the kidneys, secrete, and it is essential that the secretions should be perfect in these places. What, then, do you observe? You find the blood circulating in every organ of the animal body. I now wish you to observe that the blood is situated between the organs of ingestion and digestion—between the stomach, the small intestines, and the lungs, and the other organs: those of secretion, the liver, and the kidneys. Why do I mention this subject just now?—just to show you, that if the small intestines do not perform their duty, the functions of the blood cannot be performed; and if the liver and the kidneys do not perform their office, the blood cannot be purified; it cannot be deprived of those particles which, if they remain in the blood, remain as poisons in the blood. I have had to notice this fact in a medical as well as a practical point of view, to show that there is great danger if the kidneys do not perform their office. You have no doubt seen, within the walls of this hospital, cases where the kidneys have not performed their office. Where the secretions are of such a nature as to be charged with albumen, and the blood cannot perform its office, what happens? There is a danger of this kind, that you will have an attack of apoplexy, or palsy, or epilepsy, from this superficial cause. Now, I have not another word to say on this subject, for it does not belong to my department, except inasmuch as it is necessary to show how the well-being of the nervous system depends on the well-being of every other part of the body, and that the well-being of the nervous system depends on the well-being of the blood.

We now then proceed to the subject of the nervous system and especially to circulation. Every part of the nervous system—the brain and the spinal marrow, and the ganglionic system is pervaded by the blood. It may be said, indeed, that the animal frame consists of a nervous system, and a vascular system, to which must be added a muscular system, and if we have these things combined together, we may take away every other part of the skeleton, the osseous system, and everything but the nervous system, the vascular system, and the muscular system. Then, as I said before, every part of the nervous system must be supplied with blood; it must be supplied with its due quantity of blood that, blood must press upon the body with a certain degree of force, and must be perfect. If there be the slightest change in any part—the slightest defect in any of this three particulars, you will have disease, and, very strange to say, you will have similar diseases from contrary states of these things. Taking first the pressure of the blood; now, it is difficult to increase the pressure of the blood upon the brain and the spinal marrow, but there is a mode of increasing the pressure, and that is by preventing the blood from flowing from those organs. Now it so happens that in every case I have heard of blood so prevented from flowing from the brain, it has taken place in a disordered circulation. If you close the larynx—epilepsy closes the larynx—while convulsions are seen in children. Whenever the larynx is closed, you have invariably the blood prevented from returning from the brain, and the consequence is, you have the pure state of apoplexy, owing to there being too much blood in the brain. But you find this state of things only continues for a certain length of time. How long does it continue? Only until nature has had an opportunity of restoring the blood to its normal quantity, leaving neither a greater part nor too little. Suppose instead of having too much you have too little: suppose that instead of having it sent with a proper degree of force, you have it sent with too small a degree of force to the brain, what is the consequence? The phenomena are very similar. Look at the case of common syncope. I recollect a most interesting case of this kind, which had like to have proved fatal. It was a case in which the patient had been bled to a state of syncope, in the upright position. The blood was taken from the patient in the upright position, for the person who performed the operation was not aware of the importance of having the patient in an horizontal position. Now what was the consequence? The patient fell first into a state of delirium, and afterwards into a state of coma. But that was not all; he fell into another state—in fact, he was affected with violent convulsions. At present I wish to keep your attention to the mere brain, the central part of the cerebral system. I have just informed you that we had first a state of delirium, and then a state of coma. The syncope was followed by a state of coma. Now then you have these facts to bear in your minds:—

A state of coma produced by an over quantity of pressure of the blood, and the same state in an undue pressure of blood. The same thing is produced both ways. Now I have told you just now that an over pressure of blood would produce similar effects on the other parts of the nervous system as the undue pressure of the blood, but I am not prepared to give you any precise case in which convulsion is produced by the undue pressure on the spinal marrow. We know that undue pressure on the spinal marrow will produce convulsions, but I have no facts at present, and as my object is to bring only the truth before you, if I have no facts ready to adduce I do not adduce any. Now then in the case which I have mentioned we find the patient had too much blood taken from the system. He was bled to a state approaching syncope, in an upright position, and in that case there was slight delirium, then coma, and then convulsions. A friend of mine residing at Bridgwater, was called to see a physician of that place, who was attending a gentleman who had been bled in a recumbent position: and now let me tell you that no patient should ever be bled in a recumbent position: I say this because you cannot tell beforehand what the system will bear, and what the disease may require. You may guess it, but you cannot positively tell, and it may happen that you may guess wrongly; you may take fifteen or twenty-five ounces, and if you take twenty-five you may take too much, and if you take fifteen you may take too little, but if you take the patient upright, and bleed him to syncope, you may obtain the proper quantity. Well, this gentleman was bled in the horizontal position; there is no doubt too much blood was taken from him, for he fainted. I think there is danger of the patient fainting in the horizontal position. He fainted, but the hemorrhage did not subside, nor could it, because he could not be placed in the proper position; and that gentleman fell into most violent convulsions. You are aware from what I have before stated, that disease of the brain cannot produce convulsions. Now this case is one in point, to shew that too little blood in the spinal marrow will produce convulsions. Now, why may that not be the case in disease of the brain? In the first place I have told you that no disease of the brain can produce convulsions. Now I come to the spinal marrow. You may not be aware how sheep are killed. I can tell you the process. I have been to see animals killed in various modes, without being the means of ever inflicting pain or death, or any suffering, and yet I have seen the physiological effect produced. The butcher generally divides the blood vessels, and then turns the knife, and divides the spinal marrow, and so the animal bleeds to death. In so bleeding to death, Gentlemen, it always dies in violent convulsions. I went on one occasion, and desired the butcher first to kill the animal by dividing the spinal marrow; I had the head severed entirely from the body, all but the skin, and then the animal was allowed to bleed to death. You see very clearly that the head had no influence over the muscular system, because it was severed from the body—then the question came to be whether there were or not in this case to be convulsions. I watched the flow of blood for a considerable time, and found that no convulsions occurred; but the animal at length became violently convulsed, and then it was obvious that this convulsion was a spinal marrow convulsion, and that it arose from too little blood in the spinal marrow. I conclude, then, that not only will too much blood, but too little blood, will produce convulsions, and it proves also, at the same time, that its causes are very similar, in so far as regards the blood, its quantity, and its pressure. I wish to say one or two words respecting the quantity of the blood. Whenever the blood is not properly formed—whenever the stomach and the intestines do not do their duty, it is quite plain that the chyle that ought to form the blood, cannot be formed. I believe this is the case in many cases of amenorrhœa in one half of the female sex, and this also causes chlorosis and other phenomena in children and grown-up persons, especially in the female sex, about the age of 16, 18, or 20. The blood is not formed. Why is it not formed? Because the organs of deglutition, the stomach, and the bowels do not perform their functions. Under these circumstances the patient—I was going to say the little patient, because I have in my eye a little patient—is in danger of convulsions. I have a patient in Bouverie Street (where I called in my way here), the daughter of Mr. ———, one of the most interesting little girls I have seen. This little patient is about the colour of that cloth—perfectly green. She lost her breath, and became affected with convulsive movements of the left side, the day after that she had violent convulsions, and the day after another convulsion. There is no reason to suppose the convulsion was produced from any other cause. I do not mean to say that it might not depend on the state of the bowels, the diet, or the food; what I mean to say, is—that there was simultaneously a state of amenorrhœa with the convulsion; whether that convulsion arose from a state of amenorrhœa, I am not prepared to say, but the state of amenorrhœa was no protection against the convulsion. You generally find, that in the mind of the public generally, fits of convulsion, and blood-letting, are always associated; and you find, in practice, that the first thing that happens to you, when you go to see a patient affected with convulsions, is, that you are called upon to let blood; the parent will say to the medical man, "the child ought to be bled." This is the common feeling. Now, how is this to be explained? The convulsions arise from a state of amenorrhœa,—that state of amenorrhœa but from an imperfect formation of blood. But I should tell you that the little child I have been alluding to, had not lost any blood nor breath; and the reason why the blood was not formed, seems to me to be a defective action of the smaller intestines. I have one observation more, and it is one that I have, perhaps, made already. You are aware of a disease, called Bright's kidney, because that was the name of the physician who first detected it. In this disease, the urine is loaded with albumen. My object in bringing forward this fact is to shew, that whenever you have the urine loaded with albumen, it is not only a fatal disease, because the kidney is affected, but the patient is invariably exposed to attacks of convulsion. I once attended a patient, not very far from the University Hospital, who was affected with this disease: the urine was considerably albuminous, and, in the midst of the affliction, a series of epileptic attacks commenced, and terminated her existence. That was a case of albuminous urine; and from this fact you may take it for granted, that whenever the urine is not in the most healthy state—secreting what it ought to secrete, and no more—whenever it secretes sugar or albumen, there is danger to the nervous system—the danger of epilepsy, and, therefore, of convulsion. I will mention one more case, which occurred at Dublin, under the inspection of Dr. Bligh. There was nothing particular in the symptoms of the patient, to create any fear the first day and night, but, on the very next evening, the patient was taken with the most decided epileptic attack I ever saw. The man was obliged to leave his business, and has recently died. There was albuminous urine, and, with this, an attack of epilepsy, produced by the introduction of blood through the ventricle of the brain.

I have just said a few words respecting the circulating system. These parts of the animal frame may be viewed as mere machinery. This is called the real circulation; but the blood does nothing in the veins, the heart, or the arteries; all it does do, is in the capillary vessels. Then I showed you that there was a connection between the circulation of the blood, and the nervous system. Now, with regard to the actions of the true spinal marrow. I believe they are all reflex, in every instance but one, which I would call a direct action; that is, the action of tonicity in the muscular fibre. How can we prove that this is a direct action? I will tell you a simple fact, and then you will observe how I come to the conclusion that this is a direct action. I believe that the spasm after death—what is called the spasm of death—to be an action of the last kind during animal life. I took two rabbits, and killed both by a blow on the back part of the head. In one I took away the spinal marrow, and in the other I left the spinal marrow entire. I then placed them on a table, and watched to see whether there was any difference between the two, and I found that there was something more—in the one in which the spinal marrow was entire, than in the one from which the spinal marrow was removed. The one in which the spinal marrow was perfect, was free from any rigidity. Here is a perfect case of direct action. All, then, is physiological with regard to the spinal marrow, with this single exception,—it is reflex. What, then, is the conclusion? Why, that a very great part of its actions are pathological. Now, take an animal, and see it breathe. The acts of respiration are entirely physiological and reflex. Take an animal and place it under water. You will gradually find that the animal is affected with convulsions; now, these are direct, and are owing to the circulation of morbid blood upon the spinal marrow. First of all, the blood is surcharged with carbonic acid, and a state of coma is produced in the brain, from the circulation of improper and morbid blood: you then see violent struggles to escape—these cease in a second, and the animal dies perfectly still. The moment you observe it silent, you may be sure the brain is in a state of coma,—there is no convulsion, and no longer any action. By the bye, these struggles are respiratory; they are invariably taken to be struggles of respiration, and with these struggles the whole of the animal is drawn together in a state something like empros thotonus. You see this is a pathological, and a very interesting, state of things.

(To be concluded in our next.)

PRACTICAL OBSERVATIONS ON THE NATURE, PECULIARITIES, AND TREATMENT, OF SOME OF THE MOST PREVALENT DISEASES, &c. CONNECTED WITH THE POPULATION OF NORTH CHESHIRE, AND SOUTH LANCASHIRE, EMPLOYED IN COTTON FACTORIES.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Manchester.

(Continued from page 200.)

Under such circumstances, it is next to impossible that a healthy offspring can be expected. The only time the child can enjoy its natural food (the breast) is perhaps the factory meal hours, when the milk has been long pent up, and, in all probability, is much depreciated, or during the night: and if not bad of itself being mixed with the bad food previously given, soon takes on acetous fermentation, producing a never-ending catalogue of diseases under the general term of acidities, in the first passages. It would be next to impossible to attempt remedying such affections by medicine alone, and equally so to expect a change of habits sufficiently extensive to have any beneficial effect. The best artificial food I have found for early infancy, is the brown crust of a home-baked loaf of bread, boiled in a small quantity of water to a pulp. For the first few weeks the child should be fed on the liquor only, but after that on the pulp as well as the liquor. In this simple diet difficulties arise—many families have not the convenience of an oven, and most of them have not the time allowed from their occupations to bake their own bread, and have therefore to rely on that from public bakers, well known to contain alum, potatoes, and other materials, having a rapid tendency to acetous fermentation, in fact, the main source of this class of diseases in children.

It should be observed that this simple food when properly made, seldom becomes acid on the stomach, but to ensure it still more effectually from that tendency, every care should be taken not to use any of the inner portion of the loaf, but the browned crust only, the former being more disposed to become sour than the latter. As acidities in the alimentary canal are in all cases attended with great uneasiness, restlessness, and almost continuous crying, this class of people are very prone to apply remedies of their own procuring, which are invariably quack nostrums, in which there is a large proportion of opium, generally the "*Infants'*

Preservative, which is imitated by every druggist in town and country, and that sought after most, which produces the *most stupefying effects*, that is, containing most opium. Indeed vast numbers of these little beings exist only from day to day in a sort of dreamy oblivion, until some disease is brought on by such practices of greater fatality, to release the sufferers from their misery. To give some idea of the extent to which this practice is carried, I know of one locality, the population of which does not exceed twenty thousand, in which there are not less than eight chemists and druggists, all of them vending "infants' preservative" of some kind or another. *One* to my certain knowledge makes it in large quantities, about twice a week, at each making use of not less than an imperial quart of the tinct. opii. Ought not such facts to be known to our *patriotic legislators*? Can any one be surprised at the general appearance of such children after the disclosure of such practices?

The treatment most likely to relieve the acidities of the first passages is mucilaginous and cretaceous mixtures, combined with a little aniseed or a carminative. If obstinate, the addition of a little sub-carbonat. potass. will generally be sufficient; occasionally the hydrarg. c. creta. is advisable. After such treatment the common consequence observant on the use of opiate nostrums are absent, and there is the satisfaction at least, if the child dies, that the means employed have not facilitated or in any way hastened its death. I do not mean to deny that opium is not useful even in such cases, but it should be given only under the direction of a medical practitioner, and I believe its use is more limited than is generally allowed. After all, unless the child is well nursed and well fed, the best treatment will avail but little, and must frequently fail. The diseases attendant on the foregoing bad systems of nursing and feeding children, are not merely confined to such as have already been noticed, but extend to others of a far more formidable character, and more frequently fatal in their result. Perhaps the most prevalent, (and certainly a very fatal affection,) I have witnessed in this class of society, is the mesenteric glandular affection, a class of cases that has generally been considered as hopeless, the length of time required for any effectual treatment, the slow progress of amendment, if any, renders the parents careless and often indifferent; that rigid attention which alone can secure benefit is relaxed, the child is indulged with anything, and everything (under the false notion of kindness) which soon terminates its existence. From having paid great attention to this disease for many years, and after having witnessed vast numbers of cases, I am convinced the disease is to be controlled by medicine, if anything like proper attention can be secured to the diet and nursing. Where that could be obtained I have seen many recover after having suffered most extensively, and to all appearance when the case has assumed an almost hopeless position.

Some time ago, (*See Lancet, Vol.* 1. 1841-2, *p*. 886) I directed the attention of the medical profession to the analogous disease in the mesenteric glands of the adult, which led me to a line of practice in children that has invariably given satisfaction when persevered in, and when seconded by the most rigid attention to diet and nursing. The cause of this disease is sufficiently apparent when the foregoing bad habits are considered. Post-mortem have disclosed the fact, that the mesenteric glands are enlarged, or in plainer terms, they are incapable of allowing the chyme to pass through, which is necessary to become chyle. The child has a voracious appetite, but in consequence of this glandular obstruction, the system receives no nutriment; as the disease progresses, the belly swells, and becomes tympanitic, whilst the rest of the body wastes rapidly, and the child soon dies, if some means of relief are not attempted. The plan I have generally pursued is, first to regulate the diet, allowing the child to be fed at stated times, with an interval of three or four hours between each meal, [illegible] which, [illegible] food [illegible] much [illegible] or out-door air [illegible] possible, [illegible] interval [illegible]. The [illegible] character. [illegible]

A tepid bath every night up to the arm-pits, in which a little spirits of turpentine is put, say about an ounce) for about five minutes, the belly to be rubbed with soap liniment, and ol. terebinthinae in equal parts every morning. With respect to medicine, I only give a dose of the hydr. c. creta, night and morning, to each of which doses is added one-fourth of a grain of calomel. The powders are to be continued for some time, omitting the calomel occasionally. By adopting this simple plan, I have restored many to perfect health after every other means had been tried in vain. I have often found advantage in advising flannel next to the skin in marasmoid affections particularly; and this is, perhaps, more requisite from the prevalence of a moist atmosphere pervading this locality; confirmative of this, is the fact of mumps being very prevalent in infancy, but more remarkably so, in the next period of life, of which I shall say more hereafter. As might be supposed, by the congregation of numbers, and the little regard paid to cleanliness, cutaneous eruptions are very common; the ring-worm, and scald head are particularly so, and some of the cases assume a very obstinate character, and only give way to the most energetic, local, and constitutional treatment. I would just notice, independent of the constitutional treatment, I have found the use of about ten or twenty drops of the acid. sulph. rubbed down with an ounce of the ol. palmae very efficacious in dispersing the scald head: of course, neither it, nor any other local means are likely to succeed, without the constitution being attended to. Teething is generally difficult, and, perhaps, to that circumstance, so many cases of hydrocephalus are to be attributed; these latter, however, are most prevalent in families of strumous habits, and in the treatment of which there is nothing different to the plans generally followed. There are still other diseases to which we might direct attention, but as they will fall more legitimately under the next chapter, I shall defer their consideration in this, to avoid unnecessary repetition.

THE HEAD OF GOOD, THE MURDERER.

The fourth meeting of the Phrenological Society for the present session was held at the Society's Chambers, in Exeter Hall, on Monday evening last.

John Elliotson, M.D., F.R.S., &c. &c., President, in the Chair.

After the usual preliminary business, an address was delivered by Edmond S. Symes, Esq., on the correspondence between the cerebral indications and the known character of the murderer, Daniel Good, in answer to some recent arguments against phrenology. Mr. Symes gave a brief sketch of the character of Good; his poor intellect, his propensity to theft, cunning, lying, debauchery, and extreme violence,—counterbalanced only by great affection to his child, and by general respectfulness to his superiors; and then pointed out on the cast of his head the small development of the forehead, the region of the intellectual faculties, the extreme breadth at the sides, particularly at the organs disposing to violence, (destructiveness,) cunning, (secretiveness,) and love of property, (acquisitiveness;) also at the back, in the situation of cunning, (combativeness,) and physical love, (amativeness;) and the sloping of the coronal surface, (the moral religion,) together with his very large love of offspring, (philoprogenitiveness,) and large veneration, observing that this last organ did not necessarily imply any feeling of religion but might show itself, as in this case, in respect to superiors. He need not enter more fully, he said, into this comparison, as a very accurate account of the cerebral development and character of Good had been recently published in the MEDICAL TIMES of [illegible] but he had some time since attended a lecture professing to disprove phrenology, the lecturer taking for his "text" this very head. The demonstration he had just made of the perfect accordance of the cerebral development of Good with his character, was perfectly conclusive upon that point; but, although to the members of the society it would of course be a work of supererogation to undertake any refutation of arguments against their science, still, as, on the present occasion, they were honoured with the presence of many ladies and other visitors, some of whom might not be deeply versed in the principles of it, he had thought it might be not altogether uninteresting to examine a little into the lecturer's general grounds of opposition; and this, not because of any weight likely to be attached to the opinions of the individual in question, nor from any particular cogency or novelty in the objections themselves, but because they are just such as are usually adduced and eagerly adopted by opponents of phrenology, and, if treated with the contempt they deserve, might be supposed valid by those who do not know how often such arguments have been refuted.

The lecturer commenced, said Mr. Symes, by acknowledging not only that "the brain is the organ of the mind," and that, "for the proper manifestation of its functions, the brain must be in a healthy state;" but that "it is a general rule that in all persons of great mental power, we find a well developed head, and particularly a large forehead!" "But then," said the lecturer, "all this was well known and admitted before the time of Gall." Mr. S showed that so far from this truth having been generally admitted before the time of Gall, quite the contrary was the case; so that when he first announced his discoveries he was assailed on all sides by ridicule and persecution, and that it is only recently that it has become generally admitted.

The lecturer next asserted, "that the brain was not composed of a great number of distinct organs, but of single and undivided organ; the whole brain being brought into operation on every exertion of the mind;" forgetting, or not seeing, the force of his own admission, that, "in all persons of great mental power, we find a *well-developed* head, and particularly a *large forehead*." Whereas, if the brain were a single organ, mere size and quality would be sufficient, without reference to *form*. There would be no necessity for the forehead—the intellectual region—to be large; and, certainly, no mere dictum will suffice to overthrow the mass of facts by which Gall has established the multiplicity of the cerebral organs. How is it, if what the lecturer says be true, that he "has had extensive opportunities, during the last ten years, of examining vast numbers of heads, in various public asylums, and comparing them with the individuals' characters," that he does not adduce any *facts* in support of his assertions? How is it that the cases he has adduced, turn out to be only additional proof of the truth of phrenology? We see that this is so with regard to Good; and the only other cases he mentioned, those of Thurtell, Hare, and Burke, have long since been proved to be equally so.

The lecturer had next declared, that "it is impossible to ascertain the form of the brain from that of the head, for that the different parts of the skull vary in thickness from one eighth to one fourth of an inch." Mr. S. exhibited a number of skulls, and various sections of skulls, to show that, in healthy skulls their bones do not vary more than one-eighth of an inch in thickness at different parts

whereas, the differences in the size of organs is estimated by inches, and the mere one-eighth inch would be of no practical importance. Of course, in cases of exostosis, or other disease, exceptions might occur; but our rules do not apply to cases of disease, and such exceptions are extremely rare.

"Then," the lecturer "did not find these organs marked out upon the brain as upon the marked bust, nor any correspondence between the two hemispheres, the convolutions on the two sides did not run in pairs." No; no phrenologist ever pretended to find the forms of the organs so marked out; when an organ is largely developed, it shews itself externally, nearly in the form and situation indicated upon the marked bust. No one pretends to define the precise limits of different organs, any more than he could point out the exact division of the colors in the spectrum: the marked bust is merely to teach learners the ordinary forms and situations of the organs, which may be situated a little higher or lower, according to the greater or less size of neighbouring organs; but an expert phrenologist can readily distinguish them near enough for all practical purposes.

The two hemispheres correspond in a remarkable manner, but whether the forms of the convolutions on the two sides are so symmetrical that we can trace out which particular convolution belongs to each individual organ, is a point requiring further investigation. Mr. S. regretted, however, that the bust should be so marked as to give a handle to such objections as the above. Gall contented himself with placing a numeral as nearly as possible in the centre of each organ, and then shading it off, so as to shew its ordinary limits. Upon the bust, too, all the divisions are marked out, as if the functions of each were ascertained with equal certainty. Now, as regards the 27 or 28 organs discovered by Gall, the mass of evidence in support of them, is so conclusive, that we must consider them as perfectly established; but, as regards the 6 or 8 which have been added since, the functions of some of them appear to have been correctly assigned; but the evidence in favour of others is inconclusive, and of some, perhaps, untenable. But to return, said he, to our opponent:

"The convolutions at the base of the brain, and between the hemispheres, are as numerous as elsewhere, yet phrenologists assert that these are not organs."

This is altogether untrue. There are not any convolutions between the hemispheres, and so far from denying the probability of the existence of organs at the base, some facts have been recorded, tending to shew that an organ of *love of life* is there situated. As we cannot, however, distinguish the development of the base of the brain during life, it is difficult to verify this.

The lecturer objected that "Mr. Combe professes to be able to tell, from the form of the head, whether a person was a good moral character, or the contrary."

Neither Mr. Combe, nor any other phrenologist, ever pretended to predicate *actions*. What we do profess, and are able and willing to prove, is, that we can discover the *tendency* of the character from the form of the head, supposing the brain to be sound.

The lecturer found fault with phrenologists for not applying their rules; and, immediately after, exclaimed against a proposed application of them. Some one had remarked that no phrenologist ought to take any one into his service, without a previous examination of their cerebral development.

"Here is a pretty proposition," said the lecturer, "a well-conducted person who brings a good character from his last place, is to be thrown out of employment because your craniologist finds some bad bumps in his head."

Whilst the lecturer was indulging in this eloquent diatribe, there stood upon the table before him, as if in derision of his argument, a cast of the head of Courvoisier, the murderer of Lord William Russell, a man who had brought with him an excellent "character" from former masters and mistresses; yet no phrenologist, who had carefully examined his head, would have trusted an individual with such an unfortunate organization as this head presents.

Then, "Phrenologists say that the cerebral power emanates from the grey substance—and my strongest argument against them," says the lecturer, "is this, that the grey substance is not of one uniform thickness all over the brain, but is of all kinds of thicknesses."

Now, in the first place, it is an hypothesis by no means generally received among phrenologists, that the cerebral power emanates more particularly from the grey substance, though there is every reason to believe that it does emanate from the surface generally. Gall taught that the grey substance is what he terms, the matrix, for generating and nourishing the white, fibrous, portion of the brain. Dr. Fletcher, and some others, are of opinion that it is also the grey portion, more particularly, which eliminates thought and volition; but, at all events, this does not affect the principles of our science; and, certainly, it might be quite true for anything that the lecturer advanced to the contrary; for this, *his strongest argument against phrenology*, viz., that "the grey substance is of all kinds of thicknesses," is an assertion by no means true, since it is pretty equally distributed over the surface of the *cerebrum* and the lecturer did not appear to be aware that, in the *cerebellum*, the grey matter is not upon the surface, but is beautifully arranged upon its internal situation.

Mr. Symes then took up the *cui bono* argument, and entered into a disquisition upon the very extensive applications of Cerebral Physiology in Education, Medicine, Criminal Legislation, &c. &c., and concluded his address by adducing numerous pathological and physiological proofs of the truth of the science.

The president announced that as the next ordinary meeting would fall on the 2nd of January, when it was probable that many of the members would have other engagements, the meeting would be adjourned till January 16th, at the usual hour.

CURABILITY OF CONSUMPTION

To the Editor of the 'Medical Times.'

SIR,—I have discovered, with great pleasure, that the several cases, demonstrating the curability of pulmonary consumption which, lately appeared in your columns, have produced so deep an impression, that medical men are now induced, despite of the principles in which they have been schooled, to turn their attention to this important discovery, and yield to the convincing testimony of unanswerable facts. This is as it should be, and when the light of reason once begins to shine, it behoves every one to aid in dispelling the mists, which have hitherto obscured it. On this account, and encouraged by the ready insertion accorded to my former letter, I again address you, to add further corroborations of the great truth which, Dr. Ramadge has been enabled to bring forward. The subject is not only inexhaustible, but so important, and of such magnitude, that it requires to be examined in all its bearings, for only by the test of scrutiny can it become established as it deserves. The finger of nature has been pointing to it for ages, yet no eye has followed the sign. In vain had science asserted that there is no bane without an antidote; the fact, as regarded consumption, was denied, and, until Dr. Ramadge made the discovery, the hearts of all who were afflicted with that terrible disease, were left to sink in despair. He has now had the experience of nearly a quarter of a century, as senior physician to the infirmary for asthma, consumption, and other diseases of the chest; which afforded him an unrivalled field for investigating the causes effecting the cure of consumptive disease; and, as I have partaken of the knowledge gathered from that experience, by being present at his lectures, and having made myself acquainted with the details of many remarkable cures, I cannot better perform my duty to the profession than by diffusing what I have learned, and, in doing so, shall imitate the example of your excellent correspondent, "*Philanthropos*," who, very properly, gives you the sources of all he advances.

In all cases of consumption, the grand law which effects its cure, is the prevention of contraction of the chest. The localities in which this prevention appears are, as I shall have occasion to point out, various. Yet, in every variation, the antagonism to consumption is established by one ruling principle, viz., the re-adjustment of the deranged relation or balance between the organs of inspiration and expiration, through the agency of something obstructing more or less the exit of the air *in the act of expiration*. Here let it be observed by the way, that nature, in her operations under this law, rarely does her work perfectly, and, in many instances, runs from one extreme into another. The forces which represent the powers of inspiration are stronger than those forces which represent the powers of expiration; consequently, when the impediment mentioned exists, owing to the weaker expiration, and the imprisonment of air, in some degree, an enlargement of the lungs takes place, and the cure of the disease is brought about.

No sooner does consumption occur, than it is earlier or later marked by contraction of the chest. The windpipe, by retaining its original size, becomes comparatively too large for this reduced compass; the exit of the air is too free to offer antagonism to the advance of the disease, which would be attended by the occurrence of new crops of tubercles, and their presence and subsequent liquefaction in the lower lobes of the lungs. It is pleasing to observe that when nature or art interrupts the daily contraction of the lungs, before the invasion of the tubercles in the lower lobes, we find little or no disposition in the larynx or intestines to fall into diseased action. The following exhibits a hasty and imperfect catalogue of the admirable, yet simple and accidental processes by which the beneficial interruptions alluded to are brought about, and which I shall comprise under the head of

DIFFERENT MEANS BY WHICH CONSUMPTION IS ARRESTED BY NATURE.

Enlargement of the tonsils.

Diseases of the heart.

Tumours of any sort on the windpipe, or its division.

Hysteria.

Asthma.

Catarrh, symptomatic or idiopathic.

Polypus in the nose, or, indeed, any mucous intumescence in the same part, or nasal fossae.

Uterine haemorrhage, or profuse, or too frequent bleedings from any part of the body.

Disease in the vertebrae of the neck, has, in more than one instance, been noticed by my preceptor to point beneath the pharynx, and constitute a tumour standing in the way of the expired air.

I now proceed to recapitulate the *modus operandi* of these agents.—

ENLARGEMENT OF THE TONSILS.—The great rarity of manifest consumption in children is owing to the enlargement of the tonsils so commonly

observable in them.* The same strumous habit that gives rise to the foregoing state, antecedently or concomitantly, deposits tubercles in the lungs: in the majority of cases we have no opportunity of seeing these, when, after a lapse of years, death follows, from disease wholly unconnected with any chest affection, owing to their absorption; but we not unfrequently witness the black stains or indurations in the summits of the lungs, where they have been. It may be here mentioned that even the greater number of *adults* who are seen with any degree of enlarged tonsils, can recollect when only superficially questioned, that they had suffered under some antecedent affection; displaying all the constitutional symptoms of consumption.

As the greater power of the inspiratory muscles will, even under this state of enlarged tonsils, draw in the air with more freedom than it can escape, the preponderating action will, of course, expand the lungs, and, assisted by the weakness of the expiratory powers, imprison air sufficient to increase that expansion and thus enlarge the thorax; and, what is remarkable, by making the patient short-breathed or asthmatic, so completely alter the scrofulous habit as to remove the very impediment (i. e. the enlarged tonsils) which has the capability of defeating any contraction of the lungs that would lead to unmasked tuberculous phthisis. Still more extraordinary, the enlargement of the tonsils alone is sufficient to render the lungs voluminous, and to close up a cavity resulting from liquefied tubercles. Dr. Ramadge considers enlarged tonsils as indications of a scrofulous habit, and that the lungs are, or have been, tuberculated; but this enlargement is, at the same time, a sign of the non-liability of the patient to sink under phthisical disease, of which it is an indication. Whenever he perceives the absence of this sign, he recommends caution to his patients in their intercourse with consumptive persons.

Many instances can be adduced from the practice of the above-named physician of what has been here stated, and, in a future paper, I shall furnish cases in point, supported by well-authenticated facts.

DISEASES OF THE HEART.—In all lesions of the heart there is to be found congestion of the venous system; and the bronchial mucous surface is in a greater or less degree affected, owing to the difficulty which the bronchial veins experience in transmitting their blood into the larger venous trunks destined to receive it. The consequence is, that imprisonment of air is effected after the manner just explained in the preceding paragraph, and the lungs become voluminous. Though tuberculous deposits may have previously taken place in the top of one or both lungs, the disposition to form new ones is subverted by this enlargement of the lungs, which I have already described as unfavourable to the continuance of the scrofulous habit, or entirely subversive of it. The pathological researches of Dr. Ramadge have enabled him to establish the co-existence of tuberculous disease with scrofula in any part of the body. He is also satisfied that aneurism of the aorta, or of any large artery, is nothing less than the result of some previous tuberculous disease which has impaired its power of resisting sanguineous impulse. Dissection has proved in all his recent examination of aneurismal cases that this is the fact, and that there had existed, at one period or another, a tuberculous disease of the lungs. DIAPHULUS.

(To be continued.)

A BRIEF EXPOSITION OF DR. MARSHALL HALL'S LECTURE ON THE NERVOUS SYSTEM.

SIR,—I was not a little surprised to read the announcement in your paper of Dr. Hall's lectures, which I shrewdly suspect your good nature, rather than your good sense dictated. Since so much fuss has been made about what is intrinsically worthless, and positively mischievous *in practice*; allow me to offer a few remarks upon the lecture in your last number, in which I think I can shew there is both absurdity and inconsistency.

I cannot even pass over this first paragraph of *kitchen* oratory, in which the bad English is so apparent that it must strike the most superficial observer, e. g.:—

Gentlemen, it is my office (qy? duty), to bring before you the *subject* of the diseases of the nervous *system*. In introducing the *subject* to you I shall go very rapidly through the anatomy and physiology of that *system*(!) I do not think I need go very deeply into the *science*, (of what?) because many of you have very probably *listened* to the more eloquent *words* that have fallen on this *subject* from Mr. Grainger, &c.

So then because a part of Dr. Hall's audience or pupils had listened to eloquent language from Mr. Grainger, the other, possibly the majority, was not to have the advantage of that instruction for which they attend the hospital.

I need hardly tell you that along the spinal canal a *chord of nerves* runs, which has been very improperly called the spinal marrow. *I would venture to call this a chord of cerebral nerves*; for it is quite plain that from any idea of the subject that we have formed, *it is neither more nor less than a chord of nerves proceeding from the cerebrum*, and passing along the spinal canal, and out of that *into the different members of the body*.—(Line 15th, 1st col.)

We shall see presently that this is *not a chord of cerebral nerve*, according to the same authority. But to proceed:—

We will, therefore, view it a few moments as it ought to be viewed as *a mere chord of spinal nerves running along the spinal canal*.—(Line 23d, 1st col.)

What Dr. Hall says about the possibility "of removing the cerebrum, the centre of those nerves and the *ganglionic* system, and yet have *another kind* of nervous system remaining in the animal body," (line 36-37) is stark staring nonsense. It is like saying, "Gentlemen, it is possible to cut off the nose, to remove the alæ and the cartilaginous portions of that organ, and yet have another kind of nose." I am afraid it would have been a very difficult thing to persuade Sir John Coventry who had his nose cut off by the bravos of Charles II, that he had *another* kind of nose still remaining. So with Dr. Hall's "other kind of nervous system." Here follows the "simple" (query complex) experiment to prove his assertion.

You see here an animal (a frog, alas! for poor Mr. Frog! this "roly-poly," and consequently his "opera hat" were "gammon and spinach" to Dr. Hall) from which the *head*(!) has been separated, and *of course* (!) *I need not tell you, that with it the* BRAIN HAS BEEN ENTIRELY REMOVED!!

Now I really think this was highly important information, whatever some critics may think, for though it has been generally believed that animals have their brains in their heads, it is quite plain, from *personal* experience, Dr. Hall has not found this so universal as has been supposed. Has Dr. Hall then ever discovered a transposition of *organs* as others have a transposition of the senses? the brain in the epigastrium—or great toe for example? To continue:—

All the viscera have also been removed, and with the viscera *every portion of the ganglionic system*. Now, I beg to repeat, &c. (and here he repeats all that he had previously said), and yet when I pinch the extremity it moves, so as to be obviously perceptible at the remotest part of this theatre.

After another repetition of what he has once before repeated, relative to the removal of the brain and ganglia, he says, "yet you observe something remains!" To wit the *disjecta membra* of the mutilated Monsieur Grenouille! *pauvre* Grenouille!

"Now, Gentlemen, that *which remains I venture to call in* CONTRADISTINCTION FROM WHAT HAS BEEN TERMED A CHORD OF CEREBRAL NERVES, and the origin of the ganglionic system—the TRUE SPINAL MARROW.—(Line 4, 2d col.)

Here then we find a gross inconsistency. The Dr. first call it himself "a chord of cerebral nerves," and then, with matchless forgetfulness, calls it "in contradistinction *the true spinal marrow*." This is a contradiction of himself, and we must beg to add that "spinal marrow," as applied to the "chord of nerves" running through the spinal canal, is not only contrary to every physiological principle, but to common sense; for no two tissues differ more widely from each other in the human body than *marrow* and *nervous matter*. They differ not only functionally, but organically—they differ not only physically but chemically. But observe how Dr. Hall proceeds to argue against the very dictum he had laid down only a few lines above. He continues:—

It is plain in the first place that it is not a mere chord of nerves; if it were a mere chord of nerves, you might divide it, and then you would intercept its influence...(Line 10, 2d col.)

In the second paragraph in the second col, we are gravely told

If you take an animal and lay the brain perfectly bare (the horrid process of dividing the integuments and *sawing* the bones of the skull go for nothing with Dr. Hall! Why a little reflection and his own doctrine of "shock," would have told him that all power of *receiving* or *perceiving* sensation, is annihilated by that very process, and that vulgarly speaking the animal is already dead!) and lacerate the brain in every possible way you can devise, you cannot in any manner induce muscular motion.

Now I hold that the "shock" of dividing the integuments and bones is sufficient to account for this insensibility, and the example Dr. Hall himself gives, a little lower down in the same paragraph, of the *insensibility* of the brain of the horse, killed by the blow of a poleaxe to lacerations and injuries, amply bears out my assertion. But what is fatal to the position assumed by Dr. Hall is, that his *fact* is not *true*. If the skull be only partially injured, and the brain be exposed, so that pressure be made upon it, *convulsions instantly ensue*, and that fact, independent of my own experience, is vouched for both by Richerand and Combe. I have not Richerand by me, but the case is cited by many writers. It is that of *a female in whom convulsions could at any time be produced by making pressure on the brain, through an opening caused by trephining*. A similar case, or I believe *cases*, you will find in Combe. We pass on to the last paragraph of the third col., where we are told, that Dr. Hall has thought necessary to rebaptize a certain principle of the nervous system, which a very unimportant personage, called Albert Haller, named *vis nervosa*, and its appellation is now *excito-motor*. Welcome then Signor Excito-Motor, though like the Spaniard with the long name, we are afraid we cannot find room for you. But take your chance Signor Excito-Motor, you have the power *to go* whenever you please.

Dr. Hall says:—

That all the authorities have hitherto said that this *vis nervosa* acts in one direction only; that is, from the centre towards the circumference, from the spinal marrow towards the muscle to which the nerve goes.

Now no physiologists, neither Haller nor Muller, ever said anything that can be tortured into the meaning conveyed by Dr. Hall. They knew very well that if a wound is inflicted on the finger the sensation was first communicated to the finger and thence to the brain, which

then *perceived* the injury. It is true they did not call this process excito-motor, or reflex, but thought, as I still think, that *vis nervosa* was a good appellation. But I have intruded enough for the present.

ALPHA.

Dec. 28th, 1842.

A LECTURE ON THE MEDICAL PROPERTIES OF THE PAPAVERACEÆ. DELIVERED BEFORE THE ROYAL MEDICO-BOTANICAL SOCIETY.

By Dr. COOKE, F.L.S., Professor of Botany.

If I were required to point out the manner in which botany has contributed most prominently to medicine, or to prove the inseparability of the different branches of medical science, I should adduce the grand discovery that from the structure of a plant, its remedial properties can be deduced. Plants that resemble each other in structure, are, more or less, similar in their action on the animal system. This is true of individuals belonging to the same natural order, and more strictly so when applied to those of the same genus. By this doctrine we are enabled to distinguish wholesome from deleterious plants when resembling each other in general configuration, and when, from any circumstance, the one commonly used is wanting, to replace it by another, and thus, as Dr. Lindley says, are rendered as much at our ease when alone, and seemingly without resources, in a land of unknown herbs, as if in the midst of a magazine of drugs in a civilized country. This great truth, first asserted by Tournefort and Ray, extended by Adanson and the Jussieus, has since been confirmed by Richard, Desfontaines, and Decandolle, and is now universally admitted. The proposition may be thus stated. Find out the natural order of a plant, and you have in the vast majority of instances, a sure key to the effects it would produce on the living body. Probably, this would always be the case, were the true natural system discovered, or had we sufficiently investigated the true powers of every plant. At present we have certain exceptions to make to the rule I have laid down, and certain precautions to observe in the practical application of it. By attention to these, we shall find the number of exceptions will be greatly reduced. It is not my intention to enter this evening into the consideration of the exceptions; but I will notice a few of the cautions to be borne in mind. The natural order we propose to discuss to-night—the Papaveraceæ—will furnish a few instances of exceptions, and many of agreements with the rule. So many, indeed, that Decandolle views it as one of the orders most entirely favourable to his views, and so places it in his "Essai sur les Proprietes Medicales des Plantes."

The chief precautions are:—

1. That the plants to be compared shall be in the same conditions with respect to age, dryness, soil, situation, light, and air—all circumstances of known power in determining the activity of plants. A young plant has not the same quantity of active principles as a mature one—nor is one removed from the influence of light and air capable of forming its secretions equally with one fully exposed to these agents. Upon this principle the well known difference between the powers of wild and cultivated (blanched) celery is explained. Dryness, or moisture of soil, is often the cause of most essential differences, as in many of the umbelliferæ.

2. The parts of plants used should be the same; it is not fair to compare the root of one like the flower of another.

3. The mode of preparing them for administration should be the same. If more heat, &c., &c., be used to one than to another, it is obvious that powerful volatile principles may be dissipated, and the drug rendered inert.

4. Accidental or mechanical properties should not be confounded with those which are essential. The grass eaten by dogs causes them to vomit; but we must not then conclude that it possesses emetic powers. The vomiting is induced by the sharp rough edges tickling the throat like a feather.

5. A careful distinction must be observed between plants which differ in kind, and those which differ in degree only. In some the active principle is so concentrated as to render them poisonous, whilst in others, though in, perhaps, the same *absolute* quantity; it is so diluted by starch, gum, &c., as to become comparatively harmless.

6. We do not really know the properties of drugs, and hence what one author would call generally a stimulant, another would place amongst the emetics, purgatives, &c., &c.

7. The powers of drugs vary with their doses. Opium in small doses is stimulant; in larger, narcotic—is poisonous (especially if administered in the third form), sedative, depressing the powers of life without running through any appreciable stage of stimulation.

8. From the true natural system not being yet discovered, many plants are beyond doubt wrongly placed and thus form seeming exceptions to the rule. By paying attention to these circumstances, we shall be able to explain nearly all apparent anomalies.

The papaveraceæ are thalamifloral exogens herbaceous, annual plants, less frequently shrubs with fibrous roots, leaves alternate, simple, penninerved, dentate or pinnate, exstipulate, peduncles unifloral, flowers, white, red, or yellow—never blue. Sepals two, deciduous. Petals three or four, and cruciate. Stamens numerous, hypogynous. Fruit one celled with parietal placentæ. Seed numerous. Typical genera, papaver, glaucium. Papaveraceæ are known by the deciduous calyx and parietal placentæ. The first distinguishes them from the cistaceæ; the latter from ranunculaceæ and nymphæaceæ. Brassicaceæ differ in having the stamens tetradynamous.

The medical properties of the whole order are acrid and narcotic, and reside in a white or yellowish milky juice. The chief genera are in addition to those given as typical, chelidonium, argemone, sanguinaria and bocconia.

I have stated that the properties of the order are acrid and narcotic—perhaps it would be better to say that the narcotic are universal, and that in many genera the acrid are superadded. Those in which this occurs are chelidonium, argemone, and sanguinaria. The juice of these, blisters and corrodes the skin, and taken internally produces, if in small doses, stimulant after emetic or purgative effects; if in larger, powerfully irritant and narcotic. The latter quality enables some of them as argemone mexicana to relieve strangury—the fruit of sanguinaria canadensis and chelidonium majus also possess narcotic properties. No part of papaver rhœas is known to produce narcotism. This plant, and the fact of a species of argemone, having slightly laxative powers form two exceptions to the general rule.

The seeds of the whole order are innocuous, and afford a mild, bland fixed oil, which is often used with salad on the continent. Some of the genera as glaucium, are not known to have acrid properties, and the juice of papaver, is not commonly believed to be so; but it is a curious fact, that if we take the morphine from opium it will irritate and inflame the skin, and new opium will cause lachrymation and sneezing by its vapour. Few of the Papaveraceæ have, except P. somniferum, been employed in medicine, and no other enters into the pharmacopœia. Chelidonium majus has been used to destroy warts, and to remove opacities of the cornea. It has also been given as a stimulant and sudorific. Sanguinaria canadensis has been employed in phthisis, croup, pneumonia, &c.; but not extensively; and argemone mexicana is employed in India in chronic opthalmia and primary syphilitic sores. Its narcotic properties are said to be stronger than those of opium.

By far the most important of the order is P. Somniferum, from which opium is obtained. This drug is the inspissated juice of the unripe capsules. In describing its properties, I shall give a general idea of those of the whole order.

First, in small doses, (gr. ¼ to gr. ½) it is stimulant—raising the action of the heart and nervous system: in full remedial doses (gr. i. to gr. ii.) it is narcotic; i.e., stimulating at first, and afterwards depressing—at the same time arresting, nearly, if not quite, all of the secretions. Thirdly, in poisonous doses, it is sedative—depressing from the beginning. In all three doses, it is soporific and anodyne. I shall not enter upon the effects produced by the habitual use of this drug.

Opium is used, according to Dr. Pereira:—

a. In fevers, whenever there is much watchfulness, restlessness, diarrhœa, or delirium, especially delirium tremens.

b. In inflammatory diseases, especially after bleeding, to relieve pain, restlessness, and spasm, or to arrest undue secretion.

c. In painful or other affections of the genito-urinary system—as stone, retention of urine, diabetes, &c.—to relieve pain, relax spasm, or check secretion.

d. In hæmorrhages.

e. In gangrene, as a stimulant, in small doses.

f. To relieve pain of ulcers, especially those of a cancerous nature.

Much difference of opinion exists, as to the share each of the numerous principles existing in opium has in producing or modifying its peculiar effects. Some, from being insoluble, may be at once pronounced, *in the medium*, inert. Others have, perhaps, never been perfectly separated from those with which they are in combination; and, in a third class, experiments have not been made, either in sufficient number, or with sufficient care, to enable us to speak with any degree of confidence.

The chief principles found in opium are,—a volatile principle (oil?), codeine, narcotine, narceine, meconine, meconic acid, morphine, paramorphine, pseudomorphine, and extractine.

1. The volatile principle, to which opium owes its odour, would appear, from experiments by Orfila and others, to be inert. But it has never been perfectly isolated.

2. Codeine.—The statements in reference to this substance are very contradictory. Majendie says it produces sleep and stupor. Dr. Gregory found gr. vi. produced symptoms like those of intoxication, followed by sleep. Others say it is irritant and stimulant, never stupefying—and some have considered it to be the stimulating principle of opium.

3. Narcotine was at first said to be the stimulant principle of opium. It is now considered to be of but little activity, and that Majendie and Orfila, who viewed it as very active, used it imperfectly isolated. (Pereira.)—Dr. Roots gave ℈j., without any bad effects. In India it has been tried with success, as a substitute for quina, in intermittents.

4. Narceine—supposed, from experiments, to be inert.

5. Meconine—also supposed, from experiments, to be inert.

6. Meconic Acid—peculiar to the papaveraceæ—we should be tempted to believe it had some effect in producing their peculiar powers; but it has been shewn to be inert. What share it may have, in modifying the action of morphine, with which it is combined in opium, we cannot tell.

7. Morphine is the most, and, perhaps, the only, really active principle of opium; but, admitted as its activity is, the effects produced on the animal economy are differently stated. Some consider it purely sedative and and anodyne,—others, view it as possessing the same properties as opium.

8. Para Morphia, or Thebaine.—Majendie says it produces tetanic symptom, but his observations have not been confirmed.

9. Pseudomorphia is said, by Pelletier, to be morphica, which, by some other combination, has lost its poisonous properties.

10. Extractine.—This is supposed to be one of the active principles of opium; for, in the first place, after it has been separated by magnesia, it gives, by evaporation, an extract which produces the same kind of narcotic effects as opium; and, secondly, the effects of the known active principles are not powerful enough to refer the whole of the action of opium to them.

11. Fatty matter is inert.

But for further account of what is known respecting these principles, I must refer the Society to Dr. Pereira's Elements of Materia Medica, from which much of what I have stated has been gathered.

TO CORRESPONDENTS.

Mr. John Taylor Ross, at one time a [illegible] proprietor of this journal, and Mr. Thomas Bailey who succeeded him, have long ceased to be connected with its management or ownership, or in any other way whatever.

Mr. Thomas Wakley.—*Our correspondence with this honourable member did not prepare us for seeing our reply to Dr. Hall in the pages of the "Lancet." Mr. Wakley, in [illegible] of the editor's name as a [illegible] question, yet evident at it, he publishes the document [illegible] point of acknowledgment that our view [illegible] are the correct one, and an extorted [illegible], for which we are much indebted indeed to the hon. member's moral—cowardice. One circumstance characterizing the transaction deserves recording. The "reply" sent to the "Lancet" was one of three copies transcribed by an assistant from the original written by ourself; our own autograph—it the duty we owe to our own cleanliness—[illegible] of course leaving the "Medical Times" Office. Mr. Wakley in inserting this copy, pretends to print it exactly as in the original, and the transcriber in the hurry of copying, having omitted to punctuate, our reply is published in the "Lancet" almost entirely without punctuation, and of course—as Mr. Wakley expected—reads nothing the better for the omission. Mr. Wakley is a surgeon, a coroner, a member of Parliament—if, in addition, he were a* gentleman, *public taste would not have been disgusted with a mean, beggarly, and dirty trick like this, which judged by a rule similar to that which is [illegible] and pickpocketing, would imply a sort of character—pettifogging and unprincipled—against which we could never think character, property, or life, safely insured, if resting merely on the protection given by law on one side, and honesty on the other.*

Rhys Tudor.—*We published a paper on the usual and best modes of producing artificial somnambulism, or mesmerism, in No. 152, vol. 6.*

B. C. D.—*The delivery of medicines, and receipt of payment by the offender, should be witnessed in one or two cases by one or two respectable parties, and a statement (authenticated) of the whole affair laid before the Apothecaries Company, who might possibly, though not probably, prosecute. The case we think would warrant a magistrate in the committal of the delinquent for trial, on the charge of obtaining money under false pretences.*

A Constant Reader, G. B.—*We know of nothing to prevent a man with diplomas, from a German or Scotch source, or with none at all, practising* as a physician *anywhere but in London. Such diplomas, however give no title to practise as an apothecary.*

C. M. D.—A Constant Reader, Manchester—Pen—M. D. S.—An Inquirer—Mr. T. B. C.—Philoteus, M.D.—*declined.*

If Lewis will re-write his article legibly, we will read it, and give him an answer.

Dr. Ishmael Hall. *We have received a vast number of letters on this gentleman which we cannot use. Born, or bred, how or where he may have been, married or unmarried, honourable or not honourable in his private dealings,—on all such points it is our wish, and our resolve, to be entirely silent. We have had our say. We have dealt him his hardly earned* public *punishment, and we have no notion of using our power to inflict on him the refinements of private torture, which so many correspondents have so well-naturedly placed in our possession.*

Dr. Hodgskin's *paper announced last week is delayed to next, from want of space; as are "Serres on the Development of Organs," Dr. Scoffern on Chemistry, and a variety of other interesting papers.*

"Rough Reports from Guy's" next week.

ROYAL COLLEGE OF SURGEONS IN LONDON.

List of gentlemen admitted members on Friday, December 23rd, 1842:—

J. Drury, F. Morgan, W. Peskett, H. Horsfall, D. Sinclair, J. Percival, and H. W. King.

Provincial Journals, inserting the above advertisement twice, will receive the Medical Times (stamped edition) FREE *for a twelvemonth.*

THE MEDICAL TIMES.

SATURDAY, DECEMBER 31, 1842.

> Ut tamen et posco aliquid ———
> Orandum est ut sit mens sana in corpore sano.
> JUVENAL.

To be able to decide, when, and where, a Government should interfere by laws, is the distinguishing characteristic of a true statesman. There are some things which are best left to what may be called hap-hazard—to that practical legislation which will always be established by the humours, the interests, the passions, the virtues, of those who are concerned in them. There may thence arise minor evils, which would not occur under a more prying or stringent system—but the general result is more in favour of the happiness of society. There are other things, again, where the same test of ultimate greater good being applied, the intervention of law is imperiously demanded; and thus, while we are not indisposed to think that, in many points of social life, our laws have needlessly intermeddled with a perhaps pernicious influence—we feel strongly, on the other hand, that society, in its united governing capacity, has been mischievously inert and forgetful of its duties in reference to many other matters, which, if less "material," and less numismatical, are certainly not of less concern to social interests in their highest aspects. Among these, are most of the subjects affecting the government of our profession—not the least important of which is, that to which we are about to call attention, viz.,—BRITISH MEDICAL EDUCATION, IN REFERENCE TO LUNACY.

Lunacy, no rare visitation in any civilized country, is unusually frequent in our own. In Great Britain, exclusive of Ireland, it is calculated that we have about 25,000 lunatics and idiots. Supposing this large number somewhat equally distributed among our population, we have a patient within the visiting district of nearly every practitioner in the kingdom. The important question arises—How are practitioners prepared by their education for such charges? We know that lunacy is no ordinary malady,—that, while the deprivation of the noblest of earth's attributes, reason, and the loss of health, of liberty, of manhood, and of citizenship, which it entails, make it the most calamitous of human afflictions—the variety of its phases—its occult situation—its mysterious origin and development, make it among the least amenable to the resources of medical skill. It is not only a calamitous malady to the unfortunate patient, but it carries its bane to his whole family; and, while covering it with the mourning of affliction and shame, its evil omen darkens the future of the young and unborn. Thus frequent, thus vital, thus widely calamitous, it must yet, more or less, come before every medical man: he must see to it—advise on it—act for it—and how, we repeat, does his education prepare him for the serious responsibility? The answer is too ready. A few years since, there was not an institution in the kingdom where the medical student was brought in contact with the disease; and now there are but three (Hanwell, St. Luke's, and the Gloucester Asylum) where a very few pupils can purchase the privilege of witnessing the medical practice.

We know that there are some physicians who have acquired a well-deserved distinction, and who devote themselves exclusively to this branch of medicine—but the fact that they are few, that they principally reside in town, and that they are rarely called in when their experience might be of most service, when the premonitory symptoms are first shewing themselves—makes the abilities of these gentlemen in no way impair the necessity of greater competency to advise in these sad cases of visitation, on the part of those in whose hands resides the whole medical attendance of the kingdom—we mean, the General Practitioners. In lunacy, as in every other part of medicine, the especial cultivation, by the few, leaves the general cultivation, by the many, as urgent as ever.

In this matter, as in most others concerning the *regulation* of education, the French, though lately retrograding, have

been far in advance of us. Dr. Combe, who has paid to the study of lunacy an attention and ability which well qualify him as an authority, gives us this important testimony :—

The safety and even advantage to the patients, from the admission of pupils, is fortunately not a matter of mere conjecture. I had the good fortune to attend the first clinical course ever given on the subject of insanity, by the celebrated Esquirol, at the Salpêtrière at Paris in the spring of 1819. I anticipated confusion and excitement, from the indiscriminate admission; for all pupils who chose to attend went round with Esquirol, when he visited the patients before lecture. There was no restriction whatever, except that he occasionally went into a cell with only one or two of the clerks, where he thought the crowd would excite too much. But instead of that, the patients seemed amused and interested, and during the whole three months, I never saw one instance of any excitement, or other unfavourable result. On the contrary, the visit was expected with pleasure by many, and Esquirol's kind, friendly way of addressing them, and then turning round, to make a good-natured remark to the students, had a manifestly soothing and beneficial effect. Of course, the students behaved with propriety and good-humoured forbearance also, and consequently were not regarded with the suspicion, which used to be excited in the olden time by the admission of visitors, who came to stare as at wild beasts. The number of students who went round with Esquirol at that time, averaged from thirty to fifty, and no confusion of any kind occurred. I visited Charenton and Ivry with Esquirol in the autumn of 1831, and up to that time, he gave the same testimony concerning the advantages, to both patients and pupils, from the above plan; and I believe, at Bicetre also clinical lectures have been given, and students freely admitted for some years. I have devoted much attention to insanity, ever since I attended Esquirol's clinique in 1819, and every day's experience has added to my conviction of the necessity, even for the advantage of the patients, of admitting pupils to our asylums, under proper regulations. The attending physician would, of course, prohibit access to any who might in his opinion be injured by it, just as is done in the case of acute diseases in ordinary hospitals. If there was any chance of an overflow of pupils (an unlikely thing in my opinion), it would be easy to divide them into several classes, each to have admission to certain wards only. It is no advantage to a student to have scores of patients under his eye, at the same time. Infinitely more instructive is it, to confine his observations to such a number, as his mind can easily embrace, so as to digest and comprehend their peculiarities. To benefit by his opportunities, he must not only observe, but think and compare, and in doing so, the physician may help him most efficiently, by a few judicious remarks.

Dr Webster, who has recently visited France, mainly to acquire information on this interesting subject, tells us, in his recently-published pamphlet, which may be cordially recommended to our readers :—

Esquirol gave lectures on mental diseases at the Salpetriere; subsequently M. Mitivié, one of the present physicians to the hospital, delivered lectures on the same subject: but whatever may be the importance to medical men to possess an adequate knowledge of this class of diseases, it must be confessed that of late the study of insanity, by lectures and clinical instruction, has, notwithstanding the very great impulse given to this part of medical education at, and subsequent to the time of Esquirol, been much neglected in France, both by masters and students. However, as the new law of 1838, and the ordonnance of the King of 1839, impose upon all medical men, and especially upon those who may henceforward be appointed physicians to lunatic establishments, the necessity of being well versed in a knowledge of the principles and treatment of mental diseases, a fresh impetus has been given to the subject. Mr. Baillarger, one of the physicians to the Salpetriere, commenced a course of lectures on diseases of the mind in 1841, including clinical instruction, illustrated by patients treated in the Salpêtrière. On these occasions, M. Baillarger used to introduce to the students the insane person, upon whose case he lectured, and no bad effects ever followed these demonstrations. Indeed, upon this point, it is impossible to give better evidence than the subjoined extract from an official report made by the director of the Salpêtrière to the supreme council of the Parisian Hospitals, in consequence of that officer being deputed to attend all the lectures given by M. Baillarger, and to see whether or not the clinical illustrations were detrimental to the insane patients introduced to the class. M. Censier's report, which I am fortunately able to give, has the following paragraph:—

"From forty to sixty auditors usually attended the lectures, all in excellent order, and everything went on with the greatest propriety. The patients did not appear to feel any disagreeable impression from finding themselves in the presence of the public, and they had no direct communication with the students. In short, I can affirm that, in consequence of the precautions taken by the council, and the prudence of the professor, the clinical conferences of M. Baillarger have been profitable to science, without producing any inconvenience to our patients, who were called upon to appear."

These lectures were, I know, much appreciated by the students, who were, throughout, zealous in their attendance; and the periodicals of the day, and the medical profession, thought them creditable to the professor, as well as highly useful to the young practitioner. Nevertheless, and in opposition to the above most favourable report from the Director of the Salpetriere, who had no object whatever in sanctioning any proceeding injurious to the afflicted patients under his jurisdiction, the supreme council of the Hospitals of Paris, last spring, did not allow M. Baillarger to resume, at the Salpêtriere, the clinical illustrations of his course of lectures on mental diseases, as in the previous session. In consequence of this refusal, which, to say the least, was both arbitrary in principle, and injurious to science, M. Baillarger gave no clinical demonstrations in 1842; and his lectures from necessity only embraced the general principle of mental diseases, their nature, and treatment. This proceeding on the part of the supreme council of the Parisian Hospitals, may appear singular, and quite inconsistent with the liberality hitherto characterising most of the public functionaries connected with education in Paris, and in France. But new views seem to have taken possession of the minds of some members of the above Council, since that body not only refused permission to M. Baillarger to continue his clinical lectures at the Salpêtriere, but they have also, it is said, thrown difficulties in the way of students attending cases of midwifery; and it was even feared they would interdict the autopsy of all patients dying in the Parisian Hospitals, unless with the permission of friends, where that was practicable. However, the whole medical profession rose as one man against such an innovation, when it was first whispered abroad; so that the proposition, if it had ever been in contemplation, was not seriously brought forward. Nevertheless, the above circumstance shows the feelings actuating some members of the Council, and as that body, unfortunately for medical science, contains only one professional man among seventeen noblemen, deputies, and high officials, the fact of not continuing the permission granted the previous year to M. Baillarger, appears the less remarkable; but, perhaps, next season, they may be led to reconsider their decision, so as to give every facility to the promotion of sound and practical education on this most important branch of the healing art.

At Bicêtre, also, lectures, till very recently, were delivered by M. Ferrus, who numbered 151 pupils on his list.

At Salpêtriere, at Bicêtre, and at Hanwell, the plan of giving clinical lectures has succeeded: the patients have been benefitted by the novelty—the pupils improved—the physicians stimulated to more active exertions, —why shall it not be tried more extensively? Is it not a matter worthy of the consideration of the governors of all such institutions, and, above all, of a paternal Government, to whom the prevention of a fatal malady, of so hereditary a tendency, ought to be an object of primary importance?

REVIEWS.

A System of Practical Surgery. By WILLIAM FERGUSSON, F.R.S.C., *Professor of Surgery in King's College, London; Surgeon to King's College Hospital, &c., &c.*

HOWEVER much we are inclined to review in a fair and even favourable spirit, the useful little work before us, we are constrained at the very outset to say that we are surprised that the author should have been either so vain or so imprudent as to affix the dignified title of "System" to his production. The work is neither *systematic* as a *whole*, nor in the disposition of its *subordinate parts.* It is simply a Manual, or Compendium of Practical Surgery, and from the lucid manner in which the subject is discussed, as well as from the excellence of the wood-cuts, by which the text is illustrated, it cannot fail, we think, of being popular. The elementary nature of the work precludes a lengthened analysis in our pages. Our survey must, therefore, be of a general kind. The author divides his subject into *five* parts. In the *first* or introductory part the "*elements*" of practical surgery are adverted to, and then a part is devoted respectively to the upper extremity—to the lower extremity—to the heart and neck—to the chest, abdomen, and pelvis. Our author seems to have aimed not at explaining or elucidating the more difficult branches of surgery, but in furnishing an epitome of facts regarding the treatment of all the usual or common surgical affections; and he has successfully accomplished his purpose. His descriptions of diseases, so far as they go, are generally correct, and the treatment he inculcates, consistent with

the most approved practice of the present day, and either founded on the basis of his own experience, or on a critical knowledge of the opinions and practice of others. As illustrations of the nature of the work and as favourable instances of our author's manner, we shall transfer to our pages his opinions on two very important subjects; the comparative merits of amputation by the circular incision, and by flaps, and the treatment of vesical calculus. With regard to the first our author remarks:—

"It is impossible to argue that non-union, suppuration, protrusion of bone, exfoliation, tumours on the ends of nerves, and so forth, have not followed the circular operation,—all these evils must be admitted; but the same results have occurred from the method by flap. It is, indeed, difficult to imagine why the circular incisions should cause all the above troublesome results, whilst the flap method should avoid them: for my part, I shall not feel convinced on the subject, until I see that such is really the case,—until I see a certain number of amputations by these two methods, done by the same surgeon, or by two who are equally competent, and find all the evils on one side, and the advantage on the other. It seems to me that some such proof as this is still wanting for the surgeons of the present day. It is not to be overlooked that some of the most distinguished in the profession have almost invariably performed the circular operation, and surely all the stumps formed by these gentlemen were not so bad as the advocates for the flap would lead us to suppose. I believe I am correct in stating that, even in the present day, more amputations are done by the circular than by the other mode; and, fifteen or twenty years back, I imagine that not one surgeon in fifty ever thought of performing any other operation than the circular. I know of excellent practitioners in large practice, who have never seen the flap, and can vouch for the excellence of the stumps made by these gentlemen.

If a circular operation is improperly performed, the whole catalogue of evils may result; but the same may ensue from the method by flap. I do not here speak from conjecture, for I have seen as thorough protrusion of bone after a flap operation as after a circular. If, in the latter, the incisions are made directly down to the bone, no adequate provision being made for covering its cut end, or if the operator has failed in doing so, then there is no calculating what may follow: if, by the other operation, the flaps are not made well,—too short, and selected from improper parts of the limb,—the same evils may ensue. In short, in so far as my experience goes, the evils resulting from one operation may be as great as from the other, according to the manner in which each is performed, the nature of the coverings, the condition of the parts, or of the constitution: and all, too, must be the result of a badly-performed operation by either mode. The latter circumstance constitutes, I believe, the main part of the difference between the two, as a circular operation is much more likely to be ill-done than one by flap. It is, in fact, a more difficult proceeding, or at all events there is greater chance of a mistake occurring in the one than in the other.

The chapter on stone in the bladder, and on the treatment by Solution, Lithotrity and Lithotomy is both full and satisfactory, and tends to impart a very favourable view of our author's judgment and scientific and literary acquirements. We are sorry we cannot transfer the whole chapter to our Journal, for our readers would find it both interesting and useful. On the *solution* of the stone our author observes —

Various solvents have been used on these occasions, from simple water to nitric acid—the latter being so weakened as not to injure the mucus lining of the bladder. Hales was aware of the power of a solution of carbonate or subcarbonate of soda over certain kinds of calculi, and the efficacy of the Vichy water, whether as an internal or as a local remedy, depends, in a great measure, on the bicarbonate of soda which it holds in solution. Dr. Rutherford used lime water; Dr. Ritter, caustic potash; Sir Benjamin Brodie, nitric acid—all, of course in a diluted state. Dr. Hoskins, of Guernsey, affirms that he has discovered (by an elaborate process, if I understand him aright) an effectual and safe solvent for phosphatic calculi, and only awaits the result of some trials now making with it, to give the formula publicity. Gruithuisen, although seemingly impressed with the virtues of simple water, entertained the idea that the strength of its current might have no inconsiderable influence, and so (perhaps with more mechanical ingenuity than surgical discretion) proposed to convey a stream through his double catheter by a tube communicating with a reservoir on the top of a two-story house! Professor Jurine, of Geneva, was of opinion that injections of water had caused such a change on a large calculus in one of his female patients, that it broke down into many fragments.

This method of treating stone may now be more favourably resorted to than in former years; for, instead of the periphery alone being attacked, the object may be previously broken into fragments, whereby a vast extent of additional surface may be exposed to the dissolving and disintegrating influence of the menstruum.

The fluid may be carried into the bladder by means of a catheter and syringe,—the latter such as is used for hydrocele,—or one made longer on purpose, or a caoutchouc bag with a proper nozzle may answer. A double tube so constructed as to resemble externally a common catheter had better be used, whereby, if it is desired, a continued stream may be kept up. For this purpose Hales, Gruithuisen, and others, used the instrument like a syphon,—a dish with a communicating tube being kept above, another below. A Read's syringe may be applied for the purpose, and such an apparatus I have had by me for many years. A flexible caoutchouc catheter may be used on these occasions; silver, however, is generally preferred; and when Sir Benjamin Brodie injected nitric acid, the catheter was made of gold. Mr. Weiss has lately constructed some instruments in the form of those which I have used, and had them gilt so that they will resist the action of any ordinary solvent.

With regard to lithotrity we have the following remarks:—

In modern times the methods of drilling, percussing, and crushing the stone into sand or into such small fragments as to pass away spontaneously, or to be removed by appropriate instruments, have been devised, proposed and carried into execution, with the excellent motive of saving the necessity for resorting to a cutting operation, which until within these twenty years was deemed the only certain method of cure,—although one attended with so much difficulty and hazard as to make it in every respect a last resource.

Like many other novelties, lithotrity has undoubtedly been too much vaunted by its professed advocates and performers; but it is equally clear that in many instances it forms an admirable substitute for lithotomy. Notwithstanding the reputed success of Civiale, it seems to me that in the present stage of its history we have not sufficiently authentic data by which to determine the comparative safety of lithotrity to that of lithotomy; but regarding the applicability of the former, and even its superiority in many instances, there need be no doubt. Years must yet elapse, and the operation must be tested in our public hospitals by the same class of surgeons as those on whose proceedings the statistics of lithotomy have been founded, before an unbiassed professional judgment can be given on the subject.

There are certain circumstances adverse to the success of lithotrity, which should always be inquired into, ere it is determined to resort to this operation. The diameter of the urethra before the age of puberty is most unfavourable, both on account of the smallness of the instrument which must of necessity be used, as also that the fragments cannot pass away in such large portions. Besides, in early years the urethra and bladder are more irritable—less callous to the contact of the needful apparatus. At any period of life a small urethra is objectionable on the above grounds, whether there be stricture or a natural want of development. Any obstruction to the free passage of instruments or of urine, must be a great hindrance, and in advanced years the natural enlargement of the prostate, and what may be termed the diseased enlargement, present impediments which the utmost skill may not be able to surmount. Should the bladder be sacculated—a condition which can scarcely be ascertained on the living subject—the chances of success will be further diminished; for, supposing the stone to be broken into various fragments, the probability of some of these lodging in such pouches, must always render the results of the proceeding uncertain. But from my own experience I should say, that the most formidable objection to lithotrity is the apparent irritability of the urinary organs: if the patient does more than wince while being sounded; if the application of the steel to the urethra seems to occasion pain—I mean more than that sensation which patients usually have on such occasions—if the mucous surface of the bladder is so tender as to cause the contact of the instrument to be borne with difficulty; and if the muscular fibres are excited to such violent contraction as to occasion the evacuation of the fluid contents along the side of the instrument, or to excite an irresistible desire to micturate, then assuredly the circumstances are peculiarly unfavourable to the proceeding. A stricture may be cured; the natural calibre of the urethra may be increased by dilation; even in certain cases the objectionable state of the prostate may be in some measure overcome by means of large catheters, scoops, and proper position whilst voiding urine; but the irritability—excitability, I may call it—and tendency to inflammation, which are almost certain accompaniments, cannot so readily be coped with. It is very certain that in some instances the organs become more callous after the application of instruments; but it is equally certain that the conditions above referred to often rather increase than otherwise, after the first, second, or third sitting; and, in addition, that in certain cases, where the conditions have not been by any means conspicuous before the operation, they have been so developed as to retard the whole proceedings, making each succeeding attempt more painful than the preceding one, so that the cure (if cure it can be called) is ultimately completed amidst the most miserable sufferings—miserable to the patient, and disheartening to the surgeon,—when, from time to time, as a favourable opportunity presents, he has again to resume his attack upon the original cause of the suffering—the stone—which may at this time be already comminuted into a variety of fragments.

While I do not hesitate to assert that the above picture is by no means overdrawn, it must be admitted that the effects are very different in the majority of cases in which lithotrity is properly applicable; and here, be it remarked, there is a vast difference between such examples and those in which, unfortunately, it is attempted; for when the circumstances are favourable, viz., when there is a large and callous urethra, a capacious and apathetic bladder (if I may so call it), with good muscular power, a healthy prostate, and a small or moderately-sized stone, the operation may be done once, twice, or as often as may be required, with as little annoyance to the patient as if he were only undergoing the treatment for stricture.

Our space will not admit of more extended extraction from the work.

As a manual of practical surgery, we can recommend it to the medical student. The work is of too elementary a cast to *add* much to the well-earned reputation of its learned author, but assuredly it will not diminish it; and we hope it will prove the happy forerunner of those more original and splendid efforts in surgical science, of which we *know* him to be capable.

Chemical Manipulation, &c. By MICHAEL FARADAY, F.R.S., &c. (Third Edition Revised.) London: John Murray.

WE know of only one class of persons who will not hail the appearance of a new edition of Faraday's Manipulation with delight. We allude to the second-hand booksellers, who, during the last two years, have sold such old copies of the second edition as they could procure, for double the price at which the work was originally published!—Few authors can boast of a similar compliment. In the preface to this edition, the author states that it is little more than a reprint of the preceding one,—"circumstances of health and occupation prevented its being otherwise." The validity of this highly-gifted and amiable philosopher's plea is, unfortunately, so well known, that criticism on the subject of omissions relative to manipulations of very recent origin, would be unfair,—still our regrets are not the less, that the delicate processes of organic chemistry, as perfected in the German school, and the management of recently-invented Voltaic combinations, together with the process of Electrotype, are not touched upon in the third edition of this very valuable treatise.

—

"*Health of Towns*."—*An Examination of the Report and Evidence of the Select Committee, &c.* Snow.

THIS is a pamphlet defensive of "the vested rights" of dissenters to their town burial-places. Two positions are maintained with equal boldness,—the harmlessness of the present system to public health, and the injury to dissenters' interests of any such measure as that proposed by Mr. Mackinnon. The author, we think, succeeds in establishing the latter position — as he egregiously fails in his attempts to raise the former. There is much power of satire, a happy command of ridicule, with no want of ammunition and apt illustration, spread throughout the book,—but no abilities can varnish over the horrors of the present system of interments, or disprove their mischievous influence either on morals or health. If they could, we should ask with the writer, and with more reason, "Has common sense abdicated her ancient throne in favour of a new occupant?" The appearance of this pamphlet is one of the indications of the vigorous opposition prepared by the dissenting body to Mr. Mackinnon, and attests the wisdom of an early remark we made on the imprudence of raising, as he has done, needless resistance, by interfering with more interests than were *necessarily* opposed to him.

—

The Mineral Springs of England. By EDWIN LEE, Esq., M.R.C.S.

WE have a precursory favourable judgment of a book which, like this, is small, though on a big subject—and after perusal, in this case, has justified the prepossession. Mr. Lee's *coup d'œil* of British watering-places is that of a master. Everything unimportant in his subject escapes notice—while everything which is of value to the invalid, or the medical man, he seizes with intuitive sagacity, and places before his readers, with a precision and concise elegance, which makes his little book a treat even to the fastidious scholar. There is, however, one part of Mr. Lee's arrangement which does not please us. We have, first, a preface—secondly, a postscript—thirdly, an "*avant propos*"—and, fourthly, thirteen pages of "Introductory Remarks," before we get to the *book* itself,—and, finally, when the "book" is finished, and the printer's name duly announced, we have an extra page given on Artesian Wells, for which awkwardly supplementary form there appears no excuse, inasmuch as it bears date, March, 1840, while the preface is dated, December, 1840. The book is thus made (erroneously, we believe) to begin its career with a shew of literary dandyism, and finishes it with a demonstration of negligence far too slovenly to be graceful. All this, however, may be mended in a second edition, which we heartily wish the author. As a specimen of his style, we give his remarks explanatory of his views on the action of mineral waters on the system. Our readers will observe that the *reading* of the author, and that of Dr. Marshall Hall, have run much in the same direction.

"Lesion of the solid parts of the body, and changes of structure, have been too exclusively considered in estimating the diseased condition of parts, while the altered state of the fluids, and of the nervous influence from which so many, particularly chronic diseases, originate, has been, from the days of the humoral pathology until lately, too frequently overlooked, or regarded only in the light of an effect. Indeed, a late distinguished physician considered a morbid state of the blood, and of the nervous substance, as the sole cause of chronic diseases, and observed, 'Physicians are in the habit of regarding the solid parts as the primary agents of life, to which the fluids are subordinate; but, on the contrary, the blood and the nervous substance are the primitive and essential instruments of all the organic functions, while the solid parts occupy an inferior grade, and are but of secondary importance in disease. The elements of general and internal disease, or the morbid predispositions which form the most important objects of treatment, may then all be reduced to vitiated states (*dyscrasies*) of the blood, and of the lymph, or to derangement of the nervous system.'"*

The attention of the profession, both in this country and on the continent, has, however, of late years been more particularly directed to the primary changes in the functions of the nervous system, and in the blood and secretions, to which the more advanced state of organic chemistry has materially contributed, and has tended to elucidate the pathology of several diseases. Thus, it is now ascertained that the quantity of fibrine is increased in acute inflammations, and also in phthisis; in typhus the blood is watery, and in the last stage of this disease appears scarcely to contain any fibrine. In most chronic diseases the quantity of fibrine in the blood is diminished. The blood of females is more watery than that of males, and that of children and old persons is also more so than in healthy adults. According to the microscopical investigations of Schultz, the globules of blood are not entirely fluid, as has been supposed, but are hollow bladders into which air is absorbed in the process of respiration. By the continued use of alkalis the blood is rendered more fluid, the coagulation of its fibrine is prevented, and its colour becomes brighter; on the other hand, the use of nitric acid produces an inflammatory coat; after the exhibition of certain narcotic substances, the blood becomes more fluid and darker coloured. The quantity of iron is in direct proportion to that of its red globules; by the abstraction of blood, the iron is diminished, and by the exhibition of the preparations of this metal, the fibrine is increased, and the blood assumes a brighter red colour. According to Dr. Carswell, tubercles are never formed when the blood is not in a diseased state. Crystals of the salts eliminated in gout have been found by Jahn in the blood of gouty patients.†

The experiments of MM. Prevost, Dumas, and Müller, have thrown considerable light upon the action of particular substances on the blood. Thus, it was observed in a frog, that when a drop of water comes into contact with a drop of blood, the globule, which has naturally an elliptical flattened shape, becomes round, and its course is accelerated. When, however, the experiment is made with a saline solution, as common salt, or subcarbonate of potass, in water, no alteration of form occurs. The dimension of the globule is altered by contact with particular substances; thus liquor potassæ, though it does not alter the form of the globules, renders them smaller;—a minute quantity of pure soda added to the blood abstracted from a vein prevents its coagulation. Acids produce increased oxidisation, coagulation, and redness of the blood, whereas the action of alkalies is more solvent, rendering the blood thinner and more liable to decomposition. It has been also demonstrated by experiments on rabbits, that iron is absorbed into the blood only in a limited proportion, the remainder of the quantity given being excreted.*

Alterations in the quantity and chemical composition of the different secretions, it is well known, may depend upon the influence of the nervous system, and of an altered condition of the blood, either occurring from morbid causes, or from the introduction of particular substances into the circulation: of which the flow of tears from mental emotion, the change in the urine of hysterical patients, increased alkalinity of this secretion from injury or disease of the nervous centres, the calcareous concretion deposited in the joints of gouty persons, may be mentioned as familiar examples; but the agency of the organic nerves in producing these changes, both in the blood and secretions, and in inducing various diseased states, is not in general sufficiently considered. Scirrhous tumours, for example, are not unfrequently caused by depressing emotions, as grief, anxiety, &c., acting primarily upon the cerebro-spinal system, and consecutively upon the capillary vessels of the part; so, in like manner, indurations of viscera, and other local functional and structural changes of organs, may be induced by derangement of the functions, or by direct lesion of the sympathetic or organic nerves, which, united by numerous inosculations with those of the cerebro-spinal system, extend their influence to all parts of the body, and which have been proved, by the experiments of M. Brachet, to preside over the action of the capillary vessels, and of the functions of nutrition and secretion. An anormal condition of the organic nervous system, or part of it, frequently depends upon alteration of the quantity or the quality of the blood by which it is nourished; and when this is the case, it does not fail to react upon, and increase the disordered condition of the vascular system. When, several years ago, it was observed that a section or mechanical lesion of the branch of the fifth pair of nerves supplying the eye produced increased vascularity, with subsequent sloughing of the cornea, acute inflammation was supposed to have been produced by the experiment, and to have given rise to this result. A similar effect, however, was subsequently found to ensue in animals which were fed upon sugar or other substances in too concentrated a state to afford them proper nourishment; and M. Brachet clearly demonstrated that the circumstance did not depend upon inflammation, but simply upon mechanical distension and consequent obstruction of the circulation through the capillary vessels, from their privation of nervous energy. He observes, "Let us remember that the ganglionic nervous system presides over the secretions and capillary circulation. When, therefore, in consequence of lesion of the ganglionic nerves of an organ, its secretory and capillary action are paralysed, it does not cease on that account to receive blood, as this fluid is forced into the vessels by the contraction of the heart; but no longer finding in the capillaries the energy necessary for their reaction, it gradually distends them and remains almost in a state of stagnation, puffs up (*boursouffle*) the parts where the textures are sufficiently lax to admit of it, and determines redness and swelling as in the conjunctiva."†

† Du Système Nerveux Ganglionaire.

Hence we may see that various states which have been considered as inflammatory, are not so, but depend upon impaired nervous energy, and why depleting measures would be prejudicial, while those calculated to give tone to the nervous system would be most successful; why the spleen should be so frequently congested after attacks of intermittents, while the more dense texture of the liver is comparatively seldom affected, and why quinine tends to reduce the splenic enlargement; why the congested state of the vessels of the eye in that state which is termed strumous ophthalmia should continue so long without producing serious injury; and why, though the local abstraction of blood may occasionally be of service in relieving the congestion, its too frequent repetition predisposes to relapses, which are best prevented, and a cure most permanently effected, by tonic remedies and local stimulants, which strengthen the system generally, and excite the torpid and relaxed vessels to action. Chilblain is another illustration of the same principle; congestion taking place in parts of the body remote from the centre of circulation, when their nervous energy has been depressed by cold. Dropsical effusions also very frequently occur in the same manner, the serum of the blood transuding through the capillaries into parts where the cellular texture is lax, and whence the blood meets with obstacles in returning to the heart. Softening of the nervous centres, and paralysis, doubtless occur not unfrequently from the same cause, viz. deficiency of nutrition of their substance, from the nervous energy of the capillaries being impaired, as is pretty evident by these diseases most generally occurring in elderly persons, and those in whom the vital powers have become depressed. I have met with several cases of paralysis consequent upon excesses, from the influence of malaria, &c., or occurring idiopathically, in which the too indiscriminate use of blood letting, and other depleting measures, had been extremely prejudicial, and in which the subsequent use of a tonic regimen had been productive of the highest benefit. That a diminution of the organic nervous influence of the capillaries of the nervous centres is frequently the cause of congestion and its consequences, is clearly shown by an experiment of Brachet. After removal of the upper cervical ganglion in a dog, the eyes became red and tumefied, as in the other experiments, coma supervened, and after the animal's death the capillaries of the brain and its membranes were found to be gorged to the utmost with blood, on which Brachet justly remarks—"Hence many diseases, apparently of the brain, have, in fact, a very different origin. Suppose the occurrence of an analogous instance to the above-mentioned experiment—symptoms of disease of the brain takes place, the post-mortem examination demonstrates pathological alterations in this organ, the consequences seem to be natural, and yet it is nothing of the kind; *the brain has only become diseased secondarily*, the organ truly affected is the ganglionic system, the action of which being paralysed produced the phenomena which the brain presented. If the diminution or the abstraction of the influence of the ganglionic system could so frequently occasion the phenomena observed in the preceding experiment, may we not reasonably infer that the same thing will take place whenever this influence is modified by any pathological affection of the upper part of the ganglionic system?"

Extirpation of a Dropsical Ovarium. —Mr. Henry Walne gives, in the *Medical Gazette*, a successful case of this kind, where the removal was effected by the large incision. The operation, which appears to have been modelled on those performed by Dr. C. Clay, (as given in recent numbers of our Journal) took place on Nov. 7th. On the 11th, bad symptoms appeared, which, however, were overcome by the 13th; and, by the 29th, the patient felt quite well; the wound being healed, with the exception of a seton-like opening at the lower end of it.

COURT OF COMMON PLEAS, Wednesday, December 21.

(*Sittings at Nisi Prius, at Guildhall, before Lord Chief Justice* Tindal *and Special Juries.*

BEALE v. SELF.

Sir T. Wilde, Mr. Hoggins, and Mr. E. James conducted the plaintiff's case, and Mr. Serjeant Talfourd and Mr. Butt that of the defendant.

The action was for slanderous words spoken of the plaintiff, who is a surgeon and accoucheur residing in Bedford-square, Stepney, by the defendant, who is also a medical practitioner, and a near neighbour of the plaintiff, on different occasions in the month of December, last year. The defendant pleaded—first, the general issue; secondly, as to so much of the third count of the declaration as related to the speaking of the words that a Mrs. Neek was improperly treated by the plaintiff, that she did receive improper treatment; and, thirdly, as to the use of the words mentioned in the second count, "that the plaintiff was a dissecting room beadle," that such words were true.

Sir T. Wilde stated the case to the jury, and called the following witnesses:—

Mr. James Norris.—On the evening of Wednesday, Dec 29, last year, I was at the house of Mrs. Hough, between 6 and 7 o'clock. Mr. William Rowland, collector of poor-rates, was also there. The defendant was present. Mr. Rowland said he had heard that the defendant had been to Lambeth street police court, and that he knew what the defendant had been there about. Some conversation took place between Rowland and the defendant about an inquest which was to be held on a person whom I afterwards ascertained to be Mrs. Neek. The defendant said that the plaintiff, Mr. Beale, was incompetent to practise as a medical man. The defendant said to me, "If you were ill, would you call in a waggoner to attend you?" I said that Mr. Beale was a surgeon. The defendant replied, "He has never been anything but a surgeon's beadle to a hospital or dissecting-room," and that Mr. Beale was not a surgeon.

Cross-examined.—I have been told that an action is pending against the plaintiff, which action has been brought against him by the Apothecaries' Company for practising without a certificate from them.

Mr. Edward Porter examined.—On the 27th of December last I had occasion to go to Lambeth-street police-court, and there I saw Mr. Self, the defendant. He said, "You are about to summon a jury on a coroner's inquest upon Mrs. Neek." He said, "You have seen Mr. Dale this morning; my name is Self." Mr. Dale (the defendant in a similar action) had before this mentioned Mr. Self's name to me. The defendant said, "The deceased Mrs. Neek, has been very improperly treated by Mr. Beale, who is no surgeon." I asked him what he particularly wanted with me. He said it was about summoning the jury. I asked if he wished to be one of the jury. He said I might summon him. I filled up a summons in the police court, and gave it to him then and there. I had a warrant from the coroner to call the jury on the 30th of Dec. I told the defendant that Mr. Dale had told me that morning that Mr. Beale was nothing but a quack, and I said, "I hate quackery as much as any one, and you may be one of the jury." I also said, "I will summon a jury of doctors, if you will give me a list of those who are properly qualified." It was agreed that I should call on the defendant, previously to summoning the jury for that list. On the morning of the day for which the inquest was summoned, I called on Mr. Self for the list. I asked Mr. Self if he had prepared the list, and he said "No; we have ascertained that Mr. Beale is a surgeon, and we intend to let the affair take its natural course." I said, "Then I shall summon a respectable jury," and Mr. Self said he should attend. The coroner's inquest was held that evening before Mr. Baker. Mr. Self was not on the jury. Mr. Beale was there; so was Mr. Bennett, and Mr. Farrer, and Mr. Dale. Mr. Neek, the husband of the deceased, was present. Mr. Self put some questions to Mr. Beale, but not so many as Mr. Dale did. Mr. Pearce, a medical man, also asked some questions. I was myself on the jury. The verdict was "Natural death," and the jury said they thought Mr. Beale had treated the deceased in a very proper manner. I have not seen the defendant since. I was led to believe, from what Mr. Self had told me, that Mr. Beale was not a surgeon.

Cross-examined.—I am an auctioneer and appraiser, and summon the jury for the constable, who is unwell. I never saw Mr. Beale till I summoned him to attend.

Mrs. Letitia Sarah Josephine Burr examined.—I live in King street, Stepney. My husband is an officer in the Customs. In December, 1841, I expected to be confined. I sent my sister on the 29th of November to Mr. Beale's house, to tell him to hold himself in readiness to attend me. I know Mr. Self as a medical man, who had attended me twice. Mr. Beale called upon me on the 2d of December. After this Mr. Self called on me, and I told him that I had intended to send to him, as I did not think it right that he should be kept in ignorance that I did not wish him to attend me in my coming confinement. Mr. Self said, "Why? could I find any fault with him? I told him no, I did not. He then said, "Did I blame him for anything that had happened to the children? I had lost some children before this. I told him no, I did not, it would be very wrong to do so. Mr. Self asked me to consult my husband on the subject, and said he would call the next day, and hear what I had to say. The next day he called. I told him I had made up my mind to call in the gentleman I had mentioned. I had said the day before that I should call in another gentleman. He then asked it was a fair question, if I would tell him whom I intended to employ? I told him I would make no secret of it; it was Mr. Beale, of Bedford-square, Stepney. Mr. Self said he thought it was something of that kind. He said, "Was I aware that Mr. Beale was an unqualified practitioner, and liable to be prosecuted every day? I told him that I was not aware of anything of the kind, and I knew he had attended my father for some time; and that my father and friends generally wished me to employ him. He asked me whether my father intended to give me anything, because, if so, he had better do so when it would be of some good to me, and not wait till I was dead. Mr. Self said if I wished to change, he would recommend some one to me of experience, but not Mr. Beale, who had not any experience. He said I was to tell my husband and my father that if any thing happened to me, he would call a coroner's inquest on my body, and have the matter properly investigated. He said, "There was no such person as Mr. Thos. Beale, a surgeon." He said that, as if he believed that there was no such a person. He had said before that Mr. Beale had been a beadle to a hospital, and that he had had no proper medical education. I asked him what a beadle was, and he said it was a man who had to clear away the guts and garbage. He said that there something on foot about a coroner's inquest. The same evening I was taken ill, and sent for Mr. Self. I did not send for Mr. Beale, in consequence of what Mr. Self had said. My confinement took place on the 17th of Dec. The conversation I have been speaking about took place on the 3d of December. I afterwards sent to Mr. Beale, and explained to him why I had not called him in. This was about three week after the 17th of Dec. At that time I informed Mr. Beale what Mr. Self had said of him. Afterwards I told Mr. Self that I had seen Mr. Beale. Mr. Self said, that he had since ascertained that Mr. Beale was a surgeon. I said I was very sorry I was implicated in it, and that I had rather it had been any other person. Before this I had been told that my evidence would be required: that caused me to make the observation. Mr. Self said that I had no occasion to say anything. Afterwards he said that he had heard I had been with Mr. Beale to his lawyer.

Cross-examined. It was either in the latter part of January or the beginning of February that I went to Mr. Beale's lawyer. I have been twice there in all. What I said was written down, but I did not require it. Mr. Beale has attended my father, and I think his complaint was erysipelas. He also attended my sister, but I do not know what her complaint was. Mr. Beale sent medicines. When Mr. Self told me that he had discovered

that Mr. Beale was a surgeon, he said that Mr. Beale became a surgeon in July 1844. He said he had nothing to say against Mr. Beale as an accoucheur, because anybody had a right to practise midwifery, but he said he had no right to administer medicines.

Re-examined. When he said this, he added that I might as well employ a midwife, for that if I did, and anything was to happen, I could soon send for a medical man, but that when a gentleman was employed one ought to be able to place confidence in him. I told Mr. Beale's lawyer that Mr. Self had spoken to me on the subject as a friend, and I, therefore, declined to say all that I have said to-day. I paid a guinea for my confinement, exclusive of medicine.

Mr. C. Neck examined.—I am a schoolmaster, and live in Philpot-street, Commercial-road. I have known the plaintiff about four years. I am the husband of Mrs. Neck, who died on the 25th of December last. Mr. Beale had attended her. She had been ill just nine days. Her illness was sudden, and was owing to a twisting of the bowels, or something of that kind. Mr. Beale, so far as I could judge, treated her skilfully for that disorder. Mr. Beale brought Mr. Farrer to see her. Mr. Farrer is a surgeon and apothecary in the neighbourhood. Mr. Beale attended my wife all the time of her illness but the fourth day, which was Sunday. Mr. Beale left me at 10 o'clock on the Saturday evening, under the impression that he had done all that could be done under the circumstances. On the Sunday morning Mr. Beale's son came to ask how Mrs. Neck was, and I told him she was much worse, and I wished him to go for his father directly. He said that his father had gone by the first boat that morning to Gravesend. We then sent for Mr. Bennett, a medical man. Mr. Beale returned that evening, and came to my house. It became a question whether he should continue his attendance, and my wife said "Mr. Beale;" thereby implying that she wished him to attend her. Mr. Beale first intimated that there was danger on the Friday morning. I believe that Mr. Farrar was aware of the treatment pursued. After my wife's death I allowed a *post mortem* examination to be made. Mr. Farrer and Mr. Beale attended it. The day after the examination Mr. Self called on me, and asked me what was done in the first instance? I told him that Mr. Beale administered whatever medicines he thought proper; that he was constantly in and out, and that whatever he directed was done. Mr. Self asked if leeches had been applied; I said, yes, six. He said, that at least forty or fifty ought to have been applied. Mr. Self said, that Mr Beale was nothing but a porter, and that he had no more right to practise than I had. That was all that he said to me, with the exception of a few remarks about his standing forward for the respectability of the profession. I recollect the inquest on my wife. I had taken no steps to call one, and was astonished when I was served with a summons. I was examined as a witness. When Mr Self called there was nothing to lead me to believe that an inquest would be summoned.

Cross-examined. I have known Mr. Beale four years, and during that time he had attended my family, and sent medicines. I have had five of Mr. Beale's sons at my school at one time. My wife was taken ill on Thursday, the 16th of December. Six leeches were applied at once. No warm bath was used. A small blister was applied to the pit of the stomach on the Saturday.

Re-examined.—Mr. Beale ordered fomentations in the middle of the day as hot as they could be applied, and they were continued.

Mr. Farrer examined.—I was called in by Mr. Beale to see the deceased Mrs. Neck. When I saw her the symptoms were like those of a person passing gall-stones. I attended the *post-mortem* examination. Mr. Beale operated, and did so in a decidedly skilful manner. A portion of the smaller intestines were twisted or strangulated to the extent of about six inches, and this part was approaching to gangrene.

Cross-examined.—I should judge the twisting to have existed six or eight days. I decidedly think that if more active remedies had been used, and a greater number of leeches applied, it would have given the patient a better chance. Considering the extent of pain I witnessed, I should think that six leeches were not enough; and in my judgment a great many more ought to have been applied. Supposing that the pain had continued on the Saturday, and that the bowels were not relieved, I should have thought that I had been mistaken in supposing that the patient was passing gall-stones. I should not have felt justified in leaving the case from Saturday to Sunday night without providing a substitute. I consider the case to have been a medical case.

Re-examined. I wrote down a short statement of the *post mortem* examination some little time afterwards. (The statement was handed to the witness, who looked over it.) It is correct. It is there said that the pulse was feeble, the patient very low, and seemingly exhausted. Upon the *post mortem* examination I found the gall-bladder large, and full of fluid. The application of leeches would depend upon the subsequent condition of the patient. I should have suspected that there must be acute inflammation going on, as shown by the feeble state of the pulse. Bleeding would have had a good effect if it had been applied nine or ten days before death took place. If she had not got better, I should have bled her till some degree of faintness was produced. I cannot say how much blood the patient would have lost before she became faint; patients vary so very much. If the case had gone to the public hospitals, they would have taken it as a medical and not as a surgical case. I am quite clear on that.

By Mr. Serjeant Talfourd.—The seat of the disease was lower than where the intestines were twisted. The twisting might be the cause or the effect of inflammation.

Mr. W. G. Merritt examined.—I knew Mr. Beale when he attended at the London Hospital. I saw him there often collecting subjects for demonstration, and engaged as a curator in the Museum. He injected the arteries and veins of the subjects. He also articulated the bones. I have seen a person who was under him sweep and clean the place. I considered the plaintiff a very promising young man.

Cross-examined by Mr. Serjeant Talfourd.—I have known the office which Mr. Beale held called by various names. I know it is called that of dissecting beadle to the hospital. I have also heard that officer called assistant to the lecturer. The person who swept the Museum was a servant of the dissecting-room. His name was Merritt. He was no relation of mine.

Mr. Serjeant Talfourd.—Another order of merit, I suppose?

Witness.—I cannot say.

Re-examined.—The opportunities of seeing anatomy afforded to a person holding that office would be the most brilliant of all, and the plaintiff paid the most arduous attention to his duties while he remained there.

Dr. Charles Waller examined.—I am a physician and consulting accoucheur to the London and Southwark Lying-In Institution. I have known the plaintiff ten or twelve years. He attended two courses of lectures of mine on midwifery, and the diseases of women and children.—He attended with more diligence than most pupils. I had every reason to believe that he was a well-informed man, and as regards the department in which he attended me, I have no hesitation in stating that he was perfectly competent.

Cross-examined.—I have attended several labours with him. I renewed my acquaintance with him about six years ago.

Mr. Frederick Tyrrell.—I am surgeon to St. Thomas's Hospital. Formerly, for many years, I gave lectures in surgery. I know the plaintiff well. About 1826 or 1827 I became acquainted with him. He then became an assistant in the dissecting-room in a school which I was the principal means of founding, in Aldersgate-street. The plaintiff remained there as long as I did, and I believe longer, but I left in 1829, when I was solicited to take a professorship at St. Thomas's. Mr. Beale had constant opportunities afforded him of becoming acquainted with the profession, and his attention was unremitting. When he was there he asked me to allow him to attend my lectures for the purpose of enabling him to follow the profession at some future period. He attended a course of lectures in anatomy and physiology which I delivered in conjunction with Dr. Quain, and a separate course delivered by myself on the principles and practice of anatomy. When I left the school, his knowledge of the profession appeared to me to be very good, and I should say that it was much beyond mediocrity. In the case mentioned by Mr. Farrer to-day, the case would have gone to the hospital physician in the first instance, but if the symptoms continued the physician would probably ask for the assistance of the surgeon. There must be other symptoms than those I have heard described to day to enable me to judge of the treatment that should have been pursued. With the suspicion that there were gall-stones passing, the treatment pursued by Mr. Beale would have been proper. The six leeches were a sort of trial, and if that had been found to afford relief, and the pulse rose, more might have been applied. I should have said that the application of 30 or 40 leeches, when the patient was in a state of extreme depression, would have been a hazardous mode of treatment. It would show a want of skill, as you cannot recal blood. There may be various causes of obstruction of the bowels. It would not have been judicious to increase the number of leeches under a low condition of the circulation. I should say that the obstruction did not arise from inflammation, but from ligature.

Cross-examined.—I think that inflammation would not have arisen in nine days. Mr. Beale's whole time, up to 1829, was devoted to the school in Aldersgate-street. He was paid between 20s. and 30s. a week. We termed him assistant curator. I gave him the certificates produced for attending lectures in the course of the medical sessions 1827-8 and 1828-9.

Re-examined.—When I left the school he was competent to pass his examination in anatomy and physiology, but not in surgery.

Mr. Aston Key examined.—I am a surgeon at Guy's Hospital. I have heard Mr. Farrar's evidence. I think the opinion might have been formed without impugning the plaintiff's want of skill, that gall-stones were passing. I think that thirty or forty leeches would have endangered life. The powers of the patient would be exhausted by bleeding, and thereby her danger would be increased. The case appears to me to have been very peculiar in wanting the symptoms of acute inflammation. From what I have heard, I should say that the obstruction arose from adhesion, and that the case was wholly beyond the reach of art.

Mr. Neck recalled.—Down to the time of my wife's death her health was pretty good, but she was rather an ailing woman. My wife used to say that her heart appeared to be too large for her body.

The diploma of the plaintiff from the Royal College of Surgeons was put in.

This was the plaintiff's case.

Lord Chief Justice Tindal inquired if Mr. Serjeant Talfourd intended to call witnesses?

The learned Serjeant said that he should be glad of an opportunity of considering the evidence but he would not say that even as then advised he would call witnesses for the defence.

An adjournment was then agreed to.

This morning Mr. Serjeant Talfourd addressed the jury for the defence in mitigation of damages, but no witnesses were called in support of the pleas of justification.

The Lord Chief Justice summed up, and the jury, after some deliberation, found their verdict for the plaintiff, with £100. damages.

In Beale v. Dale, being a similar action against another defendant, the case was concluded by a compromise, a verdict being entered for plaintiff, with 40s. damages.

MOLLITIES OSSIUM.

(To the Editor of the "Medical Times.")

SIR,—In your report of Mr. Solly's observations on a case of mollities ossium, I observe that that gentleman in alluding to the microscopic appearances of sections of the bone alludes to the existence of "some particles of matter" which were "believed" to be worms. Mr. Solly then decides that these particles of matter are not worms, but "little filaments separated from the bones." The reasons assigned for this decision is, "because the cleaner we cut the sections there was less appearance of worms, and, at last, by the greatest care, not a portion of the supposed worms could be seen in the section."

I beg leave, with great deference for the superior powers of observation with which Mr Solly is endowed, humbly to dissent from this decision, because in a portion of the calvarium which I had an opportunity of examining by the kindness of Mr. Topping, of Brule Street, Liverpool Road, notwithstanding the greatest precautions were used to ensure perfect cleanliness of the cutter, the bodies alluded to were, I think, constantly visible.—I am sure that their absence was the rare exception, their presence the general rule, for the numerous sections which I examined with Mr. Topping; I am equally confident that what I saw, were not extraneous bodies, but did really and truly exist in the substance of the diseased bone. Whether they be, or be not "worms," I do not presume to judge, being neither microscopist, or comparative anatomist enough to form an opinion at variance with one who deservedly ranks high in both capacities, but I take the liberty of addressing these few remarks to you, in order that attention may be given to the microscopic observation of this or any future examples of this disease which may occur, its real nature, equally with its causes being buried in such profound obscurities, it is incumbent on us to use every means in our power to throw light on its origin.

I have the honour to be, Sir,

Your obedient Servant,

W. B. KESTEVEN,

Junior Surgeon to the Holloway and North Islington Dispensary.

Upper Holloway, Dec. 27th, 1842.

PERISCOPE OF THE WEEK.

SHORT SIGHT.—Those who are engaged in occupations which require the long-continued employment of the eyes on minute objects are more apt to become near-sighted than those who are not thus employed. Mr. Lawrence attended a book-sale, and found that out of twenty three persons who were present, twelve of the number wore glasses.—Like several other affections of the eye, myopia is sometimes hereditary; the children of short sighted parents being more apt than others to be affected with the disease. All minute occupations, such as sewing, long continued reading, drawing, &c., should be abandoned; the head should be kept erect: the coverings of the neck should be loose; and straining of every kind should be avoided, to prevent increase of congestion. Mild unirritating diet, pure air, active exercise, and the practice of looking at distant objects in the open country, will be very beneficial. The far discerning eye of the Indian is well known; and it is asserted that near-sightedness does not exist among the Arabs or Tartars, who are used to roam about, and to look at distant objects The power also which sailors possess of seeing at great distances is only acquired by practice. An experienced "look-out man" can very soon descry the character and the nation of a distant sail, which, to an ordinary observer, might seem a mere speck on the ocean. Some of the exercises of a soldier increase the power of recognizing distant objects. "It was not unusual," says Reveillé Parise, "to observe that among the troops the sight of many near-sighted conscripts was restored." In the case of a boy born without arms, who possessed the power of writing, &c., with his toes, Dr. J. V. C. Smith relates that the point of distinct vision was so much lengthened, that the boy could not see at the usual focal distance, so well as at his feet. By the early application of concave glasses the crystalline is kept in a wrong position, and the efforts of nature to overcome the defect are prevented.—"Give," says Reveillé Parise, "a person with excellent sight a glass slightly concave, and he will at first see less distinctly than with the naked eye. He will, however, soon become so accustomed to its use, that it will not incommode, but even become indispensable to him. Gradually increase the concavity, and you shall see that the organ will change in a similar manner, so that an individual with good sight will, at the end of a few years, become affected with complete myopia, and will ultimately require glasses of the shortest focus."

EFFECT OF ADMITTING AIR INTO THE VEINS.—A man, 55 years of age, was received into one of the French hospitals, in October last, with a scirrhous tumour on the left side of the neck, extending from a little above the clavicle to the lower jaw, in the space between the larynx and the sterno-mastoid muscle. The strength of the patient was wearing away under continual vomitings of bloody mucus, and the lancinating pains felt in the tumour, the removal of which was resolved on. The man having been laid in a horizontal posture, his head turned towards the right side, the tumour was exposed in its whole extent by a crucial incision, and the flaps dissected aside, partly with the scalpel and partly by the finger. The tumour was readily separated from most of its adherences, without the exertion of much force. The arteries divided were speedily tied, the loss of blood was inconsiderable, and the operation appeared to promise a satisfactory termination, when the internal jugular vein became penetrated with the end of a scalpel, so as to admit a quantity of air. At the same moment, says the operator, who reports the case in the "Gazette des Hospitaux," Nov. 8th, "I heard, progressing from the wound towards the heart, a peculiar noise—a sort of *glou-glou*—a sound which, once heard, can never afterwards be mistaken." The patient instantly turned pale, his breathing became quick, he uttered a plaintive cry, with the exclamation that he was dying, and scarcely a minute elapsed before he was actually dead. The operator, as soon as possible, placed his finger over the place of the wound, though without any good effect. He, however retained it in that place for several minutes, and noticed that a flux and reflux movement continued in the vein for five or six minutes after life was extinct.—A *post mortem* examination was made twenty four hours afterwards. A gaping oblong-shaped opening, about two-tenths of an inch (six to eight millimetres) in length, was met with in the jugular vein, three quarters of an inch above the subclavian, and at a point where the tumour was found to be adherent to the coats of the vein. Blood pressed upwards, and made to exude through this opening, contained numerous globules of air. Air-globules were found in great quantity mixed with the blood in the right auricle and ventricle, the parietes of which were distended, and their contents of a colour decidedly less dark than venous blood generally. The blood in the superior cava, subclavian, axillary, and brachial veins, and those on the interior of the cranium, also contained air, as did a frothy fluid in the iliac arteries and aorta. The left ventricle and the cerebral sinuses were empty. It may be remarked, that death, in this case, happened earlier after the puncture than on any of the many occasions recorded by Amussat, Magendie, &c., doubtless, in consequence of the close proximity of the internal jugular vein to the centre of the circulation.

TREATMENT OF SCARLATINA.—As scarlatina, &c., are the result of poisons inhaled into the blood, and as those poisons, whilst floating in the atmosphere, are destructible by chlorine gas, a correspondent suggests that they may also admit of being destroyed by the continued inhalation of the same gas, admixed in moderate proportion with the atmospheric air. At any rate, such an admixture of chlorine gas with the air of the invalid apartment would be wholesome to the patient, and protective of others. In addition to the chlorine gas diffused in the atmosphere, water, with a slight addition of chlorine, may be taken as a beverage, for thirst and the condition of the throat, and may be used for ablution of the general surface.

STRANGULATED HERNIA.—An old woman, aged 73, was admitted into the Marylebone Infirmary, under the care of Mr. Phillips, with strangulated hernia. The history of this case shewed that the symptoms of strangulation had been present eight or nine days, though they had not been very pressing; there had been no stool for eight days. Upon examination after admission, the tumour, which was not large, was found to occupy the right femoral region. There was not much tenderness at the point, nor at any part of the abdomen; there was very slight tympanitis; there was some nausea, and occasional vomiting, but not severe. The tongue had a slight coating; the pulse was 84. Mr. Phillips pointed out that in people advanced in life it is often not prudent to wait for more decided symptoms, because the powers of life are incapable of developing them, and because it is matter of observation that they often die with symptoms which, according to the language of works on surgery, would not warrant a recourse to operation.—As it was ascertained that the taxis had been employed for a hour and a half on the previous day, it was not thought prudent to persevere longer in any further attempt at reduction, and the operation was at once had recourse to. An incision was made in the usual way, and the approach to the sac was cautiously made. A tumour, apparently omentum, and much larger than a pullet's egg, was exposed; it was invested by a membrane which was conceived to be the sac; this was opened, and the director being placed under it, it was incised upwards and downwards to such an extent as was necessary. The omentum-like mass was now fairly seen; it was very vascular, and a large number of veins on its surface appeared so tortuous as to give the impression that they were varicose. The tumour was turned up, but no intestines could be discovered under it: there was no reason to doubt that it was an omental hernia. A director passed very easily under Poupart's ligamant, and the opening was enlarged to the necessary extent. The tumor was then readily passed back under the ligament. Dr. Boyd and one of the assistants passed their fingers under the ligament, and

were satisfied that the reduction was complete. The lips of the wound were brought together by suture, and it was ordered that the patient should be left without medicine for six hours. At that time, as there had been no stool, the house-surgeon ordered a common enema, which brought away a certain quantity of fecal matter. In the night she took three grains of calomel, to be followed in the morning by a beef-tea-injection: they brought away a little more fecal matter, but stercoraceous vomiting came on, and in the course of the day she sank.—The body was examined fourteen hours after death. There were very slight traces of peritonitis. The examination was then confined to the neighbourhood of the disease. The tumor had again protruded, and a portion of intestine was involved in it; 5 or 6 inches of intestine on either side of the implicated part were removed, with the tumor, and the following state of things was revealed. The tumour was very condensed and very vascular, having much the appearance of inflamed omentum, it was surrounded by a tolerably dense investing membrane. Into the centre of this tumour a knuckle of intestine passed to the depth of rather more than an inch and a quarter, and on every side the intestine was surrounded by fat to the depth of more than a quarter of an inch: the pressure upon any part of the intestine did not appear to be great; there was, however, considerable thickening of the peritoneum at the proper neck of the sac, which was hard and unyielding. The intestine was adherent to the sac, as was the sac to the fatty mass. In this case, to which Mr. Phillips knew no parallel, it would seem that the fatty tumour must have been seated in very immediate relation with the femoral ring, probably blocking it up, and that when the protrusion of intestine took place, rather than give way, the tissue of tumour had admitted the intestine to pass into its centre. Of course the proper sac was not opened, and indeed could not have been got at without cutting down half an inch into the tumour.

Closure of the eyelids.—Closure of the eyelids is not a mere passive condition, from relaxation of the levator, as taught by Bichat, but muscular agency is employed in its accomplishment. An interesting case is detailed of paralysis of the *portio dura*, occasioning lagophthalmos, in which, as in similar cases, by no means so very uncommon, the upper eyelid assumes that position in which the force of gravity, unaided by muscular effort, would place it. With Sir C. Bell, Mr. G. Stokes thinks that, during sleep, the eyeball is turned up, whilst the affected eye remains open, in fact the lower third of the eyeball is exposed in these cases to the dropping of the upper lid over the two upper thirds, and the white of the eye alone shews, from the more or less complete action of the inferior oblique. Mr. Stokes considers the muscle as a true sphincter, for the reason that it presents all the anatomical and physiological characters peculiar to such muscles, viz., a mixed function, the voluntary power being employed during a state of wakefulness, the involuntary during sleep, regarding the orbicular and palpebral portions as but one muscle, possessed of a similar mixed function.

Operation for Strangulated Hernia at the Age of 107!—The patient, who shewed the certificate of his birth, and is well known as a musician, played on the violin with his late Majesty, George the Fourth. His name is Rochard, a Frenchman, and his faculties were quite entire. He came to St. George's Hospital with strangulated inguinal hernia, which had been fixed for some time, as no motion had passed for three or four days.—Two attempts to reduce the hernia had been made before his admission. Mr. Hawkins found that, although there had been no sickness, it was necessary to proceed at once to the operation. The sac was very thick, and on opening it a mass of apparently transparent jelly protruded, which was a considerable quantity of recent lymph, distended with the serum, which filled the sac: the contents were a few inches of inflamed small intestine glued together and to the sac by lymph, which Mr. Hawkins was obliged, after dividing the stricture, to tear away from the bowel in order to reduce it. The case went on very well afterwards, and requires no particular notice, except that the patient is now well enough to take his usual walks.

THE MEDICAL TIMES ALMANAC FOR 1843. Containing a Calendar for the Year of unique value—For mula for the Calotype Process.—An Ample Sketch of the Anatomical and Physiological Discoveries by the Microscope. A Description of the Symptoms, Treatment, and Tests of all Poisons. An Abstract of the Pharmacopœia.—With the usual matter of a Good Almanac.

PRICE 4d., STAMPED 5d.

Among a number of favourable notices of the Almanac we append the following:—

THIS is the cheapest, and, for medical men, unquestionably the best of the Almanacs which this week come under our notice. How all this really useful matter can be given for fourpence, seems wonderful, even in this day of "cheap Knowledge" wonders.—The Watchman, Dec. 20.

THE "Medical Times" Almanac for 1843, just published, [illegible], London, contains, besides the usual information of such publications, the days and hours of meeting of all the learned and scientific Societies of London, a useful abstract of the Pharmacopœia, a short article on the various Poisons, and some interesting Formulæ for Photographs, Calotype, and Chrysotype Papers, and Daguerreotype Plates.—CAMBRIDGE OBSERVER.

THE "Medical Times Almanac." This Almanac is a sort of appendage to a weekly medical work of great ability, to which we have already drawn the attention of our medical friends. We hear that it is cast "going ahead" of the LANCET. The main features of the Almanac are article on "the chief results obtained by the use of the microscope in the study of anatomy and physiology," and a carefully written abstract of the Pharmacopœia.—GLOUCESTERSHIRE CHRONICLE.

This third Almanac, like our own 'Wanderer' one, may be said to be still cheaper, for it is produced at the price of the "Medical Times"—the paper by which it is issued. It is eminently professional in every part. Its quantity of contents are a marvel. The quality of them is professionally invaluable, especially the abstract of the Pharmacopœia, the account of microscopical discoveries in anatomy and physiology, and the tests and antidotes of poisons.—[illegible] AND KELSO WARDER.

This useful Almanac, in addition to the usual matter of general interest contained in such publications, gives an abstract of the Pharmacopœia, a full account of all the Microscopic discoveries in Anatomy and Physiology, the Tests and Antidotes of Poisons, &c. To the medical profession it cannot fail to prove extremely useful.—LEEDS TIMES.

THIS Almanac contains a vast quantity of Medical information in a popular form, and useful to the man of science as well as to the general reader, on anatomy and physiology it is peculiarly instructive. We strongly recommend this valuable weekly periodical to our readers, its cheapness placing it within the reach of all.—[illegible] JOURNAL.

FOR the medical man, the "Medical Times Almanac" is likely invaluable, when we add that all this is to be had for a groat, we are quite sure that we say sufficient to commend it to the notice of our medical readers.—DEVONSHIRE COURIER.

WE have always looked upon the "Medical Times" as one of the most scientific publications of the day. The number for Dec. [illegible] is accompanied with an appropriate almanac for 1843, containing with the usual matter of a medical almanac, an able and careful abstract of the Pharmacopœia, prepared by Mr. John Foote, Surgeon, which is incorporated into it every improvement made known to the public to the present time; a full account of all the microscopic discoveries in anatomy and physiology, &c.—[illegible]

This Day is published, in Demy 8vo., price 1s.

HEALTH of TOWNS. An Examination of the Report and Evidence of the Select Committee of Mr. Mackinnon's Bill, and of the Acts for establishing Cemeteries around the Metropolis.

London: JOHN SNOW, 35, Paternoster-row.

THE CHEMIST, edited by Charles and John WATT.—A NEW SERIES of this Journal, which contains all that is New in Chemistry, Chemical Manufactures, Agricultural Chemistry, Pharmacy, Materia Medica, Therapeutics, Chemical Jurisprudence, &c., &c., &c., will be commenced on January 1, 1843. Those who have not subscribed, being unable to make up their sets, in consequence of some of the Numbers being out of print, will find this a most excellent opportunity of becoming Subscribers. No. 1 will contain above 30 Important Articles, among which may be mentioned—On the Influence of Climate and Temperature on the Solid and Fluid States of Oils and Fatty Bodies, by Charles Watt.—Donnés on the Neutral Nitrogenous Matters of Organisation, Reuben Phillips on [illegible] Acid.—Bose on the Action of Water on the Sulphurets of the Alkaline Metals.—Vogel on Pepsin.—Schonbein's New Voltaic Pile.—Pelouze on Aloumic Woulds; considered as Multiples of Hydrogen.—Improvements in the Metropolis, by C. Watt, Junr.—Hunt on Photography.—Watson on a New Method of Making Copper Casts.—New Manure.—New Medicines; and New Applications of Medicine; Reviews, &c., &c.

HASTINGS, Carey-street, and Rillheric, [illegible]-street, London.

VAN BUTCHELL on FISTULA, &c.—The Sixth Edition, [illegible] published, in 8vo., cloth boards, price 7s. 6d. (reduced).

FACTS and OBSERVATIONS relative to a Successful Mode of TREATING PILES, Fistula, Hæmorrhoidal Excrescences, Tumours, and Stricture, WITHOUT CUTTING or CONFINEMENT; illustrated with numerous Cases. Being a familiar exposition of the Practice of S. J. VAN BUTCHELL, Surgeon Accoucheur.

"It is very rare to our practice to advert to books on professional subjects, but the 'Facts and Observations' appear to be so practical and unpretending character to indicate a successful and prompt relief from the severest of most painful and distressing disorders, that we believe the work of common adaptation from it, which is, we with much sincerity, will not be thought misplaced without its use."—[illegible]

Published by H. RENSHAW, Medical Bookseller, Strand, [illegible]; also by the Author, at his residence, 17, Baker Street, Portman Square.

MESSRS. WHITTAKER & Co., AVE MARIA LANE, LONDON, Have just published, price 30s.

INFUSORIA. The History of Infusoria, living and Fossil, with descriptions of all the known species, arranged after Dr. Ehrenberg, and 500 coloured illustrations. By ANDREW PRITCHARD, M.R.I.

MICROSCOPIC ILLUSTRATIONS.—A New Edition, enlarged, [illegible] with descriptions of the Achromatic, Polarizing, and other Microscopes, and ample instructions for use. [illegible] the [illegible] of Medical Microscopy [illegible], price 2s. 6d.

ENGLISH PATENTS.—A concise Register of all that are granted in the [illegible], Arts, Agriculture, &c., in 1841, with [illegible] and the new Act to secure Designs on [illegible]—Also, Second Edition, price 1s.

A LIST of 2000 Microscopic Objects, with Remarks on the circulation in Animals and Plants, [illegible] the Microscope.

ROYAL COLLEGE OF SURGEONS AND APOTHECARIES' HALL.

DR. STEGGALL continues his Lectures and Examination for the College and Hall, and all other Medical Boards. Dr. S. has removed from No. 1, Bloomsbury Square, and his Lecture and Class Room will be in future at his private residence No. 2, Southampton-street, Bloomsbury Square.

BENTLEY'S BROWN WINDSOR SOAP is the most emollient and purest soap in use, its healing effects in case of chapped hands, roughness of skin, or other unpleasant eruptions caused by sudden atmospheric changes, are duly appreciated; its constant use will not only protect the hands, face, and arms against bleak winds, and damp air, but it will produce a whiteness and softness of Skin indescribable. In 1s., 1s. 3d., and 2s. 6d. packets. To be had of the Proprietor. Depot for the inimitable Extract of Honey for the growth and restoration of the human hair, No. 220, High Holborn, and of most Hair Dressers and Chemists.

COALS.—SAMSON and Co., Essex Wharf, Strand, and JARROW, South Shields, Coal-merchants, Exporters, &c., to acquaint their Friends that they have unusual facilities for supplying them with COALS, as the[y] are now freighting direct from the Colliery, and would advise an early order previous to the approaching rise in price. Very best screened, [illegible]; second, 24s.; Anthracite for Arnott's Stoves, 21s.; Welsh Stone Coal, [illegible] Foundry and Gas Coke, equally cheap.

WARM AND MEDICATED BATHS,

5, New Broad Street, City.

THIS Establishment is the Largest in the Kingdom, and is unequalled for comfort, economy, and efficiency of administration. The following Baths are always ready:—Shampooing, Sulphur, Hot Air, Harrogate, Medicated Vapour, Iodine, Mercurial, and every other description, besides a range of twelve rooms fitted up for the luxury of cold and warm Water Bathing. The proprietor is a qualified Surgeon, and daily in attendance from [illegible] till [illegible].

OSTEOLOGICAL AND DENTAL REPOSITORY

45, Museum Street, Bloomsbury, London.

J. HARNETT begs to call the attention of the Profession, Students, and all Gentlemen connected with the Medical Profession, to his large and select assortment of ANATOMICAL PREPARATIONS, consisting of Superior White Articulated SKELETONS, at 80s., [illegible], 100s., 120s., 140s., and 160s. each.

Ditto—Unarticulated, 20s., 40., 60s., 80., 100s., [illegible].

Entire Adult Skeletons, with Ligaments, [illegible].

Separated Skulls, quite perfect, 10s., 20s., 30s., 42s.

Ditto, Mounted, [illegible], 80s., 100s., 120s., 140., 160s.

A great variety of Fœtal Skeletons, [illegible].

Skulls, with Horizontal, Vertical, and other Sections, having the Preparation of the Internal Ear, 36s. to 45s.

Ditto, with the Second Dentition, [illegible].

Phrenological Skull, [illegible].

Upper and Lower Extremities, articulated and loose, [illegible].

Articulated Hands and Feet, Vertebræ, [illegible].

Entire Skeleton, from one to nine months, [illegible].

Female Pelvis, with Ligaments, and Fœtal Skull, [illegible].

A new and improved Apparatus for Practical Midwifery, [illegible].

Injected Arms, Legs, Heads, &c., [illegible].

A fine Collection of WAX MODELS, beautifully executed.

A large assortment of Skeletons and Skulls of rare Animals and Birds, and all preparations connected with Osteology.

J. H. also begs to state he has a DENTAL REPOSITORY, and is a Manufacturer of Mineral Teeth.

DISEASED AND HEALTHY LIVES ASSURED.

MEDICAL, INVALID, & GENERAL LIFE OFFICE, 25, PALL MALL, LONDON.

Capital, £500,000.

PRESIDENT.

Sir Henry Halford, Bart., M.D., G.C.H., F.R.S., F.S.A., President of the Royal College of Physicians, &c., &c.

Sir William Burnett, M.D., K.C.H., F.R.S., Inspector-General of the Navy, &c., &c.

Sir Matthew J. Tierney, Bart., M.D., K.C.H., &c., &c.

TRUSTEES.

J. H. Anderdon, Esq., 59, Queen Street, May Fair.

Benjamin Bond Cabbell, Esq., F.R.S., Temple.

Charles Edward Scott, Esq., 7, Cavendish Square.

DIRECTORS.

Thomas Coates, Esq., 59, Lincoln's Inn Fields.

Edward Doubleday, Esq., 249, Great Surrey Street.

George Gun Hay, Esq., 127, Sloane Street.

William Jeaffreson, Esq., 21, South Audley Street.

John M'Kenzie, Esq., 21, Tokenhouse Yard.

J. Pulman, Esq., F.R.S., 30, Cambridge Terrace, Hyde Park.

Benjamin Phillips, Esq., F.R.S., 17, Wimpole Street.

C. Richardson, Esq., 19, Bruton Street, Berkeley Square.

Henry Stevenson, Esq., F.S.A., 37, Upper Grosvenor Street.

Alfred Waddilove, D.C.L., Doctors' Commons.

Robert C. Wyllie, Esq., 107, Pall Mall.

AUDITORS.

John Purchard, Esq., Chester Terrace, Regent's Park.

Joseph Radford, Esq., Green Street, Grosvenor Square.

J. Shuttleworth, Esq., 41, Upper Gloucester Place, Dorset Square.

Mortimer Welch, Esq., Wyndham Place, Bryanston Square.

STANDING COUNSEL.

John Shapter, Esq., Lincoln's Inn.

BANKERS.

Messrs. Bosanquet and Co., Lombard Street.

Messrs. C. Hopkinson, Barton and Co., Regent Street.

Messrs. Clode, Scott and Co., Cavendish Square.

SOLICITORS.

Messrs. Richardson, Smith, and Jones, 28, Golden Square.

CONSULTING COUNSEL FOR MEDICAL STATISTICS.

William Farr, Esq., General Register Office.

ACTUARY.

F. G. P. Neison, Esq.

The Office is provided with very accurately constructed Tables, by which it can Assure UNSOUND Lives on Equitable Terms. The Extra Premium discontinued on restoration of the Assured to permanent health. A portion of the extra premium may remain as a Debt on the Policy. Survivorship Assurances where the life at present in question is suffering from disease, effected at cheaper rates than at any other office. Similar tables enable the Society to Grant Increased Annuities on Unsound Lives. The amount varying with the particular disease. Members of Consumptive Families assured at Equitable Rates. Healthy Lives Assured on lower terms than at most other Offices. Applications to be made to the Actuary.

CALEDONIAN and CITY of LONDON INFIRMARY, 144, Aldersgate Street, for the definitive Cure of Rupture, &c., so as to enable the patient to leave off all truss wearing, and, by timely application, great inconvenience may be avoided. No truss whatever is required. The only thing of the kind in the United Kingdom.—Hours of attendance from 10 to 4 o'clock.

INVALID CARRIAGE.

THE Public are respectfully informed, that this valuable invention is now brought to perfection, on a very large scale. Its advantages to Invalids are too numerous to detail and explain in an advertisement, but on an inspection, it will at once convince the most sceptical of its astonishing conveniences. In cases of accident it is invaluable, and should be kept by the proper authorities at every police station. It has been inspected by numerous scientific persons, and all are delighted with it. To all persons afflicted in any way whatever, this carriage presents immense advantages. Although a deal of money has been expended in bringing this invention to maturity, the cost will be very moderate.

For further particulars, please address (prepaid) to Mr. Walter Norris, 11, John Street, Hammersmith, who will forward drawings, together with the price, which is regulated according to the manner in which it is fitted up.

HISTORICAL GROUP IN MAGNIFICENT ARMOUR.

THE Prince and Princess Royal in their Splendid Cot, the Kings of Prussia, Commissioner Lin and his Consort, modelled expressly by Lamqua of Canton, for this exhibition, with the Original Costumes worn by them. The gorgeous coronation robes of George IV., designed by himself at a cost of £18,000, with the room fitted up for the purpose, is acknowledged to be the most splendid sight ever seen by a British public. Admittance 1s. Open from 11 till dusk, and from 7 to 10.—Madame Tussaud and Son's Bazaar, Baker-street, Portman-square.

THE FARMERS' and GENERAL FIRE and LIFE INSURANCE INSTITUTION.—Empowered by Act of Parliament. Offices, Strand, London. Capital, £500,000. With 1,000 Shareholders enrolled.

HONORARY DIRECTORS.

His Grace the Duke of Rutland. The Earl of Stamford and Warrington.
The Earl of Stradbroke. Lord Rayleigh.
The Earl of Coventry. Lord Feversham.
Earl Ducie. Lord Viscount Campden.
The Earl of Zetland.
Lord Godolphin, M.P.

And 75 other Members of Parliament and Gentlemen.

COUNTY DIRECTORS.—Upwards of 170 Gentlemen, Landed Proprietors, or otherwise connected with agriculture, holders of Fifty Shares, have been appointed County Directors.

FARMING STOCK insured without the average clause at 1s. 9d. per cent. no duty.

COMMON INSURANCE at the usual moderate rates.

INSURANCE of LIVES on an equitable scale of charge. Endowments of all kinds for future or existing children. The usual commission to Solicitors. Agents are appointed in all the Principal Towns in the Kingdom.

W. SHAW, Managing Director.

WILDENOW'S CAPSULES GELATINEUTS.—The partnership between "Wildenow and Krantz" being dissolved, JULIUS KRANTZ begs to state, that he continues the manufacture of the Capsules as before, and trusts to obtain a continuance of the patronage hitherto bestowed upon the Preparation, to merit which shall be his constant endeavour.

J. K. also cautions his friends against certain persons who falsely pretend to have been in the employ of himself and late partner, and profess to be able to supply an article of the same superior quality.

10, President Street East, King Square, Goswell Road.

GOLD LABELS.—A NEW SET, engraved in Egyptian Letter for Bottles, Drawers, &c.

H. SILVERLOCK, begs to inform his Friends, that these LABELS are now ready and that Catalogues with a sketch of the Size and Pattern may be had on application to 3, WARDROBE TERRACE, through any of the wholesale chemists, or per post. This splendid Set of Labels, the most extensive and complete ever published, contain SEVEN SIZES, for Bottles from the smallest size in use to the largest; also THREE SIZES Straight Labels for Drawers, and THREE SIZES Straight Labels, with Ornamental Ends for Drawers.

The Prices vary according to the sizes, from [illegible] per dozen. Address, H. SILVERLOCK, Medical Printing-Office and Label Warehouse, Wardrobe Terrace, Doctors' Commons, where may be had every description of LABELS ready GUMMED and CUT, for the use of Surgeons, Apothecaries, wholesale and retail Chemists, Druggists, &c., also Fancy Labels in every variety. Ornamental Labels for Bottles and Drawers on Gold, Green, or Yellow Paper. This set is engraved in a superior manner in THREE SIZES, with the new names according to the last Pharmacopœia. Seidlitz Books or Seidlitz Labels in order.

Single Label.	Yellow or Green.	Gold
	Per doz.	Per doz.
Small and Middle Sizes	1s. 0d.	[illegible]
Large	1s. [illegible]	[illegible]

In Books Green or Yellow.

Small size, containing 1,000 Label		0 17 0
Middle do.		1 5 0
Large do.		1 11 0

The Three Sizes in One Book, containing [illegible] Label [illegible]. Catalogue Gratis. Entrance and Printing every description.

HORSE CLOTHS MADE WATERPROOF by the celebrated Lycopodium of NEWBERY and Co.

This Excellent Preparation effectually [illegible] the Horse, [illegible] superseding [illegible] impervious to water [illegible].

IMPROVED HORSE CLOTHS.

Horse Cloths rendered [illegible] by a chemical [illegible] waterproof, will not impede [illegible] perspiration.

NEWBERY'S LYCOPODIUM, or Waterproofing [illegible] applicable to all the clothing of Gentlemen's Horses.

When every kind of [illegible] required, and to a [illegible] Lycopodium will be found all that can be desired [illegible] the most impervious, tough, flexible and durable [illegible] ever offered to the public.

No. 7, Applegate Buildings, Tooley Street [illegible] 21, King William Street, [illegible] Deptford, Kent.

London: Printed and Published by [illegible], at [illegible], Essex Street, Strand, in the Parish of St. Clement Danes, Westminster, in the County of Middlesex.—December [illegible], 1842.

THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs

No. 172. Vol. VII. LONDON, SATURDAY, JANUARY 7, 1843. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 1d. per Half-year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

At length we arrive, gentlemen, at a very different part of our chemical course to that on which we have hitherto been engaged. Slightly, and imperfectly, we have sketched the properties of imponderable bodies—those mystic agents which reach our grosser senses, and scarce seem to claim alliance with the mortal world. We are about to commence the description of agents altogether different in their natures,—which are recognised immediately rather than by their remote effects; and which, moreover, are amenable to the grand force of gravitation—a circumstance which confers on them their usual appellation of *ponderable bodies*. If a person could be sent upon the face of this globe, with comprehension enlarged and judgment matured—if he could be separated from his fellow men, and obliged to form an opinion of things around—probably his first supposition in regard to the world's composition would be, that the Creator had employed in making it so many different materials, as there were things of different appearances upon its surface or within its depths. A slight acquaintance, however, with the never-ceasing mutations around, would soon cause him to alter his opinions—perhaps to embrace ideas diametrically opposite to those formerly espoused. He would notice the silent disintegration of mountains, and the formation of soils:—he would observe parched and shrivelled seeds under the influence of light and heat, and showers, rise in all the freshness of vegetable life from the beds which first received them. He would see tiny animals crop those rising shoots, and grow, from their sustenance alone, into beings of sometimes gigantic size. He would see such animals, in their turn, devoured by other species—to be converted into structures which are as unlike in regard to structure and endowments from themselves as the tiger is unlike the lamb. Lastly, he would see them all die at the appointed time; their bodies, no longer under the influence of life, dissolve and decay; tens of thousands of metamorphoses result, which he had never before in his wildest moods dared to imagine,—and, lastly, of all the elaborate forms which an observer is supposed to have contemplated, there would remain tangibly before him, only a little dust!

Such remarks would convince him as soon as made, that his previous opinions were wrong, that however great the difference which his judgment had formerly imposed between the ideas of a mountain of soil, of vegetables, and of animals, there must be, nevertheless, *something* in common between the elements of which they were composed. He would now probably fall into the opposite extreme, and arriving at conclusions with a rapidity unsanctioned by inductive philosophy, would perhaps imagine that all the universe, animate and inanimate, was composed of one element, or at most three or four, modified by some supernatural power, into organic and inorganic forms. This we may imagine to be the train of reasoning which led to the idea of some ancient philosophers, that the universe consisted of four elements, merely *fire*, *earth*, *air*, and *water*. I should mention, however, that although this is termed the theory of the ancients, it was adopted by only a sect of them, Epicurus and his followers. Now I scarcely need inform you, that instead of four elements, there are fifty-four or fifty-five, of which everything, organic and inorganic, on this world or within it, is composed. Nay, we have reason to believe the whole material universe, suns, planets, comets, moons, and all, to be composed of some, or all, of our own fifty-four or fifty-five elements.

It is the province of chemistry to investigate the nature of these simple bodies, so that they may be individualized or distinguished from each other; then to unravel their various combinations, first of all in the organic kingdom, then in the more complex form of animal and vegetable life, where the hitherto well-sustained and evident relation of cause to effect is lost in the mazes of physiology and metaphysics. These latter considerations, however, we may defer until another period, our first object being to examine the simple bodies individually, and for this purpose we will pause an instant, ere we follow any particular mode of classification. As a prelude, I direct your attention to the list of simple bodies at present known.

	Eq.	Symbol
Aluminum	26	Al
Antimony (*Stibium*)	65	Sb
Arsenic	38	As
Barium	69	Ba
Bismuth	72	Bi
Boron	11	B
Bromine	78	Br
Cadmium	56	Cd
Calcium	20	Ca
Carbon	6	C
Cerium	48	Ce
Chlorine	36	Cl
Chromium	28	Cr
Cobalt	30	Co
Columbium (*Tantalum*)	185	Ta
Copper	32	Cu
Fluorine	18	F
Glucinum	18	G
Gold (*Aurum*)	200	Au
Hydrogen	1	H
Iodine	126	I
Iridium	96	Ir
Iron (*Ferrum*)	28	Fe
Lantanum		La
Lead (*Plumbum*)	104	Pb
Lithium	8	Li
Magnesium	12	Mg
Manganese	28	Ma
Mercury (*Hydrargyrum*)	200	Hg
Molybdenum	48	Mo
Nickel	28	Ni
Nitrogen	14	N
Osmium	100	Os
Oxygen	8	O
Palladium	54	Pd
Phosphorus	16	P
Platinum	99	Pt
Potassium (*Kalium*)	40	K
Rhodium	52	R
Selenium	40	Se
Silicium (*Silicon?*)	8	Si
Silver (*Argentum*)	108	Ag
Sodium (*Natrium*)	24	Na
Strontium	44	Sr
Sulphur	16	S
Tellurium	32	Te
Thorium	60	Th
Tin (*Stannum*)	58	Sn
Titanium	24	Ti
Tungsten (*Wolfram*)	100	W
Vanadium	63	V
Uranium	217	U
Yttrium	2	Y
Zinc	32	Zn
Zirconium	22	Zr

With regard to this table of simple bodies I have to remark that the atomic numbers are divested of all fractional parts, and that the symbolical abbreviations are those in use by Berzelius, and followed by almost every chemist of the present day. We shall return to their consideration hereafter.

And now, how are we to group those simple bodies, so as to facilitate their description? Why this is really a somewhat difficult question to decide; many plans have been recommended, but all are more or less open to objections. We may at least divide them into metallic and non metallic bodies; think you, there can surely be no discrepancy of opinion here? When, however, I tell you that the substance carbon, or charcoal, is considered a metal by Döbereiner, Selenium by Berzelius,—and to crown these apparent inconsistencies, when I inform you that the *gaseous* body hydrogen, the lightest ponderable substance in nature, is regarded as a metal by Mons. Dumas, it will be admitted that even this primary division of simple bodies is not so free from objections as might be imagined. Granting, that for all practical purposes the difference between metallic and non-metallic bodies is sufficiently marked, still, in subdividing the list of metallic, as well as non-metallic bodies, great difficulties arise. We may arrange them under the heads of electro-positives and electro-negatives (anions and cathions,) into combustibles and supporters of combustion, or into acidifying or acidifiable; but still the propriety of either of these divisions may justly be questioned. Berzelius follows another mode of classification. He places oxygen by itself as a supporter of combustion, and into inflammable substances, in which he includes all other elements. The non-metallic bodies he divides into three classes, viz.: 1. permanently elastic, or gaseous bodies—*gazolyta*—oxygen, hydrogen, nitrogen; 2. *metalloids*—sulphur, phosphorus, carbon, boron, silicon; 3. salifying substances—*halogenia*—chlorine, fluorine, iodine, bromine. The complexity of this arrangement best demonstrates how difficult the distinguished chemist must have found the task on which we are now occupied. In the absence of any arrangement strictly correct, I shall follow one without any philosophic pretentions whatever, more than this, that it will bring conveniently before your notice, certain simple bodies, and afterwards inorganic groups of them. The arrangement alluded to is followed by Mr. Brande, and happens to be more convenient than any other with which I am acquainted. I here present it to your notice.

Non metallic simple bodies.

Oxygen
Chlorine and its combinations with oxygen
Iodine and its combinations with the preceding
Bromine and its ditto ditto
Fluorine and its ditto ditto
Hydrogen and its ditto ditto
Nitrogen and its ditto ditto
Sulphur and its ditto ditto
Selenium and its ditto ditto
Phosphorus and its ditto ditto
Carbon and its ditto ditto
Boron and its ditto ditto

With regard to the metals, they will be arranged under their own proper head.

We can scarcely with propriety begin the chemical description of simple bodies, until we have examined the principles of that nomenclature now so universal in chemistry. I am no great advocate

for burdening a mind with definitions which may not be required for days, or months. I would far rather develop a general scheme, and acquaint you with principles which, when correctly appreciated, should render the mistake of chemical terms an impossibility. Do not imagine, therefore, that I shall give you a dry dissertation on the beauties of chemical nomenclature: you will have nothing of the kind. It is merely my intention to call your attention to the subject, to point out its conveniences, to demonstrate the ease of mastering it, and to allude to the necessities which first caused its introduction.

In the early days of chemistry, when new bodies, simple and compound, were accumulating on the world, and when experimenters were actuated by no higher motives than personal vanity, they followed the very inconvenient and reprehensible plan of calling substances, either by a name like their own, or else of indicating them in reference to some imaginary property. Thus we have the term *sal Glauberi*, handed down to us as indicative of sulphate of soda, merely because Glauber is said to have discovered it, and the liquid now termed nitric acid *was* called *aqua fortis*, because of its solvent property. These I offer merely as instances of a system formerly universal. Now to place the absurdity of such a nomenclature in its strongest light, I may say with confidence, that had it been applied to the bodies and combinations of modern chemistry, a good memory and a long life would be unceasingly occupied in learning only a *very* small portion of the names. Towards the conclusion of the 18th century, this inconvenience was severely felt, and just before the great French Revolution, when all, even science was ripe for change, certain distinguished chemists, namely, Lavoisier, Guyton-Morveau, Fourcroy, and Chaptal, introduced a radical reform into the nomenclature of chemistry; one that exists with few alterations, save those of addition at the present day. All the simple bodies, so far as it was found possible, were designated by names indicative to a certain extent of their nature; and compounds received names which immediately bespoke the elements of which they were formed. As an example of the principles followed by those renowned chemists, let us just examine the names of our metallic simple bodies. To begin, then, with oxygen; there was a gas known, which, according to the ideas of Lavoisier and his colleagues, was the principle of acidity, and as such, necessarily entered into the composition of every acid, it would indeed, be proved to exist in most, and it was inferred to be present in the others. In consequence of this property, real or assumed, the gas in question was called oxygen, a word compounded of *oxus* and *gennao*, and meaning the generator of acids. This term was intended to be universal, and it might with propriety *have* been so, but the Germans disdaining to borrow from the Greek language, have called it *sauer-stoffe*, a word so nearly English, that the literal translation *sour stuff*, is scarcely necessary. The second body in our list, *chlorine* derives its name from *chloros*, on account of its yellowish green colour. Iodine is so called from *iodes*, violet coloured. Hydrogen means the water former, and is termed by the Germans wasser-stoffe, which, literally translated, is *water stuff*. Nitrogen is so called because it is found in the substance nitre, or saltpetre; I need not take up any other substance for the purpose of extending my illustrations. This much, then, in reference to the nomenclature of simple bodies, but we have also to frame names for some tens of thousands of compounds.

All combinations of oxygen, chlorine, bromine, iodine, and fluorine, with the inflammables and the metals which are not acid, are called oxides, chlorides, iodides, bromides, and fluorides; the combinations of inflammable bodies with each other, or with the metals, are distinguished by the termination *uret* as *sulphuret*, *phosphuret*, &c., and in some cases, the combinations of metals with each other are similarly designated—thus we speak of *arseniurets*, *tellurets*, &c.

We indicate different proportions of oxygen in oxides by Greek and Latin numerals prefixed; thus we have *protoxide*, *deutoxide*, or *binoxide*, *tritoxide*, or *teroxide*, and the highest state of oxidation is indicated by the term *per-oxide*; when the proportions of oxygen are as one to one-and-a-half, the result is termed a *sesqui-oxide*. The names of the acid compounds of oxygen are derived from their bases, and where there are only two compounds the terminations *ous* and *ic* indicate respectively the lesser and greater amount of oxidation. When there are more than two compounds of the same base more complicated terms are required. Thus there were formerly known only two acid compounds of oxygen and sulphur; these were indicated by the terms sulphur*ous* and sulphur*ic* acids respectively. Subsequently, however, there have been discovered two other compounds, one containing less oxygen than sulphurous acid, and which in consequence has been called *hypo*-sulphur*ous* acid, the other more oxygen than sulphurous but less than sulphuric, hence it has been termed *hypo*sulphur*ic* acid. Occasionally other terms are used, but a general knowledge of Greek and Latin will render their mention unnecessary here.

The saline combinations of the acids ending in *ous*, are distinguished by the termination *ite*, and those ending in *ic* by the termination *ate*, thus sulphur*ous* acid by uniting with a base forms a sul*phite*, and sulphur*ic* acid a sulph*ate*. Where the acid and base unite in more than one proportion,—the terms *super* and *sub* afford a loose means of distinction, more correctly expressed however by the prefixes *bi* and *di*, the former indicating two eq. of acid,—the latter two eq. of base. Furthermore, an acid occasionally unites with more than one oxide of the same metal, when the particular name of the oxide must be added as a prefix; thus we have a protosulphate, and persulphate of iron. So much, then, with regard to the principles of chemical nomenclature, and before I conclude, let me draw your attention to a subject very nearly allied,—I mean the recent introduction of symbols. Those of you who know the condensed power of expression afforded by algebraical notation, will not fail to recognise the advantages afforded by an introduction of the same system, or one very nearly resembling it into chemistry. Those of you who are *not* acquainted with algebra, will nevertheless experience the value of chemical symbols as we proceed. It is obvious that by fixing on certain letters as indicative of certain substances, we acquire an increased power of expressing them or their compounds. Thus O is much sooner written or spoken than oxygen, and $O+H=HO$ much sooner than the phrase, *Hydrogen combined with oxygen, constitutes water*. But expressions may be still further shortened by introducing arbitrary signs for certain very common elements; thus oxygen may be indicated by a dot, thus . Sulphur by a comma, thus ,. The system of chemical symbols is still further extended, but at this period I need not further allude to it. As we find with every new introduction, however useful,—there are not wanting those ready to carp at it, and make it appear ridiculous. It is argued that to many persons, symbolical chemistry is a dead language; to this the answer is short—let all make it a living one; again, it is said that the initials are not of the same power in every language; that P for instance is considered in Greek, and in Russian, which is partly derived from the Greek as R! Such objections are too puerile and ridiculous to merit much consideration. It is argued, too, that the small figure employed in the locality of an algebraical co-efficient, but a very different meaning, creates an unpleasant sensation to the mathematician: thus H^3 in algebraical language, means the third power or cube of H; but in chemical language, it signifies three atoms of hydrogen. For my own part, I cannot imagine any *very* unpleasant sensation thus produced in the head of any one, and I never heard that the nerves of mathematicians were more troublingly alive than the nerves of chemists or of any other people.

We learn from Stockholm, December 16th, that the celebrated chemist, Berzelius, had nearly fallen a victim to his scientific pursuits a few days previously; an alembic having burst, he received an injury, which fortunately was not attended with serious consequences.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

LECTURE III. (Delivered December 7, 1842.)

(Concluded from p. 214.)

There is an affection of the breathing and the respiration, which is proved to be the case, by the escape of bubbles from the air-passages. And you find this state of things results from swallowing the smoke of tobacco, which produces the action of vomiting, which is neither more nor less than an act of respiration, when the larynx is closed. Here, then, the blood is in a morbid state—it has been poisoned—surcharged with carbonic acid gas —and in this morbid state you have an effect like epilepsy. This is important, as I have told you already that every physiological action, with regard to the spinal marrow is reflex, and I mentioned one case, to shew that the pathological action of the spinal marrow is almost always direct, —that is to say, it must have originated in the spinal centre. One fact more—and that is also a repetition,—I wish you invariably to bear in mind the extraordinary difference between the two diseases I have already adduced. I believe that they illustrate this pathological state of the spinal marrow, namely, tetanus and hydrophobia: I think you will find that they are associated everywhere as examples of reflex phenomena. Now, the bones are not drawn asunder in the pathology of the one, while they are so in the other. In the pathology of tetanus you have a reflex action. You can produce this by a simple experiment. All you have to do is this: take an animal,—a cold-blooded animal for this purpose is the best, and for this purpose the tortoise is the best. In order to produce the experiment, the head is taken off; and if you irritate the extremities for a certain length of time, you will produce a state of tetanus in the whole animal frame. It is important to see that this takes place. In hydrophobia, what we do find? We find a state of things, compared with tetanus, produced by strichnine. I speak of tetanus where the action is of a direct kind, certainly arising from the impression of a morbid state of blood on the spinal marrow, which being sent to the various muscles, the whole is thrown into a tetanic action. How do we prove this? Take a frog, and apply a ligature round the head, so as to bind the sciatic nerve. You will see, on pinching the toe of that frog that it is perfectly alive to sensation, and that there is, therefore, a reflex action; therefore, the sciatic nerve was so fixed by the ligature as to prevent any action through the medium of that nerve. If you put it for a moment under the microscope, you will see there is no circulation. If you sprinkle the surface with strichnine you will wait a long while before you see any effect, but if you tie the ligature in twenty minutes, the animal is then perfectly tetanic. What do we conclude from this? That the blood has been poisoned, and that the nervous system has been poisoned. I have distinguished two cases of tetanus, the one is concentric and the other eccentric. Here, then, we have tetanus arising from reflex action, and tetanus arising in hydrophobia from the poisoned state of the blood. For in hydrophobia there is poison, and in tetanus there is no poison; that is, tetanus arising from mere lesion. It is a physical injury, as I tell you, that all that excites reflex action is physical. Nothing absorbed does; cold does it, heat does it, and lesions do it; everything that is physical will do it, but nothing that can be absorbed does it. For all that can be observed is carried to the blood, and is then carried to the spinal marrow, and issues in direct action. The actions so produced are very similar. Here, then, you have a most decided proof that poisons or morbid agents act not in one only, but in two ways; in one way, through the reflex functions, and in the other, through the direct action of the spinal marrow.

I think some time has been occupied by my

having entered more deeply than I intended to do into the preliminary questions. The question I intended to bring before you at this lecture is the subject of the diseases of the nervous system in children. You are perfectly aware I am persuaded that no subject can be more important to you on entering practice than the diseases of the nervous system in children, and you will find the subject one of deep interest to you. Affections of the cerebral system in children—what are they? Gentlemen, a child, in the first place, may receive a blow on the head, and inflammation in the cranium will ensue as a necessary consequence. In the second place, the child may not have undergone any such accident, and yet the symptoms of inflammation and affection of the brain may very early come on. The former case is one caused by a collision; this case generally speaking, we are able to trace to what is generally called water on the brain. Here the phenomena are a state of things clearly referable to inflammation; in the latter case this is doubtful. Here you have the two chief maladies, and I have to introduce to you another—a third—which is one of the most intense interest. You are aware, that after scarlatina has lasted about sixteen days, after it ceases, or is so mild as to lead to a belief that your services are no longer needed, and the little patient begins to play and to run about as if quite well, it is in such cases after about sixteen days that the child sometimes becomes affected with a bloated countenance, and with that a state of things resembling a state of apoplexy in adults, with the exception that the child's face is not bloated as in some species of dropsy. It continues exceedingly pale, and you have phenomena of a peculiar kind, besides that of coma; you have, in the third place, that which is called the water stroke. It varies from fourteen to sixteen days days after scarlatina,occurring after the mildest cases; and this is important for you to know, because it is precisely in this case I am alluding to that you have.

There is another case which I do not think is a very common case. I have recently been attending with Dr. Prout and Mr. Stone, one of the most interesting cases you can possibly imagine. The little child had just recovered from a state of purpurea all over the body. But what remained? This remained, the urine was 1-1030 degrees in specific gravity, and with the albuminous deposit there were sometimes small particles of blood, and some other matters. The child remained in an invalid state, and every day, apprehension was felt that the child was affected with some disease of the nervous system—some affection of the head—some affection probably of the spinal marrow. Now, then, we may have affections of the head like this patient had, like hydrocephalus from a state of amenorrhœa, and many other hydrocephaloid diseases, accompanied with an attack of bronchitis, or something of that sort. The child may be in a state of great exhaustion, which is a state perfectly similar to hydrocephalus. If you are not aware of that, and if you do not trace it through its past history, it is totally impossible to distinguish between the two. In a case of hydrocephalus, you may be certain of recovery. If you are certain that it is hydrocephaloid disease, you may be certain that under proper treatment it will recover. How is the prognosis formed? by this distinction. There is one case more. Sometimes you have an overloaded state of the intestines; in such a state the child may recover under the influence of purgative medicines; I have laid before you these cases—inflammation, tubercle, water-stroke from scarlatina, and a state occuring after purpurea with albuminous urine, and then hydrocephalus and the other case, of convulsions, arising from an overloaded state of the intestine. I have just time to go over the symptoms of hydrocephalus before I conclude my lecture. I shall be very brief, but I want to show you, once for all, the importance of a knowledge of the physiology of the nervous system whenever you have to observe and treat of diseases of the nervous system. Suppose you are called to a case in which there is a little child being affected with tuberculous affection of the brain. In the first place, you naturally inquire into the probable causes, whether the child has had a fall, whether any thing has happened to the child to produce anything like inflammation, and you then try to trace the affection to one of the ordinary causes. You examine whether the child is one of a family of children, of whom some have died of hydrocephalus, and I really know no more important fact than this. The next question is whether there has been any predisposition to hydrocephalus in general. I mention one fact of great importance.

I have no doubt whatever that there is a predisposition in one family to hydrocephalus in infancy and in another to tuberculous disease of the abdomen at a later period, in a third to tubercles in the lungs, pulmonary symptoms of other kinds occurring at a still later period of life. You first inquire whether there is any disposition to hydrocephalus, and I take this to be an important element in practice; if the disease is not hydrocephalitic, you inquire whether there is tuberculous affection of the intestines, and you inquire whether the child has undergone scarlatina, the water-stroke, or whether there is any morbid state of the urine. I have already told you, that if the urine is not secreted as it ought to be the blood is seasoned, and the poison is, therefore, carried to the nervous system. Look at the child's face, and you will see it is extremely pallid. You inquire—and hope—whether it has had any hydrocephaloid affection, and whether there is any cause of exhaustion. Now I want to tell you what you naturally observe—the first state of the disease is a state of over-excitement, and the second state is one of undue excitement. You observe, that the little patient's countenance exhibits a state of agony which the tongue cannot tell. If there is a pain and the patient cannot express it, you find it expressed in the state of the countenance, it is a state of over-excitement. What is the next thing you are to observe? Does the patient sleep? When it falls asleep, the sleep is disturbed, the patient is excited, and starts up in its dreams, it cannot go to sleep and seems in a state of great excitement. Look to the eye—the pupil is contracted, and what do you observe? The patient cannot bear the light—it cannot bear noises, even the skin sometimes is unduly sensitive; that is one of the things you may observe. You find all the senses unduly excited; there is an expression of pain: the patient does not enjoy sleep, but starts up with something similar to delirium, and cannot be appeased; the eyeball is contracted, and the eye itself is contracted, there is an undue sensitiveness to light, the child cannot bear the light, there is an undue sensitiveness of the organ of hearing, and an undue sensitiveness of the organ of touch, or the skin. These are the very first symptoms. There is one more symptom, and that is an undue excitement of the true spinal system. No symptom in my opinion is so important to treasure up in your minds as the circumstance of vomiting in children. If you cannot account for it by finding that some improper food has been taken into the stomach, then you always suspect some affection of the brain. If the child has had a fall, the question is, is the brain injured? Has it so suffered from the concussion as to be materially injured? If the child has had such a fall then inflammation will follow, and the question is to be determined by asking whether the child has met with an accident of that nature? But you can never leave it perfectly safe. Vomiting and sickness are the premonitory symptoms of hydrocephalus, and this is a point of the utmost importance. A very particular friend of mine consulted me about a little patient who had these symptoms of sickness. The child was sick at everything; the bowels were in a perfect state, but the child continued sick. There were no other symptoms. The question asked me was, may the child be taken out of town? I consented, but I was persuaded the child would in a short time manifest symptoms of hydrocephalus. In a fortnight the child shewed symptoms of that disease. Now a medical man ought never allow a patient to go from under his own eye.

Now, gentlemen, there is another important thing, that is the state of the pulse. Here is one of the most interesting points I can bring before you. You find, uniformly, that there is a beautiful relation between the number of the beats of the pulse, and the number of respirations. It is so beautiful that it is impossible for me to mention it in too energetic terms. Look at the child asleep. You find its respiration less frequent than usual, and so is its pulse. Look at the same in a child awake, and you find its pulse quicker in precisely the same proportion to the respiration. Let the patient fall into a sleep, and you find scarcely any pulse and scarcely any respiration. You invariably find this to be the case, the pulsations and the respirations are not in the same number, but in the same proportion. Count the number of respirations and the number of the pulse, and you will find the physiological state always changes the moment you come to the pathological. If the respiration physiologically is less frequent, so is the pulse. The same proportion is always found when it is physiological, and when you come to the pathological you find this relation is disturbed, and this exceedingly assists you in your diagnosis. Now, when we come to this little child, if the disease is hydrocephalus, the respiration is scarcely affected at all, and the pulsation is quickened. Here you see the relation is altered; the respiration is scarcely affected, and the pulsations are quickened a great deal. Now, for fear of not giving to these observations the point I wish to give them, I will just briefly go to the opposite state. When the child passes into a state of hydrocephalus, you find that all I said before becomes now contradictory. What have you? Pain expressed in the countenance, you have coma, and then you have undue sensitiveness. Now you have coma to produce deep sleep. Every thing seems altered. Hitherto there was over-sensitiveness of the eye to the light; now the eye is scarcely susceptible of light. The pupil was contracted, now it is dilated. The eyelids closed on the approach of light, now they remain gaping. The child was unduly sensitive to noises, now it is deaf, and is not able to detect anything like noise. There was an undue sensitiveness of the skin, there is now a numbness all over the skin. There are some other points so interesting, that I fear time will not allow me to enter into them, I will do it briefly. I have told you that in the first case the eyelid contracted, and dilated in the second. In the second case, when the eyelids are dilated and open, if you touch the eyelash with the point of your finger or the feather of a pen, it immediately closes; in the latter case, if you touch the eyelid it will not close. There is a third case. The pupil is dilated, and in this case it remains dilated, and as the coma becomes more intense, the pupil dilates more and more. You now find that the pulse and respiration are, as I said before, altogether contradictory. The pulse was quickened before, the respiration remaining the same. Now look at the respiration and see its characteristic. The child breathes two or three times in the natural way, and then there is a cessation of respiration. There is quite a pause in the respiration, and this it is which gives the thermometer, or measure of the coma; as the child falls more and more deeply into coma, respiration becomes more and more irregular. After a pause, the organs invariably betoken a state of things like that of infusion into the lungs from without of carbonic acid gas, and perhaps in a deep state of coma, there is an absence of all sensation of pain. The pulse is exceedingly varied, and it ceases with the breathing; it becomes exceedingly slow,and moreand more characteristic of what was noticed by Dr. Abercromby, namely, that the pulse was unequal and intermittant. There is a respiration, then a pause; then it will begin again; the pause is repeated, and then the respiration again takes place; if you count the pulse, you will find it is invariably intermittant.

ROYAL COLLEGE OF SURGEONS IN LONDON.

List of gentlemen admitted members on Friday, December 30th, 1842:—

J. L. Mackintosh, G. Green, T. Evans, T. S. Blackwell, H. Hutson, W. A. Backham, C. Evans, W. S. Britton, H. Cooper, R. Jones, J. Mullins, N. Buckley.

NAPOLEON'S LAST ILLNESS AND DEATH.

(Prepared from the German for the "Medical Times.")

[WE consider that the following contains some facts, both medical as well as historical, not before known. The author, a foreigner in the British medical service, has not prefixed his name to the title of the book, from which we make the following extract; but the fact of the work being published by a respectable firm of Leipzig, and its insertion in several German journals, fully prove the credit due to the author.]

In February, 1821, it became known that Napoleon was dangerously ill, his bodily ailments being exacerbated by the state of his mind, which had been greatly hurt by the news which reached Longwood from Europe of the sinful and disgraceful conduct of his wife, &c. He complained of constant pains in the epigastrium, weakness and entire absence of appetite. Two or three emetics, given to him by Antommarchi, placed him in the most distressing position. Shortly after, he refused altogether to take medicine, and those still offered to him, he threw out of the window. Signor Antommarchi had been a pupil of the celebrated Mascagni at Florence, and consequently was an anatomist of great ability; but, in therapeutical science, he certainly was not much skilled. I venture also to add, that the Emperor did not place the least confidence in him. General Montholon told me himself, that when Messrs. Bonavista, Vignali, and Antommarchi, arrived at Longwood; each of them had to undergo a strict examination. The two latter were Corsicans; and Cardinal Fesch, who had sent them, thought probably that they would much please the Emperor, which, however, was not the case. Bonavista, a South American bishop, and a very well-informed man, was passable with the Emperor, as was also Abbé Vignali, although a man of very inferior capacity. But the doctor was a bad chemist; and Napoleon, who, bye-the-bye, was no adept in this science, though very fond of it, as of all the exact sciences, harassed him by his questions, and dismissed him with expressions anything but complimentary. Antommarchi considered himself lost, but was consoled by the persons about the Emperor, who said, that his anger would not last long. Montholon advised him to ask for another audience, to confess himself a mere pupil in chemistry, to ascribe the fault to wrong training, and to request the loan of some chemical books from the Emperor's library. The doctor did so; but I do not know that he ever succeeded in gaining the good opinion of the Emperor; in fact, he was the only one of the suite at St. Helena who was not mentioned in the Testament—an omission which the family was obliged to repair by the grant of a pension.

The ceremonial which the great man imposed upon every one at Longwood was most harassing; and Antommarchi afterwards told me, on our passage to Europe, that he was often near fainting, having to remain two or three hours standing in the sick room of the Emperor. Napoleon seemed to know his disease very accurately, and we are induced to believe in the hereditary character of inflammation of the stomach, since we know, that beside him, his father, the princess Borghese, and queen Caroline of Naples died of the same disease. His pains convinced him of the truth of his diagnosis, and Dr. Arnott (the English Physician, who was, at a later period, called to his aid) afterwards told me, that the Emperor often placed his hand on his stomach, exclaiming, "Ah! mon pylore,—mon pylore!" The 4th of May was exceedingly stormy, and on such occasions the wind visits the island always from the same direction. At two o'clock in the morning, one of our officers, only half dressed, and without a hat, rode in full speed to my door, and called me to come immediately to Plantation House, where the youngest child of the governor had been dangerously ill. To Jamestown other surgeons had been called in haste, and telegraphs called for medical aid on all sides. The 5th of May was equally cloudy and stormy; a battle of the elements seemed to accompany the last struggles of the hero—the Emperor lay in his last agonies at Longwood. In fine, the great drama was over.

The *post mortem* examination was made in the presence of Bertrand and Montholon, some field officers of the governor—in fine, of all the medical officers of the governor, even some from the ships. Antommarchi was also present.—I had received orders from the chief medical officer (Dr. Short) to write the minutes of the autopsy, and to compose the bulletin, which was afterwards published; still, I was not permitted to sign my name to it, as I then was only an assistant surgeon, and the governor had ordered that it should be signed by no one below the rank of a regimental surgeon. Sir Walter Scott's account of the *post mortem* examination is not quite correct, as several persons, who were present, are not mentioned.

Death is often a wonderful beautifier of the human countenance. On Napoleon's features it had acted wonderfully and very advantageously; the general observation on seeing his corpse was, "How beautiful!" and all confessed to having never seen features more regular and more mild. The Italian cast of the profile was obvious in all its charms; an inconceivable serenity and purity of expression charmed every one, contrasting, as it did, with the turbulent deeds of the great hero. And as his whole life exhibits so many anomalies and things unriddled, so even the inanimate remains displayed similar phenomena. Notwithstanding the awful pains of a malady, which generally emaciates the patient, the corpse of the Emperor was found very fat. The whole frame seemed to have resisted vital encroachments to the very last, like the mind which also had remained unconquered. On the sternum I found a layer of fat one and a half inch thick; on the peritoneum it was two inches; the omentum, the kidneys, and heart, were covered with fat. The heart was remarkably small, and its muscular substance lax, quite different from what is thought to be the case in courageous and great men.

The disease, of which Napoleon died, has been matter of much dispute even during his life. O'Meara had affirmed, that the liver was the suffering organ, which Antommarchi had repeated after him; but the illustrious patient knew (as I said before) his state much more correctly, in stating the stomach to be the seat of his disease—and now the examination confirmed the truth of his assertion. The stomach was found in a perfect state of disorganization; it was all over in a state of inflammatory suppuration. The chief seat of the disease lay just where Napoleon had so often stated it to be, in the pylorus. I could on this place enter with my finger into the sack of an ulcer, which had corroded the orifice of the stomach, but which had been again covered by a slight adhesion of the liver. But the latter was free from any disease, in fact, every organ, except the stomach, was perfectly sound. There were some other peculiarities observed in the body. On one arm, he seems to have used for on some time a seton; on one of the legs I found a little scar as from a wound, which might have been however caused by a small abscess. The thorax was not very spacious, and the round arms and small hands and feet, gave to the body a feminine and delicate appearance. *Partes genitales exigitati insignis, sicut post cerebrum se.* The head was large in proportion to the body, with a fine towering broad brow. Besides these, there were no phrenological protuberances of any kind for indicating any *special* development of any *sole* quality of mind.

The causes of death were therefore obvious and palpable in the diseased state of the stomach; it seemed, indeed, incredible, how Napoleon could have lived so long with an organ, of which there was not one inch sound. Antommarchi was just about signing the bulletin after the English physicians, when Bertrand and Montholon called him aside, and after they had spoken with him, he declined to sign his signature. The reason is easily to be guessed, for by his assent to the protocol, he would have contradicted Dr. O'Meara's diagnosis of an hepatic disease. With the desire of screening O'Meara, and to cast all the odium on the government, as it were, was brought forth, which, in the shape of Gastro-hepatitis, had killed the patient. Now I assert, formally, that there is neither this, nor any endemic disease in this island. Amongst the soldiers there occurred at times (although very rarely), an inflammation of the liver, if they had been too much exposed to the burning sun of Jamestown, but the cases did not amount to the twentieth part of what we had in India. If the men were exposed to wet weather, or in the night air, here, as every where else, diarrhœa made its appearance; and I moreover state, that not one man died during a whole year in a regiment of 500 soldiers, and that that proportion was a constant one during 5 years, in which period not one of 40 officers died. The climate of St. Helena, cannot therefore be called unhealthy. J. L.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris. &c., &c., &c.

SUMMARY.—*Connection between organogeny and the zoological idea of the animal series.—The invertebrata considered in reference to the arrangement of their tissues, are permanent embryos of the vertebrata.—Invertebrated monokysts, deutokysts, &c.—Relations between the embryos of the vertebrata and the invertebrata, considered in reference to the manner in which the organs become added one to another in the embryos of the vertebrata, and the tissues in the invertebrata, according to the variability of forms evidenced in the different species.*

Having in my last remarks established the first relation of organogeny with zoogeny, I now pass to a second. If, in fact, zoonites are capable of association like organites, we may conceive that the animals resulting from this association would vary in the same way, as the organs themselves become diversified, in consequence of the mode of union of their constituent elements. The form of animals like that of organs, would then be but a secondary point, and such in fact it is. Thus a chain of *biphora* will be very different from an isolated being, although this chain represents but one animal formed by their union, and this union commences in the ovum (Dugès); so also with the *distomum duplicatum*, for the formation of which from two to six individuals become united (M. Siebold). Again, on viewing beneath the microscope the *logenula enchlora*, we might imagine that we were examining the embryonic kidney of man, or the permanent kidney of the ox, or the still more divided one of the *cetacea*. In all these cases, we find a body composed of similar parts which are associated together in a manner resembling the molecules of a mineral in forming a crystal. Hence it follows that in zoogeny, as in organogeny, the differences of form are derived from the mode of association of the elements. Thus we have radiated animals, as the *medusa*, the *asteria*, the *comatula*, &c., the elements of which are grouped around a central point; elongated ones, as the earth worm, the *tænia*, the *ascaride*, in which the elementary lines are added end to end. From these two elementary forms combined, arise the various forms of those which are neither elongated nor radiated, such as the *hippopoda*, the *rhizophysæ*, &c., as also those intestinal worms which zoologists sometimes refer to a binary, and sometimes to a circular arrangement. We have thus in some measure the repetition of the long bones, the short bones and the flat bones; we have the reproduction of the long muscles, the radiated muscles, and of those, more numerous still, which are neither radiated nor elongated. Zoogeny reproduces organic morphogeny.

The analogy is carried still farther. In organogeny, association is a species of combination in which each combined element divests itself of a part of its characters. It is the same in zoogeny, by association the elementary animals lose some of their distinctive characters, and this loss, as in organogeny, is always proportional, on the one hand to the degree of incorporation, and on the other to the extent of surface by which the associated zoonites are held in contact. It therefore follows that elementary animals will preserve so much more of their individuality as their association shall be less intimate. Thus the zoonites of the associated *botriella* change but little, and the less so in pro-

portion as their pedicle of association separates them further one from another; again, the zoonites of radiated animals combining only by a small surface, preserve their characters almost entire; hence the similitude of the *radii*, of the *asteria*, and of the *rotellina*. In zoonites associated end to end, the contiguous surface being more extended, the change is more remarkable, and even more so still where their association is more intimate. Such is the case with the *annelida*, and some species of *tænia*. By thus following step by step the degrees of incorporation among zoonites, we arrive at the composition of the *crustacea*, a subject which has been so ably treated by Dugès; and, (a circumstance especially deserving the attention of zootomists,) we are enabled to perceive that the essence of the metamorphosis of insects resides in the incorporation of the segments composing the *larva*, and in the modifications which they thereby experience. It follows, therefore, from our preceding observations, that there are, among the lower animals, solitary beings, as we find in organogeny isolated glands; and in the same way as with this organite considered as a *radical*, nature forms by association congregate glands as those of the eye-lids; agminated or contiguous as those of the intestines, or like the kidneys of fishes and the crustacea; conglomerate like the pancreas, the kidney in adult man and the liver; so also with a zoonite, combined in various degrees, nature will produce, congregate, agminated, and conglomerate animals. Here again zoogeny may be considered in some measure as the counterpart of organogeny, a thousand different forms springing from one common basis.

If, even by the assent of zootomists, who, apparently, have been the most opposed to these views, this analogy is founded, we see that through all the dissimilitudes of form, it will be possible for the physiologist to distinguish the fundamental analogy, and so systematically to combine this analogy, as to establish through its means a continued series of organisms and of animals, from the most simple up to the mammifera and man. This grand view of which Aristotle was the originator, is designated in zoology by the name of *animal series*. The supposition of an animal series in zoology is an abstract idea based on organogeny; for, viewed as a whole, the animal kingdom presents to us a determinate number of organic elements and of organs distributed by nature, according to constant laws, to all the beings endowed with animal life. But this repartition does not take place in such a manner that the number of these organs and organic elements is equal in all. The most general law presiding over this distribution is, that of the graduation and succession, whether of the organic elements, or of the organs themselves which concur in the formation of the different animals. The animal kingdom thus offers us a continued and permanent evolution and metamorphosis of the materials of animality. It is a repetition on a large scale of what passes in the evolutions and metamorphosis of organogeny in man. The method of natural classification, reproduces this graduation and inequality of division of the materials of animality; it describes, under the names of classes, families and genera, the most prominent evolutions, selecting for each division a ruling organism, the progress and development of which it rigorously traces through the series. A natural classification is thus merely a table of organogeny, indicating step by step the progress of development. Now, this gradual advance of organogeny in the animal kingdom is only a copy of the successive development of organogeny in man; the one is a repetition of the other. Thus in the animal series as in human embryogeny, the being commences by the most simple vesicular state then it becomes gradually developed by the addition of tissues, and, subsequently, of organs and organisms. The greater the development of tissues and of organs, the higher will be the rank of the animal. Animality and man progress by the same laws. By considering the advance of organogeny under this point of view, we shall be enabled to divide it into two periods; the one being relative to the development of the elementary tissues of the organisms, the other to the development of the organs themselves. From the first period issue the vertebrated animals; from the second, the vertebrata. Now, as in human organogeny the elements of the organisms precede the organs, as the primitive arrangement of the tissues is in some sort but their embryonic state, it follows that in the animal kingdom the invertebrata are permanent embryos, in relation to the vertebrata. Such being the case, we may conceive that the development of the invertebrata, as well as that of the embryo of the vertebrata, should take place in the first instance by the addition of tissues; and such is really the fact. Thus, the most simple of the invertebrata, those by which animality commences, are principally formed of the most simple of all tissues, the cellular tissues modified in various ways. This is the common basis of the *monades*, the *volvoces*, *acephalocysts*, the *ascidiæ*, of a part of the *echinococci*, and of the *polypi*. The life of these animals, distributed equally throughout all their parts is limited to the properties of this tissue, the characters of which are, on the one part, uniformity of function confined to exhalation and absorption, and on the other part a constancy of reproduction when divided. From this elementary composition result the singular properties with which these animals are endowed, as exhibited by those curious experiments where, on turning inside out such of these animals as possess an intestinal cavity, the intestine placed in the situation of the skin, fulfils the cutaneous functions, and the skin, in its turn, performs the nutritive functions of the intestine. The functions of exhalation and absorption are thus displaced at will under the hand of the experimenter, who may also, at pleasure, reproduce and multiply indefinitely these animals by dividing and sub-dividing them. The animals at the bottom of the scale thus sport, as it were, with life and death, and they owe this faculty to the primitive tissue of which they are constituted.

If to this primitive tissue be added the circumferential sanguiferous system, we advance a step in the animal scale, as in some of the *echinodermata*; if the muscular system be added, a still further advance is made, as in the *rotifera*; if these three systems be combined together, we arrive at the rank of the *helianthoida*. Lastly, the muscular system being clearly delineated in the organisation, we see appear the nervous system hitherto confounded in the various portions of the animal. From this new combination arise the *annelida*, the *mollusca*, and, perhaps, even the *crustacea*. These primitive tissues are then the fundamental bases of invertebrated animals; we have thus a complete system of histogeny presented by the comparative anatomy of their structure. The natural classifications being based upon the advance of animal organisation, zoology might, under the guiding genius of a Bichat, be so systematised, that the structure of the invertebrata should be represented by their classification. Thus we might have *monohysts* or invertebrata with a single tissue, *deutohysts* with two tissues, *tritohysts* and *tetrahysts* with three and with four tissues. We should thus see zoology, escaping from its present narrow limits, perhaps exercise over comparative physiology the same influence which the hystology of Bichat has exercised over the physiology of man; for, in the progressing and histogenic composition of the invertebrata, each tissue bearing with it its characteristic properties, the functions, would increase in the same proportion, so that the sum of life or of functions of an invertebrated animal, would be exactly represented, both by the number of tissues concurring in its composition, and by the degrees or stages of evolution through which these tissues may have passed. And in the same way, on considering at their commencement vertebrated animals, we shall see them transiently clothed with the modifications of structure offered by the invertebrata; we shall find their development to take place in the first instance by the addition of tissues, and afterwards by their evolution. Before impregnation, the animal will be represented by a vesicle and a cellular membrane enclosing an oleaginous fluid: this will be a true *monohyst*. After impregnation, the *blastoderma*, whence the constituent parts of the embryo arise, presents two membranes, the one external or serous, the other internal, cellular, or mucous; this would be a *deutohyst*. A little later a vascular membrane becomes interposed between the two first, and this would be a *tritohyst*. Lastly, it would become a *tetrahyst* when the nervous tissue, which commences the development of vertebrata, shall become clearly marked out from the original structures of the animal. If, from this common origin of organogeny and zoogeny, we trace comparatively the development of the embryos of the vertebrated and that of invertebrated animals, we shall see it take place in a somewhat different manner. In fact, an animal, as an embryo, is constantly progressing, either by some new evolution in one of its principal organs, or by the appearance of some fresh organ. Thus, in the primitive state of an embryo, as in that of the polypus or of the entozoa, the intestinal canal is found without a liver or salivary glands. The salivary glands, the liver, and the mouth, become developed subsequently in the embryos as they manifest themselves in the crustacea, in insects, and especially in the mollusca, as far as concerns the liver.

The embryo, as well as the zoophyte and the polypus, is at first devoid of all trace of isolated reproductive organs; the Wolffian and O'Kenite bodies, improperly named primitive kidneys, afterwards appear, and which are the transient reproductive organs of the vertebrata, bearing an exact resemblance to the reproductive organs of the annelida, the mollusca, and the crustacea. The permanent reproductive organs of the embryos of the vertebrata, so different in their ultimate stage, still offer in a transient manner the homogeneousness of sex which we observe in the bivalvular mollusca, and in a great number of entozoa.

The respiratory organs are formed in the invertebrata, as in the embryos of the vertebrata, by the vascular layer of the *blastoderma*, and their difference results from the different relation of this layer with the two others. Thus, in the invertebrata, the vascular layer being intimately united with the external blastodermic membrane, its evolutions will remain combined with those of this latter membrane. Hence it follows that the respiratory organs will always form a constituent part of the skin; that they will become converted into fins, feet, *antennæ*, vesicles, hair, &c., such as they are found in the annelida, the crustacea, and insects. And, on the contrary, in the embryos of the vertebrata, the vesicular layer of the *blastoderma* having more immediate relations with the internal than with the external layer, the temporary respiratory organs will have greater connections with the intestine than with the skin. Such are especially the omphalo-mesenteric vessels of the mammifera and of man, the umbilical or omphalo-mesenteric membrane of birds, and in a more advanced age of the embryo, the *allantois*, or ovo-urinary bladder of the mammifera, of birds and of reptiles. The mollusca, so remarkable among the invertebrata by the development of their intestinal apparatus, will serve as a connecting medium between these two branches; for the respiratory *apices* scattered over the external covering of the *scyllea*, the *tritones*, the *glaucus*, and the *colis;* the *branchial apices* of the *doris*, concentrated around the anus; the respiratory villosities of the *patella* and the *oscabriona;* and, lastly, the branchial cavity buried within the folds of most of the *gasteropoda*, are merely varied degrees of the omphalo-mesenteric vessels, of the *branchial* villosities of the chorion in the mammifera, and of the *allantois*, or ovo-urinary bladder. In fact, it is only in the *cephalopoda* that true *branchiæ* appear for the first time in the mollusca, similar as well to the temporary *branchiæ* of certain reptiles as to the permanent *branchiæ* of fish.

We have already seen that the embryogeny of the heart in the vertebrata, reproduces with sufficient accuracy the permanent condition of this organ in the invertebrata, without its being necessary to admit in the latter class a deviation from the common type of development, or a new plan, according to the expression of Cuvier, in reference to the two hearts of the *lingula*, and which Mr. Owen has discovered in most of the *terebratula*. It is then by a succession of evolutions that the organisms of nutrition become more complex and developed in the embryos of the vertebrata, as

well as in the class of invertebrated animals. Hence it is in these two corresponding states of animality that the terms of comparison must be sought, as well as the relations which bind together the invertebrated and the vertebrated animals, and even the different classes of the latter among themselves. Without this mode of connection, the animal series is inevitably interrupted, and confusion is introduced into the study of zoology, a circumstance which it is impossible to prevent in taking into consideration those animals only which have already reached the term of their development. It is sufficient to observe that the connection and resemblance of forms which serve as the basis of modern nomenclature are applicable only to groups, and not to the entire of the animal kingdom. The secondary divisions, the *genera*, the *families*, and even the *orders* are very naturally connected one with another; but not so with the *classes*, nor with the principal or reigning *divisions*. It is especially between the vertebrata and the invertebrata that the resemblance has appeared of most difficult demonstration, and it is there that all the efforts of classifiers have failed. But if, instead of arbitrarily dividing the field of nature, you include its entire extent within your views; if you embrace within your researches the immensity of facts furnished by organogeny, as well as those already established by comparative embryogeny, you will see these distances become lessened and the gaps become insensibly filled up. You will discover, by means of this method, that the inferior organisms of the invertebrata have their representatives in the organisms of the embryos of the vertebrata and of man. You will find in the fugitive and transient forms of embryogeny in man, and the vertebrata, the fixed and permanent forms of the organisms of the invertebrata. Indeed, of these two orders of organisms, the one will be but transitory, and its forms will have merely a fleeting existence; the other will, on the contrary, be permanent, and its duration will be subordinate to that of the animal itself. The analogies then will be in the structure of the organisms, and the difference in the duration only.

We thus come to the conclusion; first, that the great zoological question of the series of beings, reduces itself to that of the continual series of the developments of organisms considered throughout the whole of animals; secondly, that the differential method exclusively employed in zoology up to the time of the Geoffroys, was, in its nature, incomplete, since it embraced only the half of the question; and, thirdly, that the explanation of animals can never be arrived at without the union of the method of analogies with that of their differences. When this truth, which is now beginning to be received shall be fully established; when it shall be generally acknowledged that the invertebrata are merely the permanent embryos of the vertebrata, we shall no longer see the most elaborate researches upon the infusoria and other invertebrata devoted towards raising these animals to a rank which nature has refused them; we shall no longer find the most celebrated zootomists affirming that the invertebrata are constructed upon a different plan to the vertebrata, and consequently that their rules of formation, and their mode of development can no longer be the same. We shall not see men of the greatest talent wasting their time in superfluous efforts attempting to give a spinal marrow and a brain to the infusoria, the annelida, the mollusca, insects and crustacea, which, in the order of developments, neither have nor can have such organs. In a word, we shall not see in the principles of the science that disunion which contrasts so strongly with the identity of the facts which organogeny unfolds in the development of the beings of all classes.

We find on the contrary, in the application of this new relation, the reason of various characteristic peculiarities of the invertebrata, and which approximate them more nearly to the vertebrata. We shall see in the first place, that the variability of form in the invertebrata, and consequently of their classification, (a variability which contrasts in some measure, with the fixity of forms and the fixity of classification in the adult vertebrata,) is reproduced and repeated by the variability of forms in embryonic life; so that if the embryology of the vertebrata was equally advanced as that of man, and if, according to the system of differential zoology, we divided their embryos of different species and of different ages into classes, genera and species, we should find this classification of the embryos reproduce the principle divisions and marks of that of invertebrated animals. The more we ascend towards the primitive age of the embryos, the more we shall multiply the gedera and species, similar to what we find, in ascending the zoological series, with reference to the polypi, the infusoria, and even the annelida. We shall also perceive, in the second place, that, as in the young embryos, the structure of the greater number of invertebrata is constituted principally by primitive and elementary tissues, the transformations of which cause them to be varied and diversified, as they vary and diversify between them the embryos of the vertebrata. We shall see again, in a more advanced age, that the differential characters of the embryos will be furnished by the alternate balancing of their organisms, especially that of the sanguiferous and nervous systems, and of the nutritive and respiratory apparatus; it is then upon the equilibrium of these systems and apparatus that the distinctive characters of the most elevated classes of invertebrata depend. Lastly, everything that amazes, and as it were, confounds us in the life of invertebrated animals, will be found to have striking traits of analogy in the embryonic life of vertebrated animals, and even of man himself.

CURABILITY OF CONSUMPTION.

(Continued from page 216.)

To the Editor of the 'Medical Times.'

Sir,—In my last communication, I stated that DISEASES OF THE HEART form one class of the antagonisms of which nature avails herself against the invasions of phthisis. The frequency and variety of heart affections, and their important bearing on the malady under consideration, will, I trust, justify my entering a little further into details. That tumefaction of the mucous membrane lining the bronchial tubes, takes place in all cases of disturbance of the central organ of circulation, is capable of demonstration, and will, I presume, at once be conceded. The manner in which this tumefaction arrests tuberculous deposit has been already explained. Disease of the heart, however, will sometimes be found coincident with phthisis. In these cases, the formation of tubercles preceded the cardiac affection. I do not base this assertion exclusively on my own experience: my preceptor, whose opportunities of connecting symptomatological with pathological facts have been equal to, if not more extensive than those of most men of the age, has verified it by the whole course of his practice: in this particular class of affections, a patient who dies of phthisis may have contemporaneously a disease of the heart; but the latter, in every instance, will be found to have supervened upon the former. It may be safely laid down as a general rule, that where the affection of the heart is primitive, the strumous diathesis does not exist. In a majority of cases, where the former is subsequent in point of time, the latter is either arrested and cured, or masked and rendered stationary and quiescent. It may not be uninteresting to add that persons who undergo liquefaction rarely exhibit the ordinary constitutional display when the heart is affected. This is particularly the case, as far as regards the perspirations. Dr. Ramadge has shewn me many cases in his public and private practice illustrative of these positions. When we find, then, a patient with lividity of the lips, permanent distension of the jugular veins, dyspnœa, and anormal action of the heart (without entering into auscultatory minutiæ) we may, with much confidence, pronounce a favourable prognosis. If these symptoms be moderate, such a patient may, under proper treatment, survive many years. I have at times accompanied Dr. Ramadge in his professional visits, on occasions when his opinion was desired on the general health of a family; some of whose members had died of consumption, and where the entire was apprehended to be tainted with the disease. He has frequently been enabled, from the presence of indications of cardiac disturbance, to quiet the fears of anxious parents relative to one or more of their children. *Apropos:* Who has not observed the remarkable exception which gibbous, or hump-backed persons enjoy from the fatal effects of tuberculous disease? This is a singular fact, and worthy of attention. It may be readily accounted for by the displacement of the heart; consequent mucous tumefaction, and an impacted state of the lungs, to which the deformity of the chest in a great degree contributes. Again: has any practitioner met with a case of simple and genuine chlorosis terminating in phthisis? In this malady, there is always some functional disturbance of the heart, which antagonises the disposition to tuberculous deposit. A popular notion prevails, that chlorotic females are either consumptive or likely to become so. It has not escaped the common observation of mankind, that debility is often the precursor and always the attendant of phthisis. The cheek suddenly robbed of its bloom, the eye of its lustre,—

"Pallor in ore, sedens macies in corpore toto."

—apathy and despondency usurping the dominion of the mind, lately so cheerful and elastic; the bud 'of promise fair,' faintly struggling to disclose its petals, and drooping on its feeble stem, present a group of imagery sufficiently melancholy to awaken the worst forebodings. It may console this unhappy class of patients to learn that the very series of morbid changes, which the system is undergoing, securely defends them from the greater perils of phthisical disease.

When life has sometime passed its meridian, primary deposits of tubercles are of very rare occurrence. The disease, if met with, had its origin at some anterior period. At and after this time of life, there is a venous preponderance producing mucous intumescence; this is not necessarily so considerable as to superinduce catarrh, but sufficient to prolong the expiratory act,—the sure sign of obstruction somewhere in the respiratory organs. The practised auscultator will readily detect the prolonged expiratory murmur. From this we might deduce as a corollary, however heterodoxical it may appear, that a certain amount of disease is almost essential to prolong life to the full term of its natural duration in this climate. Even our winters, by causing suppressed cuticular secretion, internal venous congestion, and mucous tumefaction, &c., have a share in impeding the advance of diseases that, otherwise, would have had an earlier fatal termination; if the climate has its bane it contains also the antidote. Looking at the question in the light I view it, the very variableness of the temperature, so far from increasing the amount of phthisical mortality, actually decreases it.—I now proceed to the next division of my subject.

Tumours of any Sort on the Windpipe, or its Division.—These are useful agents here in the hand of nature. The first I shall notice is bronchocele. The mechanical pressure of this kind of tumour is sometimes lateral, and sometimes in an antero-posterior direction, according to the form and place of its enlargement. The amount of obstruction determines the amount of pulmonary enlargement, vesicular emphysema, and dyspnœa. I appeal to the experience of medical men, whether they have ever witnessed a case of fatal phthisis in a patient labouring under bronchocele? No cavity can exist in the lungs, in the face of such an impediment. Let me again repeat it,—here the contraction of the windpipe prevents the free egress of the air, imprisons it in the air cells, and makes the lungs excessively voluminous, i. e., though the bony compages of the chest are pushed outwards in every direction, and the convexity of the diaphragm diminished, yet the expanded lungs not only fill up the additional space thus gained, but would occupy more if obtainable. How is it possible that under these circumstances an excavation can exist in the lungs? or that small cavities, formed by the recent solution of tubercles, from some accidental affection, should not be rapidly closed? These may form from tubercles which had lain latent for years, but cannot progress, nor can a new crop arise in this expansive state of the pulmonary tissue.

Enlargement of the thymus gland has a similar effect in protecting children from early tuberculous deposits, and many adults refer their dyspnœal

affections to an attack of croup in infancy, which, I would observe, is always produced and kept up by irritation, from the mechanical pressure of the enlarged gland, acting as a foreign body. When children survive this affection they are generally short-breathed, and protected against phthisis in after life.

A congeries of scrofulous tumours is frequently formed at the root of the lungs; or behind and partially embracing the windpipe: diminishing its diameter and acting as before described. Aneurismal tumours are, also, powerful antagonists to phthisis. I have lately been shewn by Dr. Ramadge, in his valuable museum, a specimen of aneurism of the aorta, protuding at the point where the trachea bifurcates into the bronchi. The case was operated upon by the late Mr. Earl, ten years back, to relieve suffocative dyspnœa.

The operation was admirably performed, the man, however, died; and it appeared, on autopsy, that the opening had been made above the seat of the obstruction, which lay at the bifurcation of the trachea. His lungs exhibited the usual traces of a previously well-marked phthisical condition; arrested, no doubt, by the intervention of the tumour.

Among the other obstructions worthy of note, I might mention enlarged bronchial glands at the root of the lungs, and along the course of the principal bronchial ramifications, and calcareous deposits also, in situations where tuberculous matter had previously existed, but had either made its escape or become absorbed.

DISCIPULUS.

(To be Continued.)

EXTRACTS FROM FOREIGN JOURNALS.

(From the Berlin Medicinische Zeitung, for the 'Medical Times.')

On the Puerperal Fever in Peitz, 1842.—By Dr. SCHLESIER.—This paper contains some observations on puerperal fever, but of no practical value: he gives six cases, which he considers as completely formed puerperal fever, two of which died. Some of the cases were without any local affection of the uterus, but with typhoid symptoms. The 1st case was cured by bleeding, large doses of colomel and mercurial innuction—the 2nd, after a relapse terminated fataily on the 21st day, the treatment was bleeding general and local, mercurial innuction; digitalis and kali hydroiodic to set bounds to the exudation with which the case terminated.—In the 3rd, of which the symptoms are not given, phosphoric acid had a surprisingly good effect.—The 4th was fatal, but was certainly not a case of puerperal *peritonitis* but rather of puerperal irritation, causing attacks twice daily of ague. These were reduced to attacks at intervals of from one to two days, by strong doses of quinine and opium, and removed entirely by strong doses of decoct. cinchon, and opium, just before the attacks, but this being superseded by infus. arnicæ flor. a relapse followed—the disease was removed in 8 days by returning to the former means. She however died at the end of 5 weeks from a relapse caused by eating some indigestible berries.—The 5th case recovered. The treatment was local bleeding, calomel and mercurial innuction followed by extract rhatan.—The 6th case was cured by extract rhatan.—the woman having irritative fever, consequent on an enormous bleeding, the extract. cinchon. was given, but producing unpleasant symptoms, was superseded by the rhatany extract.

Decoction of Galls as an antidote to Cicuta Virosa, by DR. MAYER.—On the morning of March 13th, four children of 3, 5, 5, and 6 years respectively, having found some roots of cicuta virosa in a brook flowing past their village, ate the greater part of them, supposing them to be parsnips. The youngest child was immediately seized with violent pains in the bowels, vomiting, and convulsions, and expired before aid had been sought, about 1 P.M. The parents of the other children, hearing what had occurred, and having found a root of the plant on one of the children, quickly sent for the surgeon of the place, who sent for me, giving them in the meantime large quantities of milk. When I arrived, about 2 P.M., the three children had vomited a little only, from ipecac. which had been administered. Their whole bodies were cold—the countenance pale and sunken—the pupils dilated and immovable—violent pain in the bowels, and general convulsions. In two, the recollection was quite gone, the third complained at times of noise in the ears, and giddiness, and then fell into a soporific state. In one the breathing was weak, and scarcely audible, in both the others, there was unequal snoring,at times interrupted by hiccough. The heart-beats were without rhythm, often stopping for some time, then followed by stormy palpitations. A large dose of sulph. zinc was immediately given, which was followed by frequent strong vomitings, and many macerated, but easily recognisable, bits of the roots were thrown up. The vomiting was encouraged and eased by bland drinks, and rubbing upon the region of the stomach. At the same time, clysters with vinegar were administered; cold applications to the head, horse radish, and mustard plaisters were applied, and the cold extremities rubbed and covered with warm flannels. Within an hour, the narcotic effect, convulsions, and bowel pain were, in a measure relieved by the frequent evacuations upwards and downwards. The stools were thin, and colored quite yellow, by the bile. A prepared strong decoction of galls was now administered on this day in large and frequent doses, on both the following in less, and less frequent, and indeed with the best effect; for the threatening symptoms became gradually ameliorated. The three patients were completely recovered in 5 days, with no ill effects remaining. The decoct. gallæ recommended by Phöbus and Menrer, or rather the tannin therein contained, in these cases effected everything which could be desired in an antidote. For this most powerful root at this season contained a most intense poison, and it was eaten in considerable quantity. The small root found upon one of the children weighed 15 drachms, and indeed taken upon a nearly empty stomach, about 10 A.M., the breakfast, as is well known, being very early in the country: in fine, the poison had abundant time, during four hours, to develop its destructive effects in such young and irritable subjects. Consequently, the poisoning was very violent, as its effects sufficiently evidenced, and nevertheless the antidote, (after the previous vomiting indeed,) caused every trace of intoxication to disappear in a short time, in a simple, reasonable, and certain manner, without leaving behind the least prejudicial effects upon the health. I can, therefore, with as full justice praise the decoct. gallæ, as an antidote to cicuta virosa, as Dr. Ludicke has praised the tannin in poisoning from strychnine.

Dissection of the dead child was not allowed; the little corpse, although it had lain 3 hours in a warm room, was stiff in every joint; the back, arms, and legs were of a brownish blue color—the fingers greyish blue. The belly was swollen, and sounded on percussion—the face much swollen—the eyelids half closed—the balls white—the corners quite clear, and the pupils strongly dilated; the lips were violet blue, and from the fast-closed mouth and nose flowed out a bloody slime.

The Benefit of Acidum Querci Tannicum in the third stage of Hooping Cough; further confirmed by DR. SEBREGONDI.—Since I employed this excellent medicine, first recommended by Dr. Geigel, in the late epidemic hooping cough, in a great number of cases, at least 90, with an effect exceeding my highest expectations, and which I have already published in the Heidelberg medical annals, I have had opportunities of testing the healing power of this medicine in the latter stages of this disease, and now communicate two, out of many cases I have lately observed.—1st Case: A girl 4 years old had been teazed 3 months with an obstinate cough, for which much medicine had been given in vain. She had an attack in my presence, which I directly recognised as hooping cough. It ended in vomiting and expectoration of tough white mucus, streaked with blood. In the day time it came on nearly every half hour—in the night it occurred six or eight times. Immediately after the attack, the child wished for food; in other respects she was tolerably well, but was manifestly emaciated—her countenance was pale, and the tongue covered with a white slime; the appetite so great that it approached to voraciousness—the abdomen tumid, and the bowels sluggish.

From all these symptoms it could not be mistaken, that she was in the third stage of hooping cough, which had so long continued; with this was complicated a large quantity of impurities in the lesser bowels. According to my views the evil here lay, in a chronic enanthem of the epithelia of the mucous membrane of the cells of the lungs, which, separated in the form of mucus, irritates the tender papillæ of the nerves of the cells of the lungs and mucous membrane of the bronchiæ, and in this manner, according to the well known laws of the healing power of nature, calls forth the attacks of cough to remove this mucus. The affection of the mucous membrane of the alimentary canal, I held as secondary, but yet so intimate that in case I could remove the first, the latter must be relieved. I ordered the following mixture—℞ Tanni puri, gr. vj; ext. Belladon, gr. i; ext. cicutæ, iv gr., solve in infus. sennæ compos. ℥ij; aq. fœnicul, ℥. 8 gr.; althæ, ℥ij. M. half a table spoonful to be given every two hours; at the same time a plaister was laid upon the chest, composed of emplast. cicutæ et adhæsiv. The medicine soon produced fluid stools, and scarce had the child quite finished the mixture than the hooping cough was entirely gone, and did not return, as I was convinced by later visits.

2d Case: My advice was required for a boy 6 years old, who, together with his three younger brothers, had suffered three weeks from hooping cough. The attacks occurred every half hour during the day, and even in the night, as frequent, followed by strangling and vomiting of a small quantity of mucus. The breathing during the free pauses was quick, the tongue coated yellowish—the thirst great—appetite quite gone—the abdomen tense—the bowels sluggish. The boy took the following:—℞. Tanni pur. gr. vij; ext. cicutæ gr, iij; solve in infus. sennæ comp. ℥ij; syr. althæ ℥vj. M. half a table spoonful every two hours. Eight days afterwards the grandfather informed me, that the boy had completely recovered, and also his three younger brothers, to whom I had given the tannin in a simple vehicle, and in whom no complication was present.

A singular Case of Pustula Maligna.—This was caused by the sting of some kind of fly. Besides the malignant pustule, the whole arm was swollen with fever: the lymphatics shewed themselves highly inflamed by red lines along their course. It was removed by the use of aqua oxy-muriatica internally and externally, as a fomentation.

OUR SUBSCRIBERS

Are respectfully informed that the rule is to pay in advance. A number of subscriptions (a long time expected) have not yet reached us, and as we make these obligations debts of honour, we trust that this gentle memento will not need repetition.

THE MEDICAL TIMES.

Respicere exemplar vitæ morumque jubebo
Doctum imitatorem et vivas hinc ducere voces.
—HORACE.

WE know, of course, that nothing is more absurd than the folly of offering the Government of one country as a perfect exemplar for that of another. Good is only good in its fitness and adaptation. Circumstances are to things what usage is to words—"the *vis atque norma*, and the legislation which pays no regard to them is about as wise as reasoning without facts, or prophecying without foresight. But yet there are certain broad principles acting in all good Governments, which, based on a number of ideas, forming essentially the moral nature of man, must have, at least, a *general* application to the natives of every country. Amid all our varieties of mental colour (so to speak) and mental form, there is beneath an essential identity of elementary matter, and thus, though the system which is perfection in this region, may be, if unaltered, mischief and ruin in that—it must yet contain *principia* of judgment and action, which, if modified with modified circumstances, are capable of as extensive application as there are human beings to apply them to. To use another illustration—while the frame-work—the body—of a good code, must be lodged, clothed, and sustained, with variations suited to varying temperatures—its essence—its soul—is of all climates.

With these impressions, we have thought that, on the eve of a session in which British Medical Polity *must*, in some way or other, be altered or remodelled, we could not offer a better boon to our legislators, or our readers, who have not yet reached decided conclusions, than, by short and accurate descriptions of the different kinds of foreign medical government, to give them an opportunity of detecting the general principles which should regulate the coming alterations. Our first sketch will be on the *Medical Government* of Austria.

The principal characteristic of Austrian medicine is, its numerous divisions and subdivisions. The military and civil organizations are essentially distinct. In the civil code we have, first, doctors of medicine—secondly, doctors of surgery—thirdly, masters of surgery (*chirurgiæ magistri*)—fourthly, barber-surgeons (*chirurgiæ patroni*) — fifthly, licensed midwives — sixthly, dentists (*magistri dentisticæ artis*). In addition to some of the above titles, additional degrees may be taken, as accoucheurs (*magistri obstetriciæ artis*)—and oculists (*magistri oculisticæ artis.*)

QUALIFICATIONS AND PRACTICE OF THE DOCTORS OF MEDICINE.—The candidate, before he can inscribe himself as studying for this degree, must be at least 18 years of age—or, if extraordinarily distinguished during his preliminary studies, 17—must prove by certificates a course of twelve years' constant education, four of which must have been in the National Schools, six in the Gymnasia, and two at a University, in the Faculty of Philosophy. After inscription as a candidate, which must take place either at Prague, Pesth, Vienna, Pavia, or Padua, he must give five years to medical studies. The examination, on admission, is not represented as severe. The diploma then given, opens the whole Austrian empire to the doctor's practice, without, in any case, an extra charge. If not educated in Vienna, however, he must, if he would practice in that city, undergo a second examination, which is considered a very rigid one.

Doctors of medicine are restrained, under a penalty of from 10 to 50 ducats, and various periods of imprisonment, to purely *medicinal* practice. Accouchments are forbidden to them.

The position of doctors of surgery is analogous to that we have been describing, except that their studies take a surgical direction, and that they undergo a *severe* examination. Medical practice is forbidden to them as well as all ocular operations, unless there be a special diploma. As doctors of surgery, in addition to their own especial branch of science, have been obliged to master that of medicine also; and as Government extends its patronage by preference to those who have the double qualification, there are now very few doctors of surgery who are not doctors of medicine also.

The special diploma for *Operative Surgery* is open only to the masters of surgery, or those who are doctors both of medicine and surgery. They must study solely in an establishment at Vienna, founded in 1807, by Dr. Kern, and called the "Operating Institute." The studies must extend through two years, comprise both the theory and practice of operations on the living and dead subject, and are finished by an examination. There is no limit to the number. There are twelve operative students, who have more or less distinguished themselves, constantly kept at the expence of the State.

The degree of master of *ocular* medicine and surgery, is obtained by doctors of medicine and surgery, and by masters of surgery, after a special study of the subject, accompanied by strict proof of ability in that branch of science, and by success in several public operations. Before operating on the eye, this special diploma is indispensible.

The diploma of MASTER OF MIDWIFERY, though not essential to doctors of surgery and medicine, is so to masters of surgery. The preliminaries are, a rigid examination, two months' special practice, and a payment of 30 florins.

The MASTER OF SURGERY is required to prove having passed four years studies in the National Schools,—having attended three years more in the Grammar School of his district—having regularly attended each half-year in his classes—and an adequate knowledge of Latin. His professional studies take place at one of the Universities, and cost him nothing for fees. They are shorter than those of doctors, and give the right of practising all over the empire. He is restrained by heavy penalties from practising beyond the limits marked by the character of his diploma or diplomas. When there is no "doctor," however, during epidemics, he is allowed to practise medicine.

The BARBER-SURGEONS (*chirurgiæ patroni*), or petty surgeons, must have spent four years in the National Schools, and either given five years to the study of "the Humanities," or lived three years as apprentices in the shop of a patronus, who is supposed to have taught them Lat

their knowledge in which is proved by a jury formed of the State physician of the district and a certain number of "*masters*" and "*patroni*" of surgery. All this being attested by certificates, their course is now similar to that of the "masters." After undergoing several minor examinations, they are submitted to a general examination, which is final. The whole expence, including a diploma for midwifery, which is made essential, is about 85 florins.

The treatment of internal maladies, the greater operations, and ocular surgery, are not, under a heavy penalty, permitted to the "patroni." These men are under singular laws.—First, the diplomas acquired at Saltzburg, Laybach, and Clauserbourg, are only of use in their respective provinces.—Secondly, unless in a State appointment, the patronus cannot set up in business, except as in the case of our publicans—he buys the shop of a retiring patronus, or has a shop conceded to him by the local magistrates. Before 1836—when Government made the sale of one of these shops contingent on its purchase by a medical man—these shops were bought by a tradesman, or even a physician, on speculation, and confided to the care of a patronus, who shared the profits. Not unfrequently they were managed by the widow, who similarly arranged for her customers. Besides the proprietors, there are occasionally in these shops a number of assistants, apprentices, or even patroni, acting under their responsibility.

Like many of our druggists in England, the patroni carry on various other businesses, —sometimes they are barbers or farriers, grocers or cab-owners,—and, like our druggists they are frequently charged with engaging in practice far beyond the reach of their moderate skill, to the serious injury of the fully-qualified practitioner.

Military Medicine.—As we said, this is entirely governed by its own peculiar laws. The special school is at Vienna, where an unlimited number of pupils are lodged, fed, and taught at the expence of the State. There are six grades of medical men in the army. The principal physician, the *Oberstfeldarzt*, an aulic counsellor, in the receipt of 1 000 florins yearly—the *Stabsarzts*, or Inspectors-General, of whom there are twelve, receiving 800 florins yearly—the *Regimentzarzt*, receiving 600 florins—the *Oberarzt*, in the receipt of 200 florins. All candidates for the above ranks must be doctors of surgery and medicine, and possess diplomas as accoucheurs and oculists. Besides these, there is the *Unterarzt*, surgeon to a company, with 168 florins of an appointment—and the *Feldarztliche Gehilfe*, or assistant-surgeon, with 168 florins also.

The army doctors are engaged for a limited number of years. Those who, in their studies, received a pecuniary allowance from the State, serve fourteen years—those who have studied at their own expence, are only held to serve eight years. While in service, they may exercise their profession in the towns in which they are stationed; and, on retiring, they may practice in every part of the empire, without any further formality or payment.

WESTMINSTER HOSPITAL.

Mr. Guthrie's Clinical Lecture on Injuries of the Head—Case of Spontaneous Cure of Femoral Aneurism—Amputation of the Finger by Mr. Lynn—Improvement in the Affairs of this Hospital.

Sir,—I had the curiosity to step into the Westminster Hospital last Saturday about one o'clock, and was not a little surprised to find an activity and bustle for which I was totally unprepared at this holiday season of the year. Instead of finding all deserted, as I expected, the entrance hall of the hospital was in commotion with students, and following the throng, I was soon carried into the operating theatre, where Mr. Guthrie had just commenced his clinical lecture. The lecture happened to be on cases of injuries on the head, resulting, no doubt, from the *boxing* system so much in vogue at Christmas time. As the subject interested me not a little, I shall endeavour to give you some account of the lecture.

The first case to which the learned lecturer referred was of peculiar interest, and in placing it before his attentive, I might say enraptured, audience, he realised in my opinion, the *beau ideal* of clinical instruction. It was not a lecture doled out from some book of surgery. It was not a lecture that might be made to suit every such case that has existed, or may exist; it was not a lecture, in other words, of indiscriminating generalities, but a lucid exposition of the *peculiarities* of the cases before him, the *reasons* which induced him to form his diagnosis and prognosis of each case, and to change and modify the usual plans of treatment. I cannot pretend to follow the learned lecturer through all the details of his lecture, I can only refer, and that in a general way to the outlines of his discourse. The first case which principally occupied the attention of the lecturer was that of a man who fell from a height of about thirty feet, the back of his head striking the curb-stone of the pavement. The integuments were lacerated, but no fracture could, during life, be discovered. The patient was taken up in a state of total insensibility, with the pupils contracted and the respiration diaphragmatic, accompanied with a puffing or whiffing of the air from his mouth. The patient died, in a few hours after his admission into the hospital, and on inspecting the body a fracture or rather fissure was discovered in the base of the cranium, on each side of the foramen magnum. There was also an effusion of blood on the surface of the brain under the dura mater, and also a laceration of the anterior lobes close by the sides of the crista galli. Mr. Guthrie gave a very luminous explanation of the more prominent symptoms of the case, more particularly those mentioned above, and endeavoured to explain them as far as possible on physiological principles, and was most happy and successful in pointing out the *relative value* of each symptom in the establishment of a just prognosis in such injuries. Sterterous breathing, bleeding at the nose and mouth do not necessarily indicate danger. Even bleeding at the ears, though a more unfavourable symptom, does not necessarily indicate imminent danger; but if the patient, as happened in the case under consideration, puffs or whiffs the air from his mouth as we puff or whiff the smoke of tobacco, and if this symptom exist along with pure diaphragmatic respiration, the case is hopeless. Mr. Guthrie had never seen a case of recovery in which the last-mentioned symptom existed. That symptom, (pure diaphragmatic respiration) may be viewed as the most unfavourable of all the unfavourable symptoms, and the invariable precursor, therefore, of dissolution. In the treatment of the case little was done, and the postmortem examination so far as it went (for the spinal cord was not inspected) shewed that no human efforts could have been of the slightest avail.

In the second case that of a boy who fell from a height of fifteen feet; the symptoms though somewhat peculiar were less urgent than in the foremost. Six days after the accident the boy became comatose, and in this state was carried into the Hospital with a very low pulse, (about fifty) contracted pupils, and twitching of the muscles of the face. Mr. Guthrie ordered, at first, a very cautious detraction of blood. Four ounces were first drawn off, which proving to be buffed a further detraction was followed up with good effect both upon the pulse and sensibility of the patient. From the good effects of the bleeding rather than from the nature of the symptoms, Mr. Guthrie, conjectured, that the vessels of the brain had been in a state of great congestion, and that, possibly, a partial effusion of blood had taken place. The bowels were kept freely open with calomel, combined with resinous and saline purgatives, rest and low diet strongly enjoined, and the affection, Mr. Guthrie states, is fast progressing to a favourable issue.

At the termination of his remarks on injuries of the head, Mr. Guthrie introduced a case of extreme rarity to the pupils, which, he said, they had not seen, and would never see its like again. It was the case of a man who had been successfully operated upon for popliteal aneurism, who became subsequently affected with a femoral aneurism of the *opposite* thigh, and which aneurism underwent a spontaneous cure. Mr. Guthrie had no doubt that the pulsating tumour he had examined, was an aneurism of the femoral artery, and he had urged the man to submit to an operation. But fortunately as Mr. Guthrie remarked, the patient did not follow his advice. Sometime afterwards, when the patient was engaged in some trifling occupation, he felt something give way with a crack, attended with little pain. The tumour, the patient says, was immediately afterwards obviously less, and gradually diminished till it entirely disappeared. From the want of pulsation in the upper third of the femoral artery, that artery appears to be now obliterated, but how that was effected Mr. Guthrie did not attempt to explain.

After the clinique of Mr. Guthrie, Mr. Lynn introduced into the operating theatre a case of ulceration of the cartilages of one of the joints of the forefinger. The disease had resisted the usual means of cure, and the question came to be, not so much whether the finger should be amputated, as whether the amputation should take place immediately above the diseased joint, thus leaving a part of the first phalanx of the finger; or at the joint immediately above that, viz., the metacarpo-digital articulation. The consultation was carried on in a very edifying manner before the pupils, by Mr. Lynn, and that most excellent practical surgeon Mr. White, along with some of the lecturers of the school. It seems to have been the opinion of the majority, that a more useful hand to a labouring man, such as the patient, would result from the removal of the *whole* finger. The operation was accord-

ingly performed with great neatness and dexterity by Mr. Lynn. Mr. Lynn is evidently a highly experienced and judicious surgeon, and cannot fail to be sooner or later, appreciated by the public. It is only amazing that the public have not already done greater justice to his merits.

This casual visit I made to the hospital was attended with much pleasure, and I am not ashamed to add, some information. I assure you, Sir, it is quite refreshing to observe the spirit and zeal which now animates the medical officers of the Westminster Hospital. Whether this is attributable to your friendly admonitions, I cannot tell, but the hospital is now evidently much improved, and if its affairs are managed every day as they were conducted last Saturday, it cannot be long ere this school rank among the most celebrated in London, both for the quality and quantity of the instruction it affords.

If the above report is deemed suitable for your excellent Journal, you may make what use of it you think proper.

AN OLD PRACTITIONER.

Westminster, January 2, 1844.

THE THORACIC AND ABDOMINAL VISCERA.

(St. Thomas's Hospital.)

At the last evening Conversazione at St. Thomas's Hospital, which we partly noticed, on Dec. 24, Dr. Hodgkin communicated to the meeting some interesting and original observations, regarding the extent and relative position of the thoracic and abdominal viscera in health and disease. Addressing the audience he said, I confess I feel considerable difficulty at this late hour, in attempting to bring forward the subject announced to be read before you by me this evening; however, I feel that it is due to, and, that I should not be doing justice to my valuable friend, who has entrusted me with this communication, if I did not make a report of his examinations, and the result of his labours to you; and I conceive it is scarcely necessary that I should make any apology for an attempt to treat of the subject of the diagnosis and distinctions of disease, or that I should be considered stepping out of my proper course.

Then, with a view to arrive at a general knowledge of the disease of any part, it is quite obvious that it would be essentially important, that we should know the situation of the parts. We are very often led to suspect that an organ is diseased and when we know its situation, when we distinguish something unusual in the situation of that organ, and as some of the organs are, from their situation, placed out of the reach of sight and touch, it becomes increasingly important that we should call in every assistance in our power to arrive at a knowledge of their situation. Such has been the effort of the gentleman who has communicated to me, the paper of which I shall merely attempt to give you, in outline, the principal facts resulting from his labour and his discoveries. I would not, however, have you suppose that I speak for the first time on this important subject, or that the paper I am communicating to you is the first that has been written on this subject, the situation of the thoracic and abdominal viscera:—I should feel that I should be doing injustice to another valued friend if I did not very briefly allude to the labours of my friend Dr. Edward Harrison, who was one of the first, and the most accomplished of those investigators of the diseases of the chest, who had the great advantage of studying under Laennec, the inventor of the stethescope. The labours of Francis Sibson are very analagous to those of Dr. Edward Harrison, and they are found strongly to confirm each other. Though Dr. Edward Harrison has not published as much as it is to be hoped he will do, you may probably be aware of one important fact which he has pointed out, namely, that the abdominal viscera encroach somewhat more on the organs of respiration than is generally supposed to be the case. I am not by any means stating that all anatomists and practiced observers, have been usually mistaken on this subject; still from the form of the chest they have a greater tendency to occupy a greater portion than probably belongs to them. Dr. Edward Harrison points out one interesting fact among others to which I will just call your attention. Near the roof of the ensiform cartilage or a little above, there is a bulge on the right side almost in the situation of the thick part of the liver. We may consider the abdominal viscera as soft moveable ingesta enclosed in coats, appearing almost like the fluid contents of a bladder, and of a somewhat round figure. Placed in this situation, we have the round form of the full abdomen, then the lower portion of the liver with the thin covering over that, and the ribs again upon it, then the pressure of the muscles, which makes it assume somewhat the form of the rounded abdomen, which will bear some muscular pressure, tending to produce a depression above the thick part of the liver. I will not pursue this subject further, except to observe that Dr. Edw. Harrison has also pointed out the right way of indicating the position of the apex of the heart resting on the diaphragm. I felt interested on this subject from the first, and I now find from some of the antique statues, that some of the ancient sculptors must have been aware of the fact. I have a drawing of a Faun from the Vatican, in which this bulge is distinctly seen. Thus much, I thought, due to Dr. Harrison to preface. My friend Francis Sibson, the house surgeon of the Infirmary at Nottingham has directed his attention in the same direction (though he was previously perfectly ignorant of what Dr. Harrison had done) and he very soon was led to discover the fact that the liver, and the whole of the abdominal viscera somewhat more encroached on the respiratory organs than he suspected. On examining the subject very carefully and investigating the mechanism of inspiration and expiration he noticed some facts which had been observed before, and, therefore, were not totally unknown; but they had not been so generally pointed out as could have been desired. Amongst these he recognised the fact that the lungs ascend considerably higher above the clavicle than was ordinarily supposed, about two or three inches, and dissecting that part, he observed the important use of the Scaleni, as Dr. Williams has very ably shown in his work on the diseases of the chest; and Mr. Sibson has pointed out a small muscle or accessory Scaleni, having a similar origin attached to the external pleura, which covers that portion of the lung. I will not go into the minutiæ of the situation of the pleura which he has pointed out in the cases of emphysema, where the descent of the diaphragm is much lower than usual, so as to be somewhat below the ensiform cartilage occasioning the liver to descend. In cases of pthysis, too, there is an elevation of the pleura of the lungs. In order to ascertain the position of the parts lying beneath the chest, Mr. Sibson has adopted a plan similar to that used by Benjamin West to trace forms and transfer them to paper. It consists of a frame with lines crossing each other at right angles in different directions; this is placed over the object, and upon a piece of paper similarly divided by lines you can make a sketch—though you may not be an artist—sufficiently accurate to determine the situation of the organs. One part of the method was having, by percussion, ascertained the situation of the different organs, to mark them out, and by this means the situation of the viscera became distinctly indicated; and when he came to examine some diseases, such as enlarged heart, or effusion into the pericardium, some very curious results were in this way discovered. Whilst alluding to the situation of the liver, it is worth while to notice a fact observed by this gentleman, and which appears perfectly to accord with what Alex. Shaw has said with respect to the circulation through the liver. In respiration, the descent of the diaphragm was greater than the descent of the lower margin of the liver, serving to show that in the movements of inspiration and expiration the liver must be compressed, and when we consider the character of the circulation, but especially the circulation through this organ, it will at once be perceived this must materially influence the amount of blood in these visceras. This is a very important addition to the researches of Shaw laid before the British Association at the last meeting. It shows that those diseases of the chest that tend to limit the movements of the diaphragm tend to produce diseases of the liver. No part of Mr. Sibson's observations is more important than his remarks relating to the situation of the heart. When it is materially enlarged, its circulation, like in emphysema of the lung and pneumonia, has the effect of depressing the diaphragm pretty generally. When the pericardium is distended, either by inflammatory effusion or secondly, as Mr. F. Sibson sometimes produced, by an artificial dilation after death, there will be produced a more considerable bulge, than by the enlarged heart which occasions a more generally diffused change in the external appearance. We may apply this to cases occurring in the living subjects, that is to say, effusion into the pericardium, making a further extension at stated periods: and Mr. Sibson has observed that the increase of the pericardial effusion, as might naturally be expected, generally increases the extent of the fullness felt on both sides of the sternum, up almost to the clavicle, and lower down depressing the diaphragm much higher than is the case with the enlarged heart; for this reason, that the extent of the fluid is distributed over a greater space, places the lungs apart, increases the separation between the two upper lobes of the lungs and produces a greater elevation of the dull sound than is the case with the enlarged heart. As we trace the progress of the disease we shall find we come to a peculiarity which it is right to observe,—we find a diminution of the fulness; but, after a certain period, a greater increase of the fullness above takes place. This, Mr. Sibson attributes to the very important fact that adhesion has taken place; and when adhesion has taken place between the two surfaces of the pericardium, the amount of dullness is greater, although the space is not large. Then there is another curious fact, which is observable in those cases of adhesive pericardium. I have mentioned the movement increases the ordinary respiration, and naturally extends the resonant portion of the chest, and also affects the non-resonant portion of the chest; therefore, if we take the fullest inspiration, the situation of the dullness will descend, and we have a highly increased amount of resonance above that where the complete adhesion of the pericardium had taken place, and there is not the same amount of motion, and

the dull portion of the chest corresponds to the pericardial adhesion, and corresponds to the region of the heart. I shall now advert to another interesting fact that has come to light in the examination of the movements produced in respiration. Mr. Sibson paid particular attention to the movements of the ribs, and he noticed that whilst there was considerable movement in the lower ribs, there was less separation between the 7th and 11th ribs than the other ribs; and this calls to my recollection a fact I have constantly observed in the numerous inspections that it has been my place to make:—I was considerably struck with the fact, that whenever the cartilages of the ribs are ossified at all, it is almost certain to be the cartilages of the 7th, 8th or 9th ribs. I did not comprehend the cause of this, whether it was disease or not. It appears to me, now, from what Mr. Sibson has pointed out, that there is less mutual movement between these ribs than the others, which seems satisfactorily to account for the cartilages of these ribs being more prone to become ossified than other ribs. Some observations have been made with regard to the situation of the stomach, which is a very important organ for us to ascertain the situation of, more so than appears to be the case at first sight; inasmuch as the situation of the stomach enables us, on the left side, very accurately to determine the situation of the diaphragm, and the situation of the heart above it.

In bringing this paper to a conclusion, I should observe, that Mr. Sibson assures me that the constant repetition of this mode of investigation, and recording the limits of the different organs in this very accurate manner, has had the effect of making him so intimately acquainted with the portions of the organs, as if for a moment the whole of the flesh and the skin of the ribs was removed, he has such familiarity with the situation of the organs as greatly to facilitate his knowledge of their condition. I have no doubt that much of this knowledge will be useful to others. But there is one important reason which has induced me to bring forward this subject, namely, to allude to the fact of the great addition to our knowledge from such researches, and to those made by the *Societé Medicale des Observations* of Paris; their statistical character and their great accuracy in determining disease independently of the important facts thus brought to light, must, undoubtedly, be of great importance. In this way we may hope to arrive at *clairvoyance*—not like that of the advocates of mesmerism, but one easily within the reach of all, and thus arrive at a knowledge, which others have been represented as acquiring through the mystery of the operation of the mesmerisers. It is only by individual application that we can hope to arrive at this most important knowledge—the locality of the organs, and consequently the state, and the amount of disease. Having thus brought before you, in a very imperfect manner the result of a very laborious *suite* of investigations, I cannot conclude without expressing that, as a member of the medical profession, Mr. Sibson is warmly entitled to our encouragement and thanks.

Hairs Growing on the Tongue.—The patient was a medical student, who after complaining for some time of dyspepsia and a *sticky* sensation in the mouth, discovered hairs of considerable length grew from his tongue. They were detached in vomiting, but they grew again, and when the author saw him they were an inch long.—*Dr. Forbes's Review.*

THE CRICHTON INSTITUTION FOR LUNATICS.—DUMFRIES.

We have just received the able and extremely interesting Annual Report of this Asylum. It is ably drawn up by Dr. Browne, the resident physician, and we cannot deny ourselves the pleasure of placing before our readers a few of the more interesting extracts. It appears that the inmates of last year, including the new admissions, numbered 125. Of these 18 were discharged recovered, six were removed, or improved—eight died. This statement leads to the following judicious remarks—

On Asylum Statistics.

The mere numerical results of treatment during the past year, are satisfactory. The proportion of recoveries to admissions is higher, and of deaths to the daily average of inmates, is lower than is generally the case. But such facts must not be received as evidence of the curability or the mortality of the disease. Were they regarded in this light, they would represent the former lower, the latter higher, than they really are. The truth is, that except in cases of extreme poverty, or where the manifestations of derangement are a nuisance or a source of terror, patients are not consigned to public institutions until they are found to be intractable—until the established resources of medicine have been exhausted, and they are regarded as incurable. Asylums have thus become retreats for the confirmed insane, rather than hospitals for the cure of insanity. The higher the rank of life to which the patient belongs, the more protracted is the ordinary treatment, the greater is the repugnance to have recourse to isolation. In private practice, where recent cases are promptly and judiciously treated, the success is great, and ought to be so, seeing that of chronic cases, which have been treated and despaired of, 35 per cent. are, under isolation, restored to comparative sanity. Other circumstances disturb such calculations. The majority of patients enter Asylums infirm, debilitated, diseased; many labour under complaints which are inevitably fatal, a circumstance tending to raise the apparent mortality of the confined insane. Relations often remove patients when dying or in danger, a circumstance which tends to diminish the apparent mortality. The amount of recoveries is, in like manner, not fairly estimated. The standard of sanity held by physicians in charge of the insane, and by which they measure the capacity of individuals who have improved, or are improving, is too high, and abstract, and fluctuating: is not, and cannot be, founded upon a knowledge of the previous mental calibre and character, but is framed from their own notions of what ought to be the sane and healthy state in each case. It will correspond to the intellect and acquirements of the physician, and not to those of the patient. A jury, collected in the ordinary way, would be more competent judges.

The following instances are interesting as illustrative of that too common phase in mental hallucinations—

Suicidal Mania.

That a correct notion may be formed of the ingenuity and reflection exercised at a moment of extreme despair and despondency, and upon the brink of eternity, and of the foresight and attention which are at all times, and under all circumstances, necessary, and which, however well devised and rigid, may be, and will be, frustrated, a few examples of the contrivances resorted to may be given. A young man, a volunteer into our community, was bled by leeches in the temples; a towel was, by the care and kindness of the attendant, bound round his head; he retired to bed, was repeatedly visited by the night-watch, and, upon one occasion, was detected endeavouring to suspend himself by means of the towel to the corner of his bedstead. Another, a well educated person, baffled in his design and effort to arrest respiration, by the small size of the pocket handkerchiefs which are issued, attempts to surprise the attendant engaged in shaving him, by starting suddenly, and forcing up the razor against his throat. A gigantic and powerful man, instigated by the agony of terror, and the impression that he was to be sacrificed, after incessant struggles to destroy himself, and all those around, was found in the act of self-strangulation, although his hands were partially confined in order to prevent the accomplishment of his designs, and although he must have known that he was almost under the immediate supervision of the night guardian. Foiled in this plan, he refused to take food for several months; but discovering that the wants of the system can be supplied by means of the oesophageal tube and feeding funnel, in defiance of the will of the individual; and as we have remarked in similar affections, although willing to endure death, unwilling to endure a disagreeable but transient sensation, he abandoned abstinence as ineffectual, but, at the same time, attempted to break, crunch, and swallow window-glass, with the same design. To meet this combination of distressing symptoms, it has been necessary to associate a supernumerary with the ordinary attendant of the gallery. A young woman possesses herself, while in the airing ground, of stones and pieces of coal, to which she gives angles and sharp edges by rubbing on the walls. She then swallows them thus prepared, and so far succeeds as to obstruct the deglutition of solids for weeks. A lady, long a member of our family, who had won the affections of all who could appreciate her gentleness, or estimate her suffering, passed through the various stages of anxiety, gloom, dejection, until under the promptings of a permanent despair, she seemed to concoct a scheme for self murder, in which every accessible means were to be tried in succession, and of which she spoke with composure, even with mirth, admitting, at such moments, that she had not fortitude to extinguish life suddenly. At first this design may have been suggested by a desire to put her boasted immortality to the test, or to prove it to the sceptics around, for she avers and believes, and there is no faith so sincere, genuine, and steadfast, as that of the insane, that she will not and cannot die; but, subsequently, she became incapable of devising or abiding by any consistent plan, and in refusing food for months, in attempting strangulation and precipitation, she obeyed the ruling impulse of the moment, to escape from exquisite pain. Her determination being known, she was placed in a room, from which every article of furniture was removed—which, in fact, contained nothing more than a French bed, without canopy, and a carpet. Notwithstanding these precautions it was ascertained that she had pulled the carpet from the floor, collected the nails by which it was secured, and swallowed twenty-four of them. She was then removed to another apartment, where there was no carpet, and an attendant was appointed to remain constantly with her. The bed in which she lay was covered with cotton chintz, which was attached to the wood by nails. Stealthily, silently, and without changing her position, or disturbing her companion, she succeeded in extracting a number of these, which were likewise swallowed. Since this period she has stolen and introduced into the stomach a thimble, and a small padlock. But what is even more startling and instructive, is her confession that when comparatively sane and serene, when most trusted, and most worthy of confidence, she was in the habit of devouring stones, pins, needles, and other small objects innumerable, with the settled resolution to sap the foundation of her strength and life.

Recreation of the Insane.

In a country like this, it is natural that industry should be insisted upon as an important agent in the treatment of insanity. But recreation, if well selected, is but occupation of a cheerful and agreeable kind, and has certainly been less systematically employed as a means of cure than it deserves, and than a consideration of the capabilities of the unhinged and unhappy mind could warrant. In accordance with these sentiments, the patients have participated in every public amusement which combined present gratification with prospective benefit, and in which they could mingle without excitement or injury to themselves, or offence or disturbance to others. They have

formed part of the crowds which frequented the rooms of the Exhibition of Paintings and objects of Natural History, indulging each one his own taste or fancy, unnoticed and undistinguished. They have examined and criticised unsparingly specimens of historical painting; one is a member of an Art Union; others have visited the sculptor in his studio. They have witnessed races and regattas. The camera at the Observatory has presented them with a map of Nithsdale, and transported them in fancy to distant and interesting objects, the antiquities or picturesque beauty of which they have at other periods been enabled to inspect by the assistance of the omnibus, which has carried parties to Carlaverock, Newabbey, Lochmaben, Friars' Carse, &c. They have made pedestrian excursions; they have fished in the river. They have been auditors at Concerts for music of various kinds; at lectures upon Temperance. They have been spectators at the Circus; and latterly the Theatre has been an object of great attraction. This predilection has been encouraged for many reasons; but chiefly because the Drama conveys much amusement, and some information, without imposing either sustained mental exertion or attention, supplying pastime without passion, knowledge without study; suggesting truth by means of fiction; and appealing to the happy, the cheerful, and mirthful parts of our nature. Of the correct conduct of those who attended, and of the unobtrusive but evident expression of enjoyment which they gave, their sane companions may speak. At home, concerts, public readings, evening parties, dances, games at bowls, billiards, summer-ice, cards, chess, backgammon, have afforded means of diversifying the dull routine of discipline; although, perhaps, the exhibition of the magic lantern yielded the most unalloyed pleasure, and to the greatest number.

Mental Culture of the Insane.

A determined suicide has been seduced, into temporary forgetfulness of his woes, and afforded an exemption from his purpose while translating Guizot and Vertot, turning from the transcendentalism of the former, to the bald narrative of the latter, as less trying to his powers. Another gentleman, who is omnivorous in reading, and passes over all works with a railroad speed, has been placed in connexion with a book-club that his insatiable appetite may be more readily supplied. Our own small library is in constant circulation, as may be learned from the fact that during the year that has terminated there have been 45 readers, and about 700 issues of volumes or works have been made. These are regular students, and do not include the casual readers, or the triflers over newspapers and periodicals. At one period the following books were in the possession of patients—Thierry History of the Norman Conquest, D'Aubigne's History of the Reformation, Gil Blas, Shakspeare, and many of Sir Walter Scott's novels, &c., a catalogue which shows the varied and elevated tastes which must be supplied, and the identity of the pursuits of many of the insane with those of men of strong intellect and fervid genius. To one of these students a daily task was allotted, and he subjected himself to examination by the medical attendant, in the same way that a course of history should be conducted. Another busied himself in compiling a common-place book; a third translates a treatise upon Dipsomania, ostensibly to facilitate the labours of the Superintendent; a fourth scans the newspapers, and extracts all facts bearing upon a topic of interest; while a fifth actually furnishes to a periodical the creations of his fancy. The more remarkable events of our recent domestic history have been chronicled by an individual whose former literary habits and professional pride are both gratified in officiating as the delineator of what others see and feel, but cannot describe. Indeed so numerous are the educated, the imaginative, and the learned, among our inmates, that an Asylum Annual is contemplated, and in progress. These avocations are not imposed as burdens; they are suggested as recreations; the mind is occupied, not taxed or fatigued. In a case where intemperance had first enfeebled the reason, then prostrated the will before the habit of indulgence, and ultimately swept away the acquisitions and accomplishments of a respectable education, instruction was resorted to as a means of cure. The man who had lost, or, by his own conduct, had obliterated the first elements of knowledge, was taught, and successfully taught to spell, and write, and cypher anew. The effort was made to reconstruct the mind from its own ruins; to restore it stability by giving to it the power to act in new combinations, and independently of the propensities.

Singular Effects of Opium.

Opiates have been administered, less, however, for the purpose of inducing sleep than of subduing restlessness and excitement, of soothing and tranquillising irritation, and of testing the strength and efficacy of different preparations. Some of the drugs were given to such an extent as would startle those who repose confidence in the time-honoured doses of days gone by. The quantities even alarmed those who are accustomed to deal with the singular power of resistance to medicine, which is often a characteristic of insanity, and who are somewhat sceptical as to the boasted influence of hypnotics. The course was, in fact, interrupted from fears that, although no visible effects followed the administration of the dose, it might act detrimentally, although insidiously, upon the nervous structure, as it would certainly upon the organs of assimilation. The patients were directed to take what was ordered in the morning, as it is always difficult to ascertain whether, or how long, or how soundly a lunatic has slept during the night, as the repeated visits of the night-watch, by which this could be done, disturb the patient and dispel the inclination to slumber, and effectually neutralize whatever sedative property the medicine may possess. It was further necessary to watch for other effects, and to detect any drowsiness, or lethargy, or sickness, or increased tranquillity, which might exist, and which might fairly be attributed to the narcotic. This plan put the property to a severe test, as the light, noise, society and occupation among which the subject of experiment must unavoidably be placed, act in direct opposition to the tendency expected to be induced, and with great energy in temperaments so vivacious and inflammable as generally accompany insanity. There are likewise grounds for supposing that the habit of taking rest at particular hours, the periodicity of the system, contribute much in insuring the efficacy of opiates administered in the evening, as well as the contemporary exhaustion from exercise, the darkness, silence, and solitude. But after making all necessary and reasonable allowance and deduction for these antagonist circumstances, it has occasioned surprise that, whatever the dose given, sleep has scarcely ever followed. Other effects, and these very marked, have been traced; but although triple, quadruple, in some cases six times, the amount of the ordinary dose, neither drowsiness nor sleep have been observed. But the facts that patients who were active and lively, presented dilatation of the pupil, could not read print of an ordinary size, heard dully and imperfectly, and appeared to have neither taste nor smell, seem to indicate that the narcotics used have a special and, it may be, unobserved effect upon the nervous system, apart from, and altogether independent of the production of sleep. Here was the system saturated with henbane, opium, pervigilium persisting, while there was proof, that a powerful impression had been produced. Further, the resistance to the influence of narcotics does not seem necessarily to depend upon the presence of that excitement, or irritation, or orgasm of the nervous system, causing, or coincident with furious mania; for in many of the cases tried, beyond the existence of one delusion, that system might be considered in a natural and healthy state.

The Dreams of the Insane.

We are not content with this investigation into all the minor habits and characteristics of the insane inmates; but where the patient does sleep, we follow him into his secret thoughts, into his very dreams. A record has been regularly kept of all remarkable dreams, phantasies, and visions, which have made so deep an impression as to influence the conduct of the individual, which have excited some powerful emotion at the time, or have been afterwards communicated. Latterly, certain patients have been selected for observation who are of marked character, whose habitual trains of thought are well known, and who spontaneously or willingly describe their feelings; their confidence is sought and secured, and the disclosures of every night are carefully preserved. This scheme has been adopted for the purpose of determining how far the night-dream corresponded with the day delusion; whether the events of the day exercised a similar power over the insane as they are believed to do over the sane, and to what extent the mind is rational and responsible during sleep, somnambulism, and those states between sleeping and waking. The enquiry was new, and has led to a collection of most interesting and extraordinary information as to the laws of association during sleep, which cannot be discussed here. It has established, so far as it goes, the identity of the dream with the delusion, showing that the current of morbid thought flows on uninterruptedly through the agitation and the vivid impressions of the day, and the quiet and repose of the night. In some instances, it appears that previous acts and feelings enter into, and colour and direct the dream. Thus, immediately after one of our festive meetings, the visions of one of the party is found to contain a picture of glittering and gorgeous dresses; and of another to display a dance performed by the wives of the Goths and Vandals in St. Paul's Cathedral. Much more frequently the dream, regarded as a reality, moulds and modifies the conceptions and delusions of the waking state. Thus one man is persuaded that he is destroyed by magnetism, silent combustion, and complains to the authorities that attempts are made upon his life; a second dreams that he is possessed of corn and wine, and oil, and distributes them next day; a third that he saw the books of the nation in the hands of the Lord Chancellor, and that a long black stroke was drawn across the national debt; and in the morning he announces that he is about to pay it. It is as difficult to convey any adequate notion of the extravagance, the grotesqueness, and sometimes the splendour of these reveries, as to follow the unsound mind through all its waywardness and wanderings; but it is consolatory to discover that the prevailing characteristics are pleasure and happiness. Of about seventy dreams detailed with great minuteness, four either owed their origin or their predominating features to fear; seventeen to the gratification of some sense, or the realization of some hope, wish, or ambition; four sprung from re-awakened affection or humanity; three were occupied with political triumphs; three were disturbed by anger; nine were tinged with the harmless superstitions of early days; five seemed to be the offspring of vanity; two of pride; seven of suspicion; nine of avarice or the desire of aggrandisement; three were busied with martial pomp and glory; and three with the more peaceful operations of the farm; and of the total number, whether pure creations of imagination or indistinct and distorted recollections of past events, not above fifteen could be regarded as giving pain or suffering, and as calling for sympathy.

THE LATE ACTIONS IN THE COURT OF COMMON PLEAS.

(To the Editor of the Medical Times.)

SIR,—Allow me, through the medium of your journal, to draw the attention of the members of the medical profession to the anomalous and unjustifiable verdicts recently returned in two actions tried in the Common Pleas. The plaintiff, in both instances, was a person of the name of Beale, residing at Stepney,—the defendants, medical men, practising in the neighbourhood. I gather many facts from the evidence adduced, and glean from that, that the plaintiff was not entitled to a verdict legally, "upon my honour." The action was for slander. The plaintiff, Beale, it appears, was originally a dissecting-room beadle at the Aldersgate School of Anatomy, under Mr. Tyrrell, at a salary at from 20s. to 30s. per week, in which capacity he distinguished himself by the neatness

with which he injected the bodies for the use of the students. Having a soul above buttons, he solicited Mr. Tyrrell's permission to attend his lectures, with the avowed object of following the profession at some future time—a request that was most graciously accorded by the surgeon of St. Thomas's. He was also at one time connected with the school at the London Hospital, in the same capacity as at the Aldersgate, or, as Mr. Merritt states, he was curator in the museum, the office bearing the additional titles of dissecting-room beadle, and assistant to the lecturer. Mr. Beale, for having been admitted to attend lectures by the professors, we suppose we must call him Mr. ——, now settled in practice at Stepney, and managed to pass the examination at the College of Surgeons, in July, 1841. In the month of December of the past year, he was called in to attend a Mrs. Neele, whose family he had attended for several years. She was laboring under inflammation of the bowels, caused, it is said, by a twisting of the gut, of which she died nine days after the attack commenced. A medical practitioner in the neighbourhood, named Self, conceiving the case had been mistreated, feeling indignant at the mode in which Mr. Beale had entered the profession, and perhaps annoyed by losing some of his patients, caused an inquest to be held, when a verdict of natural death was returned. The words charged as libellous were uttered by Mr. Self, to a patient of his, who had signified her intention of employing Mr. Beale, not because she was dissatisfied with Mr. Self, but because her friends had pressed her to send for Mr. Beale. The remark made was, that Mr. Beale was an unqualified practitioner, and liable to be prosecuted daily, while a further implication was made, that Mrs. Neele had been mistreated by him, and that he was only a dissecting-room porter. On this charge the jury returned a verdict, awarding £100 damages.

Now let us see how far the evidence sustains the verdict: and first, as to the statement, that Mr. Beale is an unqualified practitioner. At the trial of the action, his counsel put in the diploma of the College of Surgeons, and it was not denied that he was a member of that learned body, the diploma of which, he obtained several years after he had commenced practice. But the licence of the Worshipful Society of Apothecaries, according to the newspaper report, was not produced, and one of his own witnesses stated on oath, that he had been told, that an action was pending, which had been brought by the Company against Mr. Beale, for practising without their licence. It is fair to presume then, that the plaintiff had not passed the examination at the Hall, more especially as his advisers learned in the law would certainly have produced the certificate, if he had it, as it is the ONLY LEGAL PROOF a general practitioner can possess of his medical qualifications. It has been proved over and over again, that the diploma of the college will not qualify for practice: the general practitioner must have the certificate of the society, or have been in practice before August 12th, 1815, or he is an unqualified practitioner. If then, as I presume, Mr. Beale had not the license to practice from the Apothecaries' Company in his possession, Mr. Self was right in describing him as "an unqualified practitioner, liable to be prosecuted daily," and as such, Mr. Self was entitled to a verdict on that count. Indeed, as an unqualified practitioner, supposing my postulate correct, Mr. Beale was not entitled to bring an action at all, inasmuch as he had no *locus standi*. Being unqualified, he was not a medical practitioner, for, although a member of the College of Surgeons, yet as he practiced a branch of the profession for which he had not authority, he was decidedly out of the pale or protection of the law. The case, too, was a medical one, and required a medical man, not a mere surgeon, to treat. So far then the verdict was unjust and contrary to law—two positions not always consentaneous.

Another statement made by Mr. Self was, that Mr. Beale was a dissecting-room porter. This averment was fully borne out by the plaintiff's own witnesses, Messrs. Merritt and Tyrrell, gentlemen attached to the school where Mr. Beale had been engaged; indeed the latter gentleman tells us, to him was it owing that Beale was enabled to cast off his slough, and appear in Stepney as the practitioner of medicine and surgery. Thus far then, have the statements made by Mr. Self been fully borne out.

We come now to a more important charge, that of *mala praxis*—a statement requiring serious consideration. We shall take our evidence in this instance, also from the plaintiff's witnesses, and we must rely almost solely on the medical testimony. It appears, that Mrs. Neele labored under inflammation of the bowels, caused either by intussusception, or internal strangulation, for on that point the statements made are rather undecided, Mr. Farrer, a surgeon, who was called in by Mr. Beale to his assistance, distinctly stated, that if a greater number of leeches had been applied, the deceased would have had a better chance. If the patient had not got better, he, Mr. Farrer, would have bled her till some degree of faintness was produced. To relieve the inflammatory symptoms it appears Mr. Beale ordered only six leeches, and in this he was supported by the evidence tendered in court by Messrs. Tyrrell and Aston Key, who stated, that the application of 30 or 40 leeches would have endangered life. One of these gentlemen made the remark, that when the blood was once abstracted, it could not be replaced. Without stopping to comment on this absurd and *ad captandum* remark, that the blood could not be replaced, we would ask these surgeons if they would be content with applying six leeches to a case of abdominal inflammation, following an operation for lithotomy or hernia? Or, whether they deem that traumatic inflammation requires more energetic treatment than the idiopathic variety? We are well assured, that such milk-and-water practice, would not be adopted by them in their own practice, and if so they have no right to come forward in a court of law, and defend it in another. As Mr. Farren conscientiously remarked "if a greater number of leeches had been applied, the deceased would have had a better chance;" on this consideration then, we believe Mr. Self was entitled to a verdict, or at the very utmost, a farthing damages only was required.

In spite of all this, in the teeth of the facts that Mr. Beale had entered as it were surreptitiously into the profession, of which he was for a long time an utterly unqualified member, and is still legally so,—that he had been, as was most truly alleged, a dissecting-room porter, and that his own witnesses showed he had not only neglected his patient, but had not treated her with the vigor and decision which he should have used, the jury returned a verdict for the plaintiff, with £100 damages; thus affirming the fact, now first admitted, and constituting a most dangerous precedent, that a man legally unqualified to practice, may sustain an action for remarks against his professional character, and recover heavy damages. In fact, he has been declared by this jury to be entitled to all the privileges hitherto accorded to qualified and certificated member of the profession only.

There are other facts connected with this subject, to which, with your permission, I will advert on a future occasion.

I am, Sir,
Your obedient servant
F.

London, Dec 26, 1842.

[We have but one remark to append to this note. The uprise of Mr. Beale—nothing dishonourable being proved against him—is entirely to his credit. On the other points raised by our correspondent, our readers must be left to form their own opinions.—Ed.]

ON THE DECIDUA REFLEXA AND THE DECIDUAL CAVITY.

By R. LEE, M.D., F.R.S.

On the 10th of March, 1822, a young woman, who was in the second month of pregnancy, poisoned herself with oxalic acid. The uterus had acquired double the size which it usually exhibits in the unimpregnated state. It was five inches long, three and a half in the greatest lateral direction, and two inches in the antero posterior diameter. A longitudinal incision was carried down the middle of the posterior surface, crossed by a transverse one parallel to the entry of the fallopian tubes. The thickness of the parietes of the uterus, though greater than in the unimpregnated state, were not proportionate to the general increase in the dimensions of the organ; they were four lines at the fundus, and six lines at the cervix, gradually increasing towards that part: the chief difference was observable in the already enlarged size of the uterine venous sinuses. The deciduous membrane, which closely adhered to the inner surface of the uterus, was then laid open by two incisions parallel with the longitudinal and transverse incisions previously made in the parietes of the uterus. The cavity of the uterus being exposed, the ovum, about the size of a pullet's egg, came into view, and was observed to be situated towards the lower part of the uterus. It was lodged entirely in the cavity of the body of the uterus, and no part of it extended into the cervix. The part of the cavity to which it adhered was included beween two parallel lines, drawn, the one transversely across the uterus at the distance of half an inch below the entry of the fallopian tubes, the other at two inches distance from the os tincæ: consequently, the ovum was situated altogether below the entry of the fallopian tubes, and was unattached both at its upper and lower part, leaving a free space or canal between it and the os tincæ, corresponding to the shape of the elongated cervix and a much larger cavity, which was the decidual cavity, between the upper part of the ovum and the fundus uteri. Intervening between the superior and unattached surface of the ovum and fundus uteri was a broad cavity, measuring three inches in the lateral, and one and a half in the antero-posterior diameter, and which appeared at first only a few lines in depth, but on further inspection was ascertained to be nearly two inches in depth. The upper concave surface of the cavity formed by the decidua lining the fundus uteri, or uterine decidua, was irregular, and slightly reticulated. The inferior convex surface formed by the decidua covering the villi of the chorion, or decidua reflexa, was perfectly smooth, resembling somewhat the external serous surface of the uterus. On examining this with a magnifier, numerous small elliptical openings were seen in every part of the membrane. Into this large cavity, between the decidua reflexa and the decidua vera, the fallopian tubes opened by palpable orifices; that on the left side, by which the ovum had entered the uterus, being rather more than a line in a diameter; that in the right rather less. The cavity thus formed between the decidua lining the fundus uteri, and the decidua covering the upper and unattached portion of the ovum, or decidua reflexa, was filled with a red-coloured serous fluid. The ovum was next laid open by an incision through the chorion parallel with the longitudinal incision of the uterus, and the amnion enclosing the embryo was brought into view. The placenta was situated principally over the cervix and posterior part of the uterus, and the decidua, closely adhering to the placenta, passed across the upper part of the cervix uteri in the form of a thick reticular membrane. The decidua was then observed to extend upwards between the uterus and chorion, every where firmly connecting these together as high as the entrance of the fallopian tubes. From this point the deciduous membrane was spread out in two different directions—viz. over the upper convex and unattached surface of the ovum to form the uterine decidua. Between these membranes was the decidual cavity into which the fallopian tubes freely opened. If you examine this gravid uterus of two months, you will see the chorion and amnion enclosing the embryo, and umbilical cord,

and the placenta covered with its decidua, adhering all around to the upper part of the neck of the uterus. You will also see clearly that the decidua reflexa lies entirely above the villi of the chorion, on that side of the ovum where the placenta does not exist, and the ovum is not attached to the uterus. In all the diagrams from Dr. Hunter, Wagner, and all other anatomists, which you have seen, the placenta has invariably been represented as adhering to the fundus uteri, and the decidua reflexa has been situated near the cervix, and appearing as it mechanically depressed or pushed down before the chorion or ovum. But in this preparation it is obvious that the decidua reflexa could not have been pushed down before the ovum, because it lies above or covers the ovum—the ovum lies between the decidua reflexa and the cervix uteri—and as the ovum enlarged, the decidua reflexa must have been forced upward to the fundus uteri, which was lined with the decidua vera, instead of downward to the cervix. The decidual cavity is, you observe at the fundus uteri, above the ovum, and both fallopian tubes open into this cavity by palpable orifices. Instead of being covered with the uterine decidua, this membrane passes into them, and they are left completely pervious, so that no membrane existed which the ovum could mechanically push before it. I am not aware of the existence of any other specimen of the gravid uterus at so early a period, in which the placenta is adherent to the neck of the uterus, and the decidua reflexa is placed above the villi of the chorion, or that part of the ovum which is not attached to the uterus; but it is impossible to doubt that in all cases of placental presentation in the early months, the decidua reflexa completely invests the villi of the chorion, and that the decidual cavity is situated at the fundus of the uterus. If the statements of the authors above alluded to, and the generally received opinions respecting the formation of the decidua reflexa were well founded, it would follow that in all cases the ovum would attach itself to the uterus by the placenta, either directly over the edges of the fallopian tubes, through which it had descended, or to its immediate vicinity and that the deciduous membrane would never be found interposed between the uterus and placenta as it invariably is. The facts which have now been adduced and will hereafter be stated demonstrate that the fallopian tubes are open in the early months of gestation, that the ovum may attach itself by the placenta to the fundus body, or cervix uteri, and that the deciduous membrane forms neither a shut sac nor inorganic layer, prior or subsequent to the arival of the ovum in the cavity of the uterus. These circumstances are also strictly in accordance with the fact, that when the ovum can first be perceived, it lies loosely embedded in the soft flocculent, albuminous matter which, at this period, coats the inner surface of the uterus, and that this pulpy semifluid matter becomes gradually converted into those delicate organised membranous layers by which the attachment of the ovum to the uterus is so firmly secured, and the most important function of the ovum performed during the whole period of pregnancy. The albuminous substance interposed between the uterus and chorion becomes the decidua uteri, or decidua vera, while the albuminous matter which envelopes the unattached hemisphere of the ovum becomes the decidua reflexa. To whatever part of the uterus the ovum adheres by the placenta, its relation to the deciduous membranes will be the same, the uterine decidua forming the connecting membrane between the ovum and uterus, and the decidua reflexa covering only that part of the chorion which hangs loose within the cavity of the uterus. Dr. William Hunter offered no explanation of the manner in which the decidua reflexa is formed, and Dr. Baillie, who completed his description of the gravid uterus and its contents, says, that the manner in which the decidua envelopes the ovum has never yet been observed, and therefore can only be a subject of conjecture. The most probable supposition is, that the ovum passes from the ovarium into the cavity of the uterus, while the coagulable lymph is pouring out by the arteries of the uterus, which is afterwards changed into decidua. "One can hardly imagine," he says, "that the ovum should make its way into a membrane which is already formed, and, though tender, yet capable of some degree of resistance.—*Med. Gaz.*

PENCILLINGS OF FOREIGN MEDICAL MEN.

(Prepared from German sources, for the 'Medical Times.')

DR. SAMUEL THOMAS VON SOEMMERING.—Honoured by the first men of his age, recognised as an anatomist and physiologist of the first rank, renowned as one of the most fertile authors of Germany, loved by every one who approached him—Soemmering deserves to be ranked amongst the greatest men of the present time. The day when he celebrated the fiftieth year of his doctorial dignity, was a festival day for the whole of Germany, proving that even our age is not ungrateful to real merit.

Soemmering, born 28th January, 1755, at Thorn, in Prussia, was the son of Dr. John Thomas, who lived at that place as a practitioner and city physician, and whom the young lad accompanied at an early age to *post mortem* examinations, and thence probably imbibed his ardent love for anatomy, which branch of science he soon seized with an earnest grasp, which did not relax until his death. Instructed at the College (Gymnasium) of his native town by superior teachers and professors, he acquired a very extensive range of knowledge, and became imbued with that real love of science, which is so splendidly exhibited in all his works. Thus prepared, he went to the University of Göttingen, where he enjoyed the instruction of Wriesberg and Baldinger, and also became one of the first pupils of Blumenbach, who then had just entered on his career as a junior professor, and was still destined (the Nestor of German Natural Philosophers) to outlive his young pupil. Here not only with great promise, but even with great honour he concluded his academic career. It was not very long before, that Camper had complained to Albin, that there did not exist an accurate description of the connexion between the brain and the nerves. Soemmering endeavoured to accomplish that, which two such great professors of anatomy had pronounced to be a desideratum, and with what skill he did it, his inaugural dissertation, which he defended on the 7th of April, 1778, at Gottingen, sufficiently proves. It is entitled—De basi encephali et originibus nervorum cranio egredentium. The fame of this work and its author soon spread over Europe, and when, subsequently, Vicq d'Azyr published his description and tables of the brain, he resolved to adorn his work with some of the figures of Soemmering, as it was impossible to find anything more perfect in their way. He early acquired that indispensable art for the anatomists, of figuring his discoveries truly and instructively to a high degree, and the three plates which accompany his work, are drawn by himself after nature.

Having obtained the academic laurels in a manner most honourable, he undertook a journey to England; attended at Edinburgh the anatomical courses of Alexander Thomas; when he also devoted much time to preparations, especially to the injection of the lymphatic veins. At London he especially followed the lectures of John and William Hunter. Having thus profited during two years by the lessons of men, the most conspicuous for their researches and original ideas, he returned by way of Holland to Germany; and obtained, in 1799, the professorship of anatomy at the Collegium Carolinum of Hesse Cassell. During his passing through Holland, he stayed at Franeeker with P. Camper, who received him like a father—gave him quarters in his own house—and left him the free use of his collections and drawings. It is easy to imagine, what beneficial influence on the young mind the confidential intercourse of a man, equally conspicuous as an anatomist as well as a statesman, must have produced. The days passed away so usefully and charmingly, that their recollection was never erased from the memory of Soemmering.

Although the position which he occupied at Cassel was by no means adequate to his great talent, it still afforded him the opportunity of being able to devote himself entirely to his favourite studies. This period of his life is to be considered as that where, with unrelaxed assiduity and great genius, he built up from all he had hitherto learned one great whole, and thus prepared all which he afterwards put into such masterly execution. On occasion of the installation of a new anatomical theatre, he drew public attention to the lymphatic vessels then entirely neglected.

In 1787, Soemmering was called to the newly-erected University of Mentz, and thus may be said to have stept on a stage worthy of him. Here he lived surrounded by men the most scientific; here his unceasing activity was acknowledged and honoured, and he found himself surrounded by disciples, who eagerly received his precepts, ready to propagate them over the world. This enviable position stimulated him to the publication of several important works. He enriched comparative anatomy by his treatise on the difference of the negro from the European, which he dedicated to his friend George Forster, the great traveller, with whom he had been intimate at Cassell. His next work was on the brain and the spinal chord, in which he described the situation of those mysterious organs with an accuracy then unrivalled. But the main work, towards which all the endeavours of Soemmering were now converging, was one comprising the whole body of anatomical science, which, moreover, combining anatomy and physiology into one common centre, should propound all the doctrines on the structure of the human body. In this work (Vom Baue des menschlichen Korpers), he divided the general axioms from the especial facts and data, and thus became the founder of general anatomy. He therein communicated many new views and discoveries in the different departments of the science. Thus in osteology he stated interesting facts on the difference of bones in different nations, sexes, and ages, dilated on the use of the absorbent vessels in the formation of bones, and added an important inquiry on the teeth. In his "angiology" we admire his classic description of the heart, and Soemmering was the first who stated that there are scarcely any nerves reaching into its substance. In the chapter on the circulation, he states the agencies, which, besides the impulse of the heart, move the blood onwards, and his description of the lymphatic vessels is first rate. But the ne plus ultra of an anatomic description, is that of the brain and nerves. Five years after these volumes had appeared, he published his work on the intestines, in which he dilated on the use of the lungs in the formation of uniform animal heat, explains the formation of sound in speech, and gave a masterly description of the peritoneum and all its appendages. During the time that Soemmering was pursuing these peaceful occupations, the French revolution broke out, threatening to disturb the quiet he had hitherto enjoyed.

But the benign power, who had previously brought him amongst a circle of loving friends, promised him also a solace in this momentous catastrophe. Our stern professor led, in the year 1792, to the hymeneal altar, Miss Margaretta Grunlius, the daughter of a rich merchant at Frankfort, a lady of mild temper, and most promising qualities of mind.

(To be concluded in our next.)

DRS. DICKSON AND FORBES.

(To the Editor of the 'Medical Times.')

SIR,—Will you do me the favour to allow me, through the medium of your pages, to administer a little wholesome castigation to Dr. John Forbes, of the *British and Foreign Medical Review* notoriety? In the present January number of that periodical, Dr. Forbes pretends to review the second edition of my "Fallacies of the Faculty." The first quotation he makes from my volume, in his *fifth* page, is a misquotation—the first quotation in his *second* page is a misquotation—at the bottom of his *third* page is the following false insinuation:—"Curved spine, which Stromeyer and a few other insignificant schoolmen have attributed to paralysis of certain sets of muscles, is also in the opinion of Dr. Dickson, a remittent affection." Certainly at the commencement,

it is a remittent affection, but not only do I distinctly state it to be of a paralytic nature, but I claim to myself the discovery of that fact, and if Dr. Forbes chooses to appeal to dates, I will prove to the world that Stromeyer and his other schoolmen have only followed in my wake.

As a specimen of the mis-quotations I have noticed in this review, take the following:—in the original the sentence stands thus—"Like every other remedial agent it (iodine) cuts two ways—atomically *attracting* or lessening volume and secretion in one case—atomically *repelling* or increasing both in another, according to the electric state of the individual body for which it may be prescribed." In the mis-quotation "anatomically" is substituted in *both* instances for "atomically!" Dr. Forbes asks if this be not stark staring nonsense. I answer certainly; but it is his nonsense, not mine. Perhaps he will ascribe these and the other mis-quotations to the printer's devil: five mis-quotations at least in a review of six pages! Such a course was worthy the plagiarist of Dr. Payne. Yet he, Dr. Forbes, has the impudence to tell his readers "We have done justice to his (Dr. Dickson's) doctrines, by giving them and the proofs in his own language!" He concludes his review by asking "has not Dr. Dickson made an ass of himself?" In return for which piece of politeness I ask you, Mr. Editor, if Dr. Forbes has not made a knave of himself? Dr. Forbes is a royal physician, so is Dr. Holland. Perhaps it is by way of revenge for my having defeated Dr. Holland's ingenious attempt to appropriate to himself my doctrines, that his friend and coadjutor, Dr. Forbes, now does his best, by an equally ingenious device, to stifle their truth. The world will doubtless cry "Arcades ambo!"

I remain, Sir,
Your most obed. servt.
J. Dickson.

Clarges Street, January 3. 1843.

ROUGH REPORTS FROM GUY'S.

Tumour.—Ann Hall, Æt. 20, was admitted into Guy's Hospital, under Mr. Aston Key, Nov. 29th, 1842. She is a strong, stout girl, dark hair, and ruddy complexion: her habits of life good, has lived in the country,—occasionally troubled with sick headache. When she was born, the tumour was about the size of a pea; since that time, it has become gradually larger, but did not increase in size *very* perceptibly till she had attained the age of 16: since which time it has been rapidly increasing. It is now the size of a large walnut, and occasionally obstructs the vision, by falling, &c. Has had leeches applied, but no other means tried. A tumour about the size of a large walnut, situate over the external angular process of the frontal bone, beneath the orbicularis muscle of the right side, extending inwards half across the superciliary ridge, and also somewhat outward on the temple. Encysted, soft and pappy, to the feel,—no pain upon pressure. It contained some fluid matter, which was of a *cheesy* character. The tumour was removed by an incision made two inches in length, from the middle of the eyebrow to the outer part of the tumour. The whole was then turned out from the adjacent parts with scarcely any bleeding. Cold water dressing for 3 hours; after that time a piece of lint, dipped in Tn. Benz. Co. was laid over the part, (in which there were two very fine sutures,) and warm water dressing.—Dec, 2d.: The outer part suppurating, poultice was applied.—Dec. 3d.: The sutures were removed, the whole having adhered, with the exception of a small point at the outer part, which was suppurating.—Dec. 9: The whole has united, and scarcely any mark left.

Revival after Freezing.—In the winter of 1828-9 in Iceland, Gaimard found that toads could be completely frozen, so that ice lay in small pieces between their muscles, their bodies became quite hard, stiff, and motionless, broke easily and without any effusion of blood, so that, in short, every trace of life disappeared, and yet in ten or twelve minutes they could be revived by immersing them in very slightly warmed water. If they were too quickly frozen they did not revive.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 173. Vol. VII. LONDON, SATURDAY, JANUARY 14, 1843. PRICE FOURPENCE. STAMPED EDITION, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

(LECTURE IV., Delivered December 9, 1842.)

Gentlemen,—I have now to bring before you some remarks respecting *Hydrocephalus*, and then to go on to notice some convulsive diseases. I have often watched a case of hydrocephalus with the same kind of interest as I have watched the most delicate philosophical experiment; and so far is it from being true, that that which is physiological is not useful in actual practice, that I should say it is totally impossible to view a case of hydrocephalus, with the degree of interest which it ought always to excite, without being physiologists. You remember what I said in the former lecture; namely, that diseases of the head in children are to be divided into—those that are tuberculous in their character; those of the nature of the water-stroke, following scarlatina; and the hydrocephaloid diseases, as I ventured to denominate that state of things that comes on in cases of exhaustion, and which we may assimilate to hydrocephaloid diseases arising from disordered states of the intestines. With regard to inflammation of the bronchi and hydrocephalus, I believe that one is to be compared to acute disease, and the other to insidious disease, and they must be described together, because their symptoms are so similar, that there is scarcely any difference between them; it only being, with regard to the first, the suddenness with which the symptoms come on; and if I were to make a distinction between them, it would involve a great deal of repetition.

Now, with regard to the causes of inflammation in the head, in children. You remember, in the last lecture, I adverted particularly to a fall or a blow. Many a fall or a blow has happened to a child through the carelessness of its nurse, or any other cause, which are never made known to the friends or the parents, or to the medical practitioner. Well, but a blow is likely to induce a serious malady, and I believe it is almost invariably the case that there is violent vomiting, persistent vomiting; and I make this remark to call your attention once more to the important symptoms of vomiting. If you are called to attend a child, and the child is affected with vomiting, and you cannot subdue it by attention to the diet or the state of the bowels, you may suspect that there is inflammation, than which there cannot be a more important admonitory piece of advice.

Now with regard to the symptoms to be noticed in the case of an acute inflammation, or in the case of a slower disease; the tuberculous hydrocephalus. The very first symptom of all is a pain, which the individual cannot express by words; but there is an expression of pain in the countenances of children which, if you are watchful and observant of it, you may learn to read it in their countenances. The child, you perceive, becomes irritable, fretful, and is cross; and these are very important symptoms—for a child is never fretful without a reason: of course there may be many other causes of fretfulness, but very often fretfulness is the very first symptom of hydrocephalus. And why?—Because it is in children similar to the expression of pain of adults. There is another kind of language written on the countenance, in which it is impossible for an observer to be mistaken. The child is still disturbed, and the eye of the child you see is contracted, particularly if it be taken to the light: for in the first stage of hydrocephalus there is more or less of abhorrence of light; the child is also disturbed by noises, and there is an abhorrence of noise. Very often you can prove the sense of touch, by passing your finger along the skin. In the first stage of hydrocephalus, you have these symptoms, all arising from undue excitement of the brain. In the first stage of hydrocephalus, or inflammation within the head, you have this series of symptoms, all which arise from undue excitement in the centre of the cerebral system:—The child cannot sleep at night; it is in a state of half dosing during the day, and with this half dosing state—which is neither more nor less than a dislike to be disturbed—with these symptoms arising from undue excitement, there is another symptom. I have been hitherto speaking of those symptoms that relate to the cerebral system, but the next class are those that relate to the true spinal.

What are the symptoms relating to the true spinal system? I have already alluded to the subject of vomiting, but there are symptoms connected with the true spinal system whenever you have paroxysms of vomiting, which you may suppose to arise from some inflammatory or tuberculous disease going on, and you may always infer that there is tuberculous inflammation going on. There are other symptoms: for instance—we have the contracted pupil. I need hardly remind you of what you often see when a child is exposed suddenly to a glare of light. There is another symptom which you cannot have failed to observe, namely, *strabismus*. The child does not see what it is apparently looking at; the object may be drawn backwards and forwards, and in an opposite direction, and still there is the state of strabismus; and the symptom I have watched very often, is that arising from some affection of the pathetic trochlear's muscle of the eye, causing the rocking motion of the eye. All these are true spinal symptoms. I need hardly tell you, that the eye is an organ in which all the symptoms are true spinal symptoms. Any organ of the body may be affected in the same manner; for instance—nothing is so familiar as to see the toe drawn into the sole of the foot, and the foot entirely drawn back by the contraction of the gastrocnemii muscles. All these symptoms are connected with the true spinal system.

Then, in the first stage of hydrocephalus what have we? Undue excitement of the cerebral system, and undue excitement of the spinal system. By the bye, with regard to the symptom of vomiting, it is very often mentioned as one of the first symptoms of hydrocephalus. Now this statement is both true and false. In the first place it is true, because one of the first symptoms I have met with in hydrocephalus has been an attack of vomiting; but in other cases of hydrocephalus there have been other symptoms that have not been observed. Vomiting cannot fail to be observed. The child is restless and irritable from want of sleep; all this may pass unobserved, it is ascribed to the stomach and fretfulness. But it should be borne in mind that almost all these symptoms precede an attack of vomiting, because the excitement of the cerebral system precedes the excitement of the true spinal system. It may be said that the first stage of hydrocephalus is denoted by undue excitement of the cerebral system, and undue excitement of the true spinal system. The disease varies. Where the inflammation is more acute the disease is tuberculous affection within the cranium, and where it is an insidious and slowly formed disease there is a total change in the phenomena from over excitement to undue excitement—restlessness and wakefulness become stupor and coma; sometimes the symptoms are spasmodic, and very often there is paralysis.

What then are the symptoms which characterise the second stage of hydrocephalus? You have only to run over in your own mind the rule I have laid down, and you have then a sort of mnemonic, which, if you bear it in mind, will always enable you to go over every symptom, and consider what are the changes. For instance, the expression of pain; there is now a total vacancy of countenance, there was a deficiency of sleep, with a restlessness at night, and now there is coma or stupor, night and day. There was intolerance of light—now there is blindness; there was intolerance of hearing—now there is deafness. The child is in a state of undue excitement or inexcitability, and all the senses are benumbed. This state of coma obscures even other pains; for I have seen repeatedly in the countenance of an infant just such a contraction of the features as denotes the coming on of this state when all other pains have subsided, and when the child is in this state, pain is scarcely felt, and is never expressed in the natural way, so as to give the idea that there was any pain. There is an utter insensibility, or general state of the senses; stupor, or coma, and fretfulness all take place.

Besides these symptoms that may be said to be from undue excitement of the cerebral system, there are other symptoms connected with the true spinal system; for it is in this stage of the disease that you have, more than in any other, the phenomena connected with the true spinal system. Now the pupil of the eye is dilated. There are two stages of the gaping eye. In one stage, if you take a feather and pass it over the eye-lash it closes; in the second stage, it does not close. You see, then, that in the first part of the second stage, the eyelid may be still closed if you touch the eyelash; but, that in the first or third stage, the gaping eye is not closed when you touch the eyelash, the pupil being permanently dilated; but still, if you approach the light the pupil is contractile, and the eyelid will also close. But, when the eyelid no longer closes and you touch the eyelash, you will see that at that moment the pupil ceases to be contractile, if you bring the light near it: the eye still gapes. In regard to all the true spinal symptoms they all also remain. The strabismus is tenfold, and there is contraction of the hand.

One remark I have to make, and that is this:—In hydrocephalus you do not have paralysis, but in inflammation you have it very often, and the reason is this, that in inflammation you have suffusion into the substance of the brain, and the paralysis occurs opposite to the side affected, whereas in hydrocephalus you have only a dilated state of the ventricle pressing on the brain generally, and which does *not in* general produce paralysis, though it does produce spasmodic actions. You recollect a case of pressure on the medulla oblongata which produced convulsions, and there is a case related by Dr. Abercrombie in which it produced spasmodic action. There is a case I did not mention, a case that completes the category, and was seen by my friend, Mr. Evans, of Hampstead. The case was one in which the child was laid on its back, and the pressure

on the fontanelle invariably produced a state of spasmodic action. This is important to remember, because a child should never be laid in that position.

Paralysis arises from injury. In a case I have lately attended, with my friend Mr. Barton, the child was thrown down by a horse, and its head fell against the curbstone, and from that time there were the regular symptoms of inflammation of the brain, there was vomiting, and also paralysis on one side of the body. I concluded there was not mere inflammation, as hydrocephalus came on so rapidly, and the respirations were irregular, because there was paralysis. On examination being made after death there was found a considerable suffusion in the opposite hemisphere of the brain.

Then we have first the symptoms attached to the cerebral system, and to the true spinal system, these symptoms being over excitement; in the second state we have the symptoms of the cerebral system and the true spinal, there being over excitement. The last stage of all is that in which the patient may be said to be in the sinking state, and you observe here that not only the cerebral and the spinal systems, but the ganglionic system is in fault. How do I account for that? I will tell you what I have observed, and you will judge from the character of the observations. If the child could not close the bronchial tubes, there was a considerable quantity of matter diffused over a considerable part of the lungs; therefore the progress of absorption was not properly balanced, and as the secretions are under the influence of the ganglionic system, I therefore concluded that the ganglionic system was involved.

Another state takes place, a state arising from distension of the intestines. Why do I refer to the ganglionic system? Simply on this account: —the secretion is probably under the influence of that system, which guides or which influences the whole of the secretions; therefore when there is a superabundance of secretion, like that to which I have referred, I conclude it arises from the derangement of the ganglionic system. I give this reason as the most probable, and it is highly interesting to observe that, whereas in the first stage of inflammation two parts are involved, in the last stage, not only the cerebral and true spinal systems, but the ganglionic system is involved. With these views in our mind, it is impossible for us to watch a case of inflammation in the cranium, or hydrocephalus, without detecting the nature of the disease.

I must now say a few words respecting the morbid anatomy in the case of inflammation from a fall, or from a blow, or any other cause. In these cases you have the usual phenomena of inflammation; effusion into the membranes, in the cavities, or the surface of the brain, and at the base of the cranium. It is very likely that effusion will account for some of the phenomena, though they may be accounted for by pressure, or it may be from the [illegible] of the ventricles, and so, from the general [illegible] produced by the pressure on the base of the brain, however that may be, effusion is the common [illegible]. Sometimes the membranes are a little opaque, but in cases in which the cerebral system is [illegible], you have more or less of the [illegible] liquid effusion. I need hardly tell you that [illegible] in all acute cases of suffusion. [illegible] of suffusion in which there [illegible]. Suffusion accounts for this paralysis [illegible] serve constantly, that where suffusion affects the substance of the brain, it [illegible] part more than the other.

In a case of true hydrocephalus, these are the appearances:—in the first place, effusion of the ventricles, and I should say there was a larger quantity of fluid than in a case of inflammation, then effusion both on the surface and at the base of the brain; then there is another very interesting point, for if you look at the membranes very accurately, and especially at the base of the brain, you may see what was first pointed out by Dr. ——, formerly of Paris, and who is, I think, in Demerara now; I am not quite sure. He pointed out what he called granulations, which he repeatedly perceived most under the arachnoid membrane, just under the base of the brain. Whenever you find these spots on the arachnoid membrane, you may be almost sure, if you look accurately into the other organs of the body, you will find tuberculous hydrocephalus; and from the time Dr. —— found true tuberculous hydrocephalus, he never met with a single instance in which he did not find these spots in the lungs. This shows the nature of the affection, and leads us to modify our prognosis. If you are called to a second case in the same family, if the disease comes on in the same manner, you may be sure the case will terminate fatally, if it is like the first. If you look into the other organs, you will find tuberculous hydrocephalus in the mesenteric glands especially. I only mention this circumstance to show that the event confirms our ideas of the true character of hydrocephalus—tuberculous hydrocephalus.

A few words respecting the treatment: I am myself disposed to treat every case as if there were full inflammation. I need not tell you, that if I had a case to treat in which there had been inflammation, I should act very differently, because there would have arisen the tuberculous disease in the lungs and the system. In treating a case of hydrocephalus I would recommend the free use of cold water in the morning, living in the open air, general tonics, and pursuing altogether a mild plan, as the best preventative. When the symptoms come on, nothing can prevent them so much as to subdue the inflammatory action. If the inflammation, however, is insidious, I should, in the very first instant, have the patient upright, and produce an impression, once for all, on the system. I would open the jugular vein, then a vein in the arm, then cup or apply leeches, until I saw a little pallid state of the countenance. The reason for placing the patient in the upright state is, that you can measure the extent to which you can go in drawing blood. I believe children bear the loss of blood well once; I do not think they bear it a second time. I am always disappointed when a patient has been bled once, because I do not, in that case, pursue the energetic plan I have described to you; otherwise, I do not hesitate to adopt that measure. I think you do not go beyond that which is safe, and you do not fall short of that which is safe by adopting this measure. If the patient is robust and strong, you may take more blood, and if there is acute disease, or severe inflammation, you may take more blood. Without some guide of this kind it is mere guess-work. The question comes after taking the blood how much have you taken? In the first place you have taken the proper quantity of blood if you find the quantity taken confirms the diagnosis. If you find in a very few moments the patient turn pallid, you may be sure the case is not one of inflammation, or that it is of a character that will not bear the bleeding any farther. If you have taken a large quantity you may be sure the case is inflammation, and therefore requires the loss of blood. The next thing is to apply fomentation to the head; let the head be fomented, and then you may put the system under the influence of mercury as soon as possible. I believe immediately after blood-letting [illegible] decidedly. I do not know that anything further can be done, except that the child must be fed on a diet of barley water, or something of that sort, and the bowels kept free and open.

QUININE IN ASTHMA, by B. R. HOGAN, Esq., United States.—The author asserts that quinine, administered in doses of from two to eight grains, repeated in an hour, if relief does not follow, has cured every case of asthma in which he has tried it. He was induced to try it in asthma, in consequence of its known efficacy in all paroxysmal and congestive diseases. He also alleges that in the "forming stage" of croup, in the case of a child, two years old, a couple of grains of quinine, and a "snuff" plaster on the chest, warded off the attack.

PRACTICAL OBSERVATIONS ON THE NATURE, PECULIARITIES, AND TREATMENT, OF SOME OF THE MOST PREVALENT DISEASES, &c. CONNECTED WITH THE POPULATION OF NORTH CHESHIRE, AND SOUTH LANCASHIRE, EMPLOYED IN COTTON FACTORIES.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Manchester.

CHAPTER II. FROM THE COMPLETION OF THE SECOND, TO THE FOURTEENTH, OR FIFTEENTH YEAR.

From the second to the fifteenth year, is an important epoch in the life of a factory operative; as all who have the physical ability, are compelled to earn their own subsistence, even at that early period of life, when it must be admitted (*medically*) they are far from being properly fitted for such an employment, in a confined, and artificially heated atmosphere. Before the protection afforded by the Factories Regulation Act, children were forced into employment at much earlier ages than at present; even the protection now afforded, is neither sufficient, nor is it appreciated by the operatives, to the full extent of its worth; which is evident, from the single fact, that every means are tried by parents to deceive the inspectors, and force children into employment, before the ages specified by the act, by giving the most false and positive assurances as to age, &c. From the ninth to the thirteenth year, government protects children from more than eight hours employment, per diem; and from the thirteenth, to the eighteenth, they are protected from more than twelve hours labour, per diem. Beyond *that age*, legislative enactment does not interfere. Without entering into the consideration of the more equitable system of controlling the moving power, to avoid the deceptions practised on the plan of age of the individual, it must be evident that children from nine to thirteen years are but little fitted for such extraordinary exertions, and it is lamentable that such should be required of them, the consequences of which are but too apparent on the community in these localities. It became a matter of serious importance to regulate their being employed, by strictly testing the age; and as baptismal registers were not always to be had, and in many cases were procured, did not answer as a test of age, as many were months, and not a few, several years of age, before baptismal rites were performed, other means had to be resorted to, amongst which medical men were directed to examine, and give their opinion in reference to age, from the development of the constitutional powers, tested by general appearances. As I had been extensively engaged in putting the Factories Regulation Act into operation on its first application under the chief inspector, R. Rickards, Esq., I directed the attention of the inspectors, particularly, to the fact that the chief reliance as to age, should be placed on the progressive development of the Dentes Incisores and Caninæ, a circumstance, to which I had paid particular attention, and I had to tell in so many instances, that I could with ease tell to a very trifle, the age of the child, without parental evidence, and frequently so correctly as to astonish the parties interested. In consequence of the sudden death of Inspector Rickards, these suggestions were not followed up at the time, though it was the intention of that gentleman, had he lived a little longer so to do. Some time after this, the government directed Mr. Saunders to make inquiries into the matter, and report thereon: this was done without reference to myself, although I had been practically applying the test for some time, and it was evident from the report, the information collected by Inspector Rickards and myself had facilitated the inquiry considerably. The subject was again neglected for some time in consequence of a new suggestion of determining the age by the standard of height, by Leonard Horner, then chief inspector, who had been at an immensity of trouble in collecting facts for forming an average standard for certain ages. This apparently easy method however, soon proved very fallacious, inasmuch,

it very frequently happened, that the younger (and consequently weaker constitutioned) child in a family by reason of its height, was forced into a laborious employment, whilst an older child in the same family, of shorter stature, but much stronger constitutional powers, was refused employment, and obliged to remain at home in idleness, eating the hard earned bread of the younger child's procuring. The standard of height very soon became notorious, as a fallacy; and an order in council abolished it entirely, excepting only as a corroborative test to other evidence. The development of the teeth now assumed its proper place, and certainly is the best *simple* test, and when combined with other testimony affords a conclusion not easily contradicted; and certainly where deception is practised inteded to be, it is the best remedy at command; but such is the determination of the operative class, to deceive in regard to their children, that it will always be difficult to come to conclusions strictly true.

The appearance of children at the ages, from two to fifteen, in these districts is miserably bad: sallow in complexion, lean, even emaciated, inkneed, and of precocious intellect, all of which are symptomatic of constitutional debility. There is a marked contrast between these children, and those of the coal miners in the same locality; the latter displaying considerably more physical power, and it has often been remarked, when playing together, that the little miners are a match for double their number of factory children, in feats of strength. Much has been said and written on the precocity of factory children, and, to a certain extent, it must be admitted as correct; the very congregation of numbers, and the general mixture of adults and children, tends to that end; but when some authors insist on early menstruation as a natural consequence of factory employment it is, in my opinion, going too far. I think, with Mr. Roberton of Manchester, who read a paper before the British Association, at its last meeting in Manchester, that menstruation is more an affair of constitution than of climate or employment. I do not mean to deny but that there are very many instances of early menstruation in the factory children, as I have witnessed myself many such cases. I may mention one case of a three months abortion at the age of thirteen years and two months; and another who was a wife, and mother of a living child, when she was two months short of fourteen years of age: still this is by no means general; indeed, I think cases of long deferred menstruation are equally prevalent in this class of society. It can scarcely be otherwise when it is considered that although confined in an artificially heated atmosphere for a considerable portion of their time, in consequence of which they are thinly clothed (arising, perhaps, as much from poverty as otherwise), yet they are frequently, and without any additional protection, exposed at meal times to a generally cold and moist atmosphere without: comfortless homes, thin bedding, and unwholesome low priced indigestible food. One of the most formidable appearances at the age at present under consideration, is that of scrofula, not unfrequently combined with, and in many cases the forerunner of, consumption; indeed, there appears a strong connecting link between these diseases; and though consumption's greatest ravages are after this period of life, yet it is frequently seen in the early years of childhood, and its victims can frequently, if not in all cases, be traced to those who have previously been subject to attacks of scrofula. There are many other diseases very prevalent; the mere enumeration of some of the principal will convince the observer that their origin in the main, is caused by the constitutional debility so generally prevalent—such as Menorrhagia, Diarrhœa, Chorea, Prolapsus Ani, Vermes, Fevers, and Inflammatory Affections of the Bronchia, Substance of the Lungs, Pleura, and Abdominal Viscera. Some of the eruptive diseases are also very prevalent, such as the Porigo Favosa, Scald Head, Psora, since the introduction of gas into the manufactories. Opthalmia has been more prevalent, and from its repeated attacks, opacities of the Cornea are very common appearances at all ages, but most of them originate about this time of life. In the treatment of Chorea, the best success has always followed the exhibition of powerful tonics, such as the Solut, Arsenici, with bitter infusions, proving it to arise more from general debility than the irritation of worms, &c. Some cautions are requisite in practising the antiphlogistic treatment in Inflammatory diseases: fevers, &c., lest the depletion be carried too far and the patient lost by unconquerable debility, which often comes on so rapidly that the patient is gone before the practitioner has time to look about him. The frequency of Bronchitis, Scarlet Fever, Mumps, and similar diseases sufficiently tells the cold moist atmosphere of the neighbourhood to which they are more than usually susceptible, in consequence of the excessive perspiration carried on during the hours of employment, and their want of clothing when not employed. Diarrhœa is often followed by obstinate Prolapsus Ani; and in the autumn, cases of the fruit-cholera are very abundant, some of them very difficult of management, and not unfrequently attended by fatal results. Strabismus is also a common occurrence amongst this class of children, which may often be traced to the attacks of convulsions from teething or acidities in earlier infancy. Such is the brief sketch of some of the principal features of diseases, their causes, consequences, and treatment during this period of life. Children so situated require more legislative protection than they at present enjoy, but the great matter is to learn to take care of themselves, to avoid those practices which are inimical to their health and comfort, and adopt such as are really advantageous; but this, neither pursuasion, nor legislative enactments can accomplish, until their education is more cared for, when they will be enabled to see things in the light of common sense. In the next chapter I shall consider this subject in reference to that period of life, from the fifteenth to the twenty or twenty-first year, a short space of human life, but no less liable to disease, in some of its worst forms than the periods preceding.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

By C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

Gentlemen,—The next antiphlogistic remedy to be noticed is *mercury*. It was first introduced as an anti-inflammatory agent, by Dr. Hamilton. He gave it in doses of four grains, after venesection, in conjunction with a quarter of a grain of opium, also with tartar emetic and camphor. The preparation of mercury that he employed was calomel. It is generally desirable to clear out the alimentary passages by a large dose of calomel (five to ten grains) before giving it in smaller quantities with opium to affect the system. If these remedies were not productive of decided relief in twenty-four hours, Dr. Hamilton was accustomed to repeat the venesection. Calomel is now frequently administered much more freely than formerly, and especially in tropical climates. Doses of ten to forty grains are not very uncommon. The modus operandi of mercury has been much disputed, and is not at all satisfactorily understood. Dr. Farre supposed that it excited an erythematic inflammation in the system, differing from the inflammation previously determined, which is of the phlegmonous or adhesive character, having a tendency to produce effusions. He tried it first in a case of iritis, and found that absorption of the lymph thrown out was undoubtedly promoted. Mercury is often beneficial in causing the absorption of the callous margins of syphilitic sores. In other kinds of ulcers its administration is generally injurious.—Nevertheless, wounds will often heal during the presence of salivation. Mercury is especially useful in peritonitis, and in all cases where the buffy coat is most abundant. It increases greatly the lymphatic and intestinal secretions, and may be regarded as acting exclusively upon the capillary vessels. There is often a discharge of greenish matter from the intestines before salivation, and the inflammation becomes diminished. Dr. Armstrong imagined that the chief benefit arising in inflammation from calomel and opium, was chiefly, if not entirely, due to the latter ingredient, viz. the opium. In some cases there can be no question that the opium is essential, and acts a much more important part than merely preventing the removal of the mercury from the bowels. The proportion of opium should be augmented when the nervous irritation is found to be predominant over the vascular excitement; also in cases where inflammation has proceeded to results attended with severe pain, and where it is important to produce as much quietness as possible; thus in perforation of the pleura or peritoneum, large doses of opium may be advantageously administered. It is in cases where the blood is altered, and the tendency to fibrinous effusions becomes considerable, that a large quantity of mercury is especially indicated; hence it is peculiarly adapted to the *later* stages of inflammation, and is less suitable at the very commencement of the disease. At the onset we have already noticed that *antimony* is the most efficient remedy. When fever runs high, as it does frequently at the beginning of an inflammatory attack, it is with difficulty that mercury can be brought to act upon the system, and this fact shows clearly the impropriety and inutility of trusting to it, without the assistance of previous depletion. There is no evidence to prove that mercury has any *direct* sedative influence upon the heart—it may certainly produce a sedative effect indirectly, viz., by increasing the secretions from the alimentary canal. When a very speedy effect is desired upon the whole system, inunction must be employed as well as the internal administration. When the gums become affected, the local inflammation is generally relieved, although the accompanying *fever* may still continue without any important abatement. Another medicine that has been much extolled by some as an antiphlogistic remedy is *Digitalis*. This you will find an exceedingly *uncertain* agent, and one upon which not the slightest reliance can be placed. *Colchicum* has also been tried in inflammations and in those of a gouty or rheumatic character it has been productive of strikingly beneficial results. It increases the secretion of the liver and kidneys, and aids in the purification of the blood. The sedative effect of colchicum is rather uncertain. Neutral salines may be given with advantage in cases of inflammation. They seem to have a refrigerant influence, and may act as attenuants of the blood. Salines ought to diminish its spissitude considerably. Some of the Italian physicians treat pneumonia almost exclusively with the carbonate of potass: it is supposed to render the circulating fluid less viscid, and the general secretions more free. We regard these medicines as mere subsidiary *aids*, and should never think of trusting to any of them alone. A very important item in the treatment of inflammatian is the *Regimen*. It must be evident that all circumstances tending to cause excitement of the heart's action, must be most carefully avoided and removed. Hence, a quiet room should be chosen, and the horizontal posture in bed maintained. All noise must be as far as possible prevented, and only little light should be admitted, because the senses are so many inlets, through which excitement may be communicated to the brain, and by it may be converted to the heart. The temperature of the air and of the patient must be cautiously regarded. If much *heat* is allowed, an increase of the fever will be induced, because, as you know, the effect of heat is stimulation. On the

other hand, *cold* is exceedingly injurious by checking the external secretions, and causing serious internal congestions. It is clear, therefore, that a continuance of either extreme must be avoided, and a *moderate* temperature maintained. The old system of smothering up patients in blankets, and unventilated apartments for the cure of inflammations indiscriminately cannot be too strongly deprecated. From what I formerly stated to you about the arrest of the gastric secretion, during the existence of inflammatory action, you will at once see the great necessity for prohibiting the supply of solid food. There are two reasons for this prohibition, viz., that digestion cannot proceed, and, secondly, that if it could, the nourishment acquired would be decidedly hurtful by augmenting the inflammation. The only diet required, is just so much as will keep the stomach from inflaming, as it were, itself, and for this purpose *diluents* are by far the best.

We have now alluded to the principal agents that are of use in combatting inflammatory disease, viz., blood letting (general and local), antimony, opium, and mercury, all of which may be assisted by salines, diluents, and the anti-phlogistic *regimen*. We must proceed to make a few observations upon the treatment of the *results* of inflammation. It will be apparent at the outset that these are not to be removed by any one class of medicines. The first of these results that we considered was *effusion*. The remedies for this have been called *evacuants, sorbefacients*, and *discutients*. The first of these terms would apply to any measures by which a direct removal of the matters effused could be accomplished. The second term, sorbefacients, would seem to be only nominal, inasmuch as we do not know of any substances that act upon the absorbents simply. Discutients are stimulant applications for dispersing effusions, such as solutions of ammonia, vinegar, salt water, and the like. *Friction* with stimulating liniments, is also of much service in some cases. It acts by increasing the circulation through the veins, and should therefore always be performed in a direction towards the heart. After effusion has occurred, the inflammatory action becomes diminished, but may still remain in a low degree, so that blisters and other local applications may be required. The best and most effectual remedy for the removal of effusions, is, as we before noticed, *mercury*. It appears to have some specific influence upon the economy whereby the absorption of foreign matters is determined. The efficacy of mercury for this purpose is well seen in cases of iritis, in which lymph is poured out and resists all attempts made for its removal, until the system is brought under the specific influence of mercurial preparations. The beneficial operation of blood letting and antimony in the ulterior stages of inflammation, is not to be compared with that of mercury. When the chief result of inflammation is congestion, antimony may be as useful as mercury. Sometimes congestions are better treated by tonics than by either. The same may be said of fluxes after all inflammation has ceased. In fluxes of mucous membranes, turpentines and balsams are very efficacious—they appear to have a specific influence over these cases. Liquid effusions into sacs must be treated with blisters, also with iodide of potassium, and diuretics and purgatives. When there are slight remains of inflammations, iodine is very effectual. If after effusion has taken place, the inflammation becomes *chronic*, iodine and mercury must be given. Here also *counter-irritants* come in with great advantage. If the chronic inflammation is superficial, blisters are best. If the inflammation is deeper or more severe, the *suppurative* counter-irritants may be employed. Sometimes there is scarcely any effusion discoverable, but merely a relic of inflammatory action, and in such cases simple rubefacients are often very useful. All these remedies must be employed before disorganization has taken place, or organic disease supervened.

When *suppuration* is established it lowers the vital powers. If the vascular action is strong, inflammation may continue, especially if the pus is *pent up*, and cannot escape. In this case incisions may be made, and hot poultices applied: or else, if the pus cannot be removed, the system must be supported, especially if any symptoms of depression are present. When suppuration is limited, there may still remain enough slight inflammation to indicate the further employment of antiphlogistic measures. The symptoms that are produced by the diffusion of pus through the system, have already been enumerated on a former occasion, viz. hiccup, subsultus tendinum, cold sweats, and ere long, death. The best palliatives that can be given are, bark and ammonia, wine, camphor, opium. Where the system is weakened by the discharge of purulent fluid, generous diet and tonics must be freely administered.

Gangrene must be treated much in a similar manner. If it causes depression, the system must be *supported*. We must try to excite the parts to inflammation, so as to throw off the dead matters. Sometimes, however, gangrene is attended with an amount of inflammation that becomes dangerous, and the excitement of the system may even require considerable depletion. The pernicious influence of the gangrene must be obviated by antiseptics. In gangrene affecting the throat, for example, a gargle may be used, consisting of from iij to vj drachms, of the solution of chlorinated lime, and vj to viij ounces of water. The chloride of lime has been of service in gangrene of the lungs. *Nitro-muriatic* acid is still better. Creosote is also good. Various inhalations are useful where the throat is affected. Another result of inflammation is *ulceration*. This is more common in the alimentary canal than in other parts. Such ulcerations must not be treated merely anti-phlogistically, but we must endeavour to excite a new and healthy action in the affected parts. Mercury may be given as an alterative in small doses; also, nitrate of silver, acetate of lead, sulphate of copper, or sulphate of zinc, or astringent decoctions, as decoction of logwood. The same substances may be of use also in ulceration affecting the larynx, &c.

The treatment of *erysipelatous* inflammation varies with its peculiar character. Sometimes erysipelas assumes the typhoid form, and requires the employment of powerful stimulants. In other instances, again, it is decidedly *inflammatory*, and demands the most active depletion, together with antimony, salines, &c. As a general rule, erysipelas is inflammatory at the commencement of the attack, but requires the use of tonic remedies towards its termination. Velpeau states that erysipelas consists essentially of inflammation of the capillary *veins*. One of the dangers connected with it is its special tendency to affect the membranes of the *brain*.

Rheumatic inflammation generally requires pretty free blood letting, and also the exhibition of what may be termed *specific* medicines such as *colchicum*. The combination of calomel, antimony and opium is also productive of especial benefit.

The *diphtheritic* inflammation is characterised by the formation on a mucous surface of a pellicle of lymph, which often emits a fetid odour. It is usually of a low type, and is most successfully treated by stimulants and alteratives applied to the part. Mild mercurials and salines may also be given. Bark is frequently indicated.

With the treatment and nature of *syphilitic* inflammation and its results, we have nothing to do here.

The next subject for our brief consideration is *chronic inflammation*, which, by continuing in a low form for a length of time, as its name implies, is frequently followed by the most serious and uncontrollable consequences. It produces gradual alterations in the *nutritive* functions, and thus also alterations in the *structure* of organs. The vessels are excited and throw out too great a quantity of solid matter. Hence may arise hypertrophy, induration, stricture, dilation, ulceration, &c. The effects usually predominate in one elementary tissue more than in another, and the results in the different tissues present many varieties of alteration. Thus when a tube consisting of several tissues is inflamed, it generally happens that the most vascular constituent is the especial seat of the mischief; for example, in inflammation of the urethra, we find that the submucous membrane has undergone the process of thickening. There is a difference in the susceptibility of tissues to inflammation,—thus, serous tissue is very easily affected, whereas, fibrous tissue is much less liable to the inflammatory process. Both, however, become affected if the inflammation is *chronic*. The deposits arising from the inflammation may vary from simple lymph to complete bone. When the liver is inflamed, an albuminous matter is deposited of lower vitality than that which usually nourishes the organ; it becomes contracted, and as a consequence, the entire organ shrinks. The product encroaches upon the vessels of the organ, and, therefore, its proper function becomes impaired.

Chronic inflammation seems to accelerate the occurrence of ordinary changes. It makes cellular texture dense and fibrous—muscular structures become tendinous—fibrous tissues become cartilaginous, and the cartilaginous become ossified.

Parenchymatous tissues generally undergo induration—Sometimes they become softened. In serous cavities, chronic inflammation may keep up the effusion to which the acute gave rise—but with this difference, that the chronic action causes a *degradation* in the character of the effused matter.

LECTURE XXI.

GENTLEMEN,—We are now entering on that department, or division of our course, which treats of individual diseases, rendered special by their affecting individual organs, or rendered so by their constituting such a group that they are constantly occurring together, more or less, with a constant relation to each other. And these in a great measure arise out of the general doctrines of *pathology* applied to individual organs, or, as it is sometimes instanced, individual functions connected with various parts of the body, constituting individual and special diseases. The first subject we shall begin upon will be the organs of respiration—the respiratory organs from the nostrils to the diaphragm, and we shall afterwards go, by a very natural connection, to the organ of circulation.

Now, preliminary to the consideration of individual organs, we have two generalities to consider and to notice respecting each group,—certain other matters with respect to the constitution of the organs, their functions, the manner in which they may be deranged, and consequently to the manner in which we may get at a knowledge of their symptoms, as they may tend to death or to other results.

Now we already find with regard to general Diagnosis and Pathology, that signs may be either

general or particular. So it is with regard to the chest.

On the one hand, particular signs proceed from derangement of the physical constitution of the organs, appealing directly to the senses. There are other symptoms, again, connected with the vital properties of the different organs, and although they often appeal to our senses in an indirect way, it is through these vital parts.

We proceed to consider, in a general way, the manner in which both sets of these may become available in teaching us the diseases of the chest. The chief peculiarity with regard to the chest is the manner in which its machinery is constituted and conducted. The chest is a machine adapted for the ingress and egress of air, and it is one admirably adapted for that purpose. But that adaptation belongs rather more to physiology and anatomy than to the particular department before us, which is to consider how that mechanism if deranged may present signs of disease. It is obvious that before it can cause signs of disease, it must act in a manner which is palpable, visible, or in some way ostensible to the senses. It is not every physical change which takes place, that can become a source of physical signs. We first of all consider, then, how we can render the disease manifest. We must examine the chest and its properties, so far as we can by sight and touch.

Now the constitution of the chest presents a given symmetry, certain symmetrical proportions on one side corresponding with the other, and these symmetrical proportions are exhibited not only in the stationary condition—what may be called the *statical* symmetry of the chest, or when the chest is comparatively at rest, or in the intermediate state between rest and motion,—but likewise a symmetry in the motions of the chest, and in a correspondence between the motions of the two sides.

We consider the natural aspect, the form and the position of the chest, which may be called the statical examination of the chest by sight and touch. By inspecting it straight, so as to view the two corresponding sides, the two are seen to correspond exactly with each other; the one half is a representative of the other half and if from an examination of the front we go to the back, we should find a correspondence between the two sides, one half a representative of the other half, a perfect correspondence between back and front.

There is another mode by which symmetry may be seen, i. e., looking down the chest so that you may perceive a correspondence between the thickness of the one side and the thickness of the other. And so you may examine the chests of patients in a similar way by looking over the shoulder, directing the patient to lay his head down, you perceive at once a correspondence between the two sides. This is a rough but an extremely useful way to obtain knowledge on the symmetry of the chest. It requires a certain amount of practice and a correct eye, to be precise in this mode of examination, but it is remarkable how soon after a little practice, accuracy is obtained, independently altogether of mensuration.

Now I shall have an opportunity of bringing before you, by way of illustration, a living model, by which a few of the particulars may be illustrated. I mention, by way of precaution, in the first instance, that as symmetry is the great object, it is obvious that it is necessary to place the individual in a perfectly natural position, that the arms shall be in a corresponding position on both sides, and the body as erect as possible; if, in a sitting posture, taking care to preserve the erectness of the trunk. Sometimes patients are too weak to bear this; under these circumstances, the patient lying in bed, you may inspect the sides from above, and if the patient is lying down, it is important that you get into a position to see the symmetry of the two sides. You must sacrifice dignity to the circumstances of the case and the desire of doing the patient good, and get on the bed and look down; you must move yourselves to suit your sight. The great object is to discover the existence or non-existence of symmetry; therefore examine fairly. This symmetrical portion of two sides is very often extremely well seen from the foot of the bed.

Now, I have stated, that symmetry is the rule of the natural condition; there are, however, in the natural condition, certain small exceptions to symmetry, trifling, in some measure, but yet they ought to be noticed—not only because they are exceptions, but because they are likely to be exaggerated by disease. The exceptions are, that the right side is in a trifling degree larger than the left side; when we come to actual measurement, it becomes more particularly evident, but it is also sometimes obvious to the eye. It may be stated to be a general rule, that on examination the right side from the lower part measures from one-eighth to half an inch more than the left; this is stated by Leibig, and considered by him a general rule. Dr. Stokes, who pointed out this incident, considers that the greater use of the right side causes it; that the right side is the strong side, and one that requires greater use and development. It is a matter of doubt whether this fact is not an effect rather than a cause, but it is a matter we cannot enter into at present. Dr. Stokes states, that in one of the instances in which the patient used his left hand as much as the right one, the left side acquired the predominance. There is not, however, enough of evidence to prove, that enlarged left sides follow invariably the increased use of the left hands. Doctor Willan, a very laborious French physician, has made a great many researches in the comparative size of the chest, and its various inequalities, both natural and unnatural; and, amongst other things, he has found that a great extension of the muscles of the chest, instead of increasing the size of the chest, diminishes it. Those artizans who are engaged in active employment, requiring the use of their upper extremities more than the lower, (the arms particularly,) have, on the average, smaller chests than those whose occupation requires both extremities to be used equally. We have, indeed, always considered that this exercise and development of one side—the effect of a person using the right hand more than the left—would increase the size of the muscles; but we cannot see how it would increase the size of the chest itself, unless there is some other development to account for it. I have always taken another cause as the reason; and before I mention it, I will state that another slight deviation from symmetry is also observed in a great number of healthy cases. The number is not such as to erect it into a rule; but it may generally be found to be the case, that besides an unusual development of the lower part of the right side,—a predominant development of the right side,—there is a greater development at the upper part of the left side than the right; and to confirm this, I may state that Doctor Willan, who has made many careful observations on the same point, observes, that in very numerous instances where there is a trifling amount of disease,it must amount to a case of enlargement; and that a departure from the natural symmetry of the chest produced disease in the greater number of the instances he met with. Now this makes it entirely (instead of being connected with the muscular development or original confirmation) owing to a greater amount of pressure in a particular direction, by which amount of pressure certain parts were disposed to enlarge and other parts to contract. Now if we wish to find what those parts should be, I have no hesitation to refer you to the position of the liver in the lower parts of the chest. The chest is expanded, and the lungs obey that expansion; all sides of the chest and lungs move freely. The motions of respiration, inspiration, and expiration take place without any impediment; and expiration takes place with the same facility. But there is a greater amount of resistance in some parts than in others. Where there is such a heavy mass interfering, with the respiratory motions, it requires a greater power to move it than if less motion took place; consequently, you may conceive that where there is a certain degree of resistance in the region of the liver to the descent of the diaphragm, in consequence of the weight of the liver, there will be a greater tendency to increase the bulge or expansion of the walls of the chest in its immediate vicinity. This takes place in inspiration, but still more in expiration. In expiration, which is a mechanical act, arising from the elasticity of the organs, there is not only the elasticity of the outer organs, but the weight of the liver to contend with,—and that takes place, on an average, in a third of the whole period of an individual's life, in a horizontal position. This seems but a little, but it is something that is going on constantly in this part more than in any other part of the chest; and it is quite sufficient to have the effect of causing a greater predominance of development on the lower part of that side. With regard to the upper part of the left side is there any proof that mechanical action has there a similar effect? There is the stomach distended with wind, which is more or less yielding, nevertheless, we find that Dr. Willan mentions, as showing changes of the chest,—arising from the resistance given by the distended stomach,—children subject to dyspepsy and flatulatory disease. Here the heart rises up—a solid body—pretty high to the chest, and though it does not apply to the lower lobe of the lung, may it not act in a similar degree with respect to the upper portion? The heart and appendages, and the other portions connected with it, rise pretty high to the left side, and it seems that a particular amount of resistance given there may cause a predominance of the upper part of the left side over the right. The other view connected with the working of the chest is important, inasmuch as the observation may lead us to a correct appreciation of the causes of these different phenomena, and their prominent signs.

So far we have been considering the statical position of size in relation to the chest. The chest expands in a state of rest without relation to these motions. We now consider the motions of the chest as expanded by the rise and fall. Now the motions of the chest as to their size are symmetrical. They are symmetrical in all directions. Remember what the motions of the lungs are—where the motions of the chest begin. Although the chest is a moving machine, the chest itself is the organ of motion; we should consider the manner in which it moves, by considering the manner in which the lungs are calculated to expand best; and pathologically considered, in relation to size, we must consider that the lungs expand from their roots. From the roots, so called; these parts, from which bronchii subdivide, and from which the vesicular texture of the lungs expand like the roots of trees from a centre. We suppose the great bronchii go in, and subdivide in various manners through the whole expansion. Well, then, the expansion of the lungs is upwards, outwards, downwards, and inwards. The expansion is over the chest in every direction; and just so, of a similar kind ought the expansion of the chest to be. In making these observations, you will do well to use the sight and touch together, placing the patient immediately before you, and placing your fingers on the chest so that you are sure you are looking at two corresponding points; then desire the patient to take a deep breath, and watch it at various degrees, and then you will see the expansion taking place in a symmetrical manner. You will observe it rises not only upwards but outwards; and this is often to be observed by placing the other hand, so that not only do the fingers rise up and down a little, but the hand and fingers are lifted outwardly. This may be observed if the patient has his clothes on; you put your hands round the chest, and you will perceive at once an uniform and general expansion, which, in some instances, will supersede the necessity of further examination, and likewise there is an expansion of the sides. The ribs are observed to rise as well as to expand outwardly—you will then come to the lower part of the abdomen. It swells outwards by the pressure of the diaphragm and the abdominal viscera. In the back you may perceive not only a general expansion, but the individual motions of the scapulæ, which may be looked upon as a metre —a mark, or index, of the motions of the chest. You will observe the different motions of the chest and the different motion of each scapulæ from the spine.

Now we may, in different diseases, detect a difference in the expansion of the two sides—in the descent of the one scapulæ from the spine, to that of the other. The motions that arise take place in inspiration; and whilst we watch these motions (and, in expiration, the opposite condition takes

place), whilst we are watching the falling, we may sometimes have the limits of a motion into the lower part of the chest, and thus discover what are the boundaries of the chest. It may seem to be not a difficult thing to talk of the boundaries of the chest. The chest, inasmuch as it is composed of bone and abdomen, is hemmed in with muscles. But, you must observe, that the abdominal viscera are in the chest, and it is very important to distinguish where the particular point of the chest corresponds with abdominal spinals only, or thoracic and abdominal spinals.

Now I have mentioned that sight and touch assist us in this, that by observing the motions of respiration in the lower part of the chest, we perceive a difference in the motions of those above the diaphragm and those below the diaphragm, and for this reason—the intercostal muscles above the diaphragm are the seat of pressure from without as well as from within. When the chest is expanded, a tendency to a vacuum is found, and if the air does not penetrate with great freedom into the lungs, that vacuum takes some time to go from the trachea into the lungs; and so, if it does not take place with great freedom at each time the diaphragm descends, there will be little concavities, as is found on laborious respiration. In a healthy person, you observe the intercostal spaces above the diaphragm that correspond with the lungs in the cavity of the chest, are concave at each respiratory effort, whereas those intercostal spaces below the diaphragm,—I do not mean actually below the attachments of the diaphragm, but below that level on which the thoracic viscera rest—those that are so, instead of being concave at each inspiratory effort, project outwards, and in fact the whole chest seems to expand and project outwards independently of that; and when inspiration is contracted, as in croup or any other case of that kind, the depression of the intercostal muscles connected with the chest is increased, whereas the external swelling and projection of all those parts below the diaphragm, corresponding with the abdominal muscles, is increased. The projection is increased in the abdominal muscles, and the opposite states exist in the chest. Some of the effects arising from this are rather interesting. These always take place peculiarly in young subjects, and their continual operation causes distortion of a particular kind. Shaw has pointed out, lately, some remarkable cases connected with that projection called *pidgeon chest*, or *chicken breast*—distortion, which in children shows a remarkable projection—a flatness of the chest, and a flatness of the sternum, and he, taking the explanation as before pointed out with regard to the intercostal muscles, ascribes it to a similarity of pressure of the inspiratory effort connected with an imperfect transmission of air through the trachea. In the cases I have already mentioned, where the air does not enter with great freedom, there will be a defective expansion of the diaphragm; and one of the great causes, perhaps the chief cause of respiration, is the weight of the lungs, which will effect the descent of the diaphragm, when the air does not enter freely, while atmospherical pressure will be exerted on the parts of the diaphragm and the ribs. If the air does not enter freely, the walls of the chest are pressed in. This is what you see in *chicken-breasted* children: the lower part of the chest is narrowed, flattened, and depressed, the continued effect of which is to cause a projection of the sternum, and this is sometimes exhibited through the whole course of an individual's life.

The point before us now, more particularly, is the manner of tracing the limits of the chest. The pressure is all outwards, by the diaphragm pressing on the abdominal viscera, outwards and downwards, and causing a temporary depression of the intercostal spaces. This is an important sign to prove the existence of the limits of the chest, and likewise the opposition to the entry of air into the proper tubes. It is in connexion with this, arising out of this difference of pressure between the abdominal part of the chest, or, more properly speaking, the *pulmonary* part of the chest, that you may perceive the outline of the projection; now there is a double one constantly produced. In indicating the actual contact of the liver with the walls of the chest, it appears a little above, to correspond with the upper part of the diaphragm, and upper portion of the liver, arising from the outward pressure I before mentioned. This seems to be the chief cause of natural projection of the chest, on the lower part of the right side.

Another fact, important to notice, in connexion with these motions is, that the ear is differently affected by the motions of respiration. Full inspiration causes the ribs to rise and to recede from the heart and the lungs, and expand between them. In the act of respiration the lungs are fully expanded, which is a healthy condition of a well-developed chest. This does not apply to narrow chests, or in disease where there is an adhesion. On the other hand, in full respiration, the lungs rise upwards to the diaphragm, and expand the greater portion, and the heart comes in contact with the walls of the chest, as in the case of *heart affection;* where the agitation and beating of the heart is caused by the heart's connexion with the chest. It may be seen likewise in the amount of the lungs' expansion; the heart comes in contact with the fourth and fifth ribs, and a considerable portion of the sternum. Healthy respiration is both *diaphragmatic* and *costellary*, and is constituted by the descent of the diaphragm and the rising of the ribs; and all varieties arise from disease, in which one of these elements of respiration or the other is absent. Thus, for instance, diaphragmatic respiration—which takes place when something or other prevents the full motion of the ribs; when the ribs are prevented from moving freely, either by excessive pain, or by ossification of the cartilages; or by actual disease taking place in the lungs; then the respiration takes place interiorly and by descent of the diaphragm. In that case the breathing is diaphragmatic or abdominal; inasmuch as the motions are not seen, and the chest no longer rises upwards and outwards. There is a greater than usual ascent of the abdomen at each breath. Again, the opposite condition takes place in what is called thoracic, or costellary respiration, or high respiration. This takes place when the diaphragm is immoveable; the diaphragm does not partake of the least movement. This may be from various causes—as when it is the seat of intense pain, or by a voluntary act it is kept motionless, in cases of pleurisy, and in case of excessive pain of the abdomen; the motion downwards may cause pain by a contraction on the abdominal muscles. In these cases the chest is moved with great activity, and under these circumstances the supplementary muscles, and the various muscles connected with the upper part of the chest, are called into increased activity; the chest moves with a greater apparent effort, and the abdomen is comparatively quiet, or it moves, or appears to move inwards; this moving inwards arising from an attempt of the abdominal muscles to contract the motion of the diaphragm. As an example of diaphragmatic respiration, I may mention a remarkable one, in which disease affects the nerves and the muscles above the diaphragm,—in case of fracture or injury of the lower animal vertebra, or a portion of the spinal marrow below the origin of the phrenic nerve. The motion of the intercostal muscles may be suspended, and still respiration be carried on by the diaphragm supplied by the phrenic nerve, which has its action by its connexion with the nerves of the medulla oblongata.

We may mention these as cases of diseased respiration, which may be partial; the motions may be *costellary* on one side, and there may be diaphragmatic respiration on the other: it may affect one side only. Another variety of diseased respirations is where there is a partial difference, compared with the symmetry of the motions; when one side moves more than the other, the parts rising unequally. Some parts rise more than others. One part may be quite mobile; this may take place from various causes: it may take place from distortion of the chest, when the organs of the chest are distended. When the whole machinery of the chest is disordered, the motions are much more free on one side than the other. Here we can only expect a partial respiration from the immobility of the walls on one side. *Ossification* may produce the same effect, as in spinal distortions. What is more important to me is, where a partial respiration sometimes takes place from disease within the chest, or the lungs itself, or from effusions into the thorax. For example—suppose the upper lobe of the lungs to be consolidated by disease; instead of air suppose there is some solid matter—a *tubercle*—it is quite clear that the motions of that part could not be freely performed, and inasmuch as the motion of each external part represents the motion and expansion of the internal part—that motion would remain fixed; so that, comparing the motion of one with the motion of the other, you will perceive the disease, and presence of inflammatory consolidation or liquid effusion instead of air.

Sometimes there is something to deceive you in the examination of the chest. Sometimes you may perceive a difference in the motion between the two sides, and yet the side most diseased will appear to move most. This is a deception of sight. There will often be an increased effort to move the diseased side, and that increased effort will raise the shoulder and clavicle, so that if you place your hand on the ribs you will see the ribs remain fixed; and when you see a greater upward motion of the shoulder and the clavicle on that side, and the ribs remain fixed, it is a more certain proof that there is disease, than if the shoulder and clavicle were less. It is the ribs that are the representatives of the chest, and they are to be watched by the expansion of the muscles.

I have mentioned different diseases; besides consolidation, *tubercle* in the lungs, effusion into the *pleura*, or contracted adhesions, and obstructions of the bronchial tubes; and whenever the air cannot get into the chest to expand it, that portion must remain comparatively motionless. But there is another condition to be observed in this motion, suppose we observe that one part of the chest is more fixed than another. It is important to observe in what condition it is fixed; whether in a state of expansion, highly distended by a quantity of air; or whether fixed in a state of collapse, in case of an insufficiency. Both cases are representative of disease. For example: suppose liquid effusion to occupy the pleura instead of the lungs; this would not only displace the lungs with such force, that the sides will be distended, but the motion of the chest will be stopped—it will be quite still, as if in a state of over distension; or as if in a state of full respiration. On the other hand, as in the contraction that takes place after pleurisy, you observe the chest is fixed in a contracted state. This is not only obvious to the sight, but it may be determined by examination. Now this practice is the most accurate mode of detecting inequalities, but it is a troublesome thing. We must not mind trouble in investigating disease, and trying to get at an accurate calculation with regard to it. You will find it advantageous to practice your eye as much as convenient; it requires a greater exposure of the patient, but it must be done if required. The plan is to take an exact measurement of the corresponding parts: that may be done by a tape passed round the chest, making it meet at the side. This is the usual mode of measurement. If you suspect liquid effusion in the lower part of the chest you should take the upper portion of the ensiform cartilage, on which you may press your finger, and dividing the string, bring it tight on the thorax. The tape should be perfectly horizontal. The measurement by the tape consumes a great deal of time, but it is more convenient than the callipers. It may be used in the measurement of the vertical diameter of the chest. Take any given portion of the spinal process; pass the tape over the shoulder to any part of the central portion of the sternum, or the clavicle, and pass the string round on the opposite side, and then you will perceive a difference on that side, taking care to apply it tight on the parts. The direct diameter is taken more conveniently by the callipers, for in that case you do not omit the bony projections. The spinal processes and vertebra are the best points to proceed from. Measurement is not always a more accurate test than inspection; for sometimes there is a change of shape without any change of size; and in many instances—in cases of considerable distortion—it is obvious to the eye; there is a sort of

flatness in one part, and an enlargement of another part, so that actual size is not determined by shape. Then there is internal measurement, tried by Abernethy and others—by directing the patient to blow into a jar of water; but this is no index of capacity; it is not what quantity of air the patient can contain, but what the muscles have the power to do. A patient may blow a large quantity of air into a jar; or from want of strength, and not from want of capacity of the lungs, the patient may blow only a little. The same objection will apply to the attempt to measure the capacity of the lungs by inspiration.

CURABILITY OF CONSUMPTION.

(Continued from page 233.)

To the Editor of the 'MEDICAL TIMES.'

SIR,—The next antagonism to phthisis, in the order I have laid down for consideration, is:—

HYSTERIA.—Individuals in consumptive families labouring under this affection, are rarely susceptible of tuberculous deposits or manifestation. It has the remarkable effect, as may be frequently observed, of giving greater or less roundness and fulness to the chest, according to its degree of severity, and the length of time it may have lasted. Spasms of the membranous portion of the trachea is the main cause of the laborious and irregular breathing. The air, being forcibly drawn in, and retained, distends the air-cells; this, together with the spasmodic action of the diaphragm, reduces the convexity of that muscle, thus enlarging the capacity of the thorax, and the frequent occurrence of the paroxysms with the long establishment of the hysteric habit in the system, ultimately lead, by these means, to permanent enlargement of the lungs, and expansion of the walls of the chest, it being a well-known fact that the latter contract or expand in the same proportion as the lungs. Dr. Ramadge, in his work on Consumption, speaking of individuals who are little liable to phthisis, says, (page 81) "To these I may subjoin persons who are affected with diseases of the convulsive kind, such as hysteria and epilepsy, or, in truth, all in which a prolonged or forcible retention of the breath is frequently seen." In hysteria of any considerable standing, the neck is rounder and fuller than usual:—if I might so express it, hypertrophied—both in the muscles and the integuments. The sterno-cleido mastoid muscles, in some cases, become so large towards their insertion as to exert a lateral pressure on the trachea, near the sternum; thus offering a permanent mechanical impediment to freedom of respiration. Some months ago, Dr. Ramadge shewed me a well-marked case, illustrative of this peculiarity, at the Infirmary for diseases of the lungs. The patient had been admitted to the institution, a short time previous, for catarrhal dyspnœa, and exhibited an extraordinary development of the sterno-cleido mastoid muscles, evidently sufficient by their lateral pressure, to diminish the area of the trachea. This person had, antecedently, laboured under consumptive disease, as appeared from auscultation and the history of the case. The dyspnœa, no doubt superinduced by the pressure of the muscles on the front of the neck, had removed all the symptoms of the former complaint. In aggravated cases of epilepsy, patients rarely die of consumption, for the reasons just mentioned under "hysteria." Every convulsive disease acts, more or less, as a prophylactic. It need not be inferred that the existence of these, or any other morbid conditions is, *per se*, a desideratum; this is by no means the opinion of the school to which I belong. I simply profess to be, however imperfectly, Nature's historian; and my object is to direct attention to her movements, with a view to their judicious imitation, that we may accomplish, more frequently and safely, that which she attempts too often without success, or only partially achieves. In her well-intended, but sometimes ill-conducted efforts, she is prone to run, as I said before, from one extreme into another. I might enter into further details under the present head, but should, by so doing, only multiply illustration, and occupy space unnecessarily.

ASTHMA.—The several varieties of this affection act in the way already described: viz. by enlarging the air-cells, which they do more or less, frequently, according to the frequency and duration of the paroxysms. Even in those cases of pure asthma, where the intervals between the attacks happen to be long, leaving time for the lungs to return to their previous dimensions, a certain amount of protective effect is gained. Indeed, I have never known an instance of pure asthma succeeded by phthisis. This I should suppose, *à priori*, would be the case, inasmuch as the exercise and expansion of the lungs, though occurring with comparative unfrequency and of short duration, can scarcely fail to exert an influence sufficient to alter the scrofulous habit, and render the lungs unproductive of tuberculous deposit.

Asthma has the effect of taking away the perpendicularity of the windpipe. The *pomum adami* in males becomes exceedingly prominent, and, in both sexes the inferior part of the trachea is retracted sometimes to a remarkable extent. The inspection of the front of the neck will frequently enable us to form an opinion of the state of the lungs, and constitutes no mean addition to the number of our diagnostic signs, in certain forms of thoracic disease. I may here observe that in this affection also the principal seat of spasmodic contraction is in the membranous portion of the trachea, forming its posterior boundary.

An interesting case, illustrative of the antagonistic power of asthma to phthisis, occurred about three years ago in the infirmary for diseases of the chest. James Walford, a pipe maker, labouring under consumption, was admitted by Dr. Ramadge as an in-patient; he displayed, unequivocally, all its auscultative signs and constitutional symptoms. He had, moreover, ulceration of the pharynx, which, in spite of suitable local applications, extended itself downwards, till, on reaching a certain point, asthmatic convulsions of a most violent description took place. A stridulous, mucous ronchus was heard in the windpipe; the lungs became suddenly and enormously emphysematous, and the difficulty of breathing almost intolerable. The asthmatic condition lasted, with few intermissions, for some months, and disappeared only when the pharyngeal ulceration was healed. During this period, from the very commencement, no phthisical symptoms had shewn themselves. The nocturnal perspirations, &c. ceased altogether, and have not since returned. He has been seen by several medical gentlemen at the institution, which is always open to the profession, and among them were three highly intelligent American physicians.

I have seen in Dr. Ramadge's case book, another interesting case, which I beg to add. The patient, who had been previously under treatment at the Middlesex Hospital for phthisis, presented himself at the infirmary for relief from severe catarrhal asthma, which, it appeared, had for some time masked the consumptive symptoms. The regulated temperature of the atmosphere of the ward, together with the medical treatment, soon removed all mucous irritation, and, with it, the spasm. He was discharged cured, and remained free from asthma and phthisis for 17 years. During this period, however, he had had an attack of insanity, and, latterly, his habits became drunken and dissipated. Being refused admission at St. George's Hospital, as a hopeless case of phthisis, he again applied to Dr. Ramadge for advice, but it was too late; he died a few days afterwards.

Here was total absence of all asthmatic interference for a very long period, possibly, in a degree, owing to the attack of insanity, which has a tendency to supersede asthma. Had the asthmatic affection recurred at intervals, the return of the consumptive state might have been prevented. From the whole, I would draw the conclusion that asthma, once introduced into the system, being in some instances a curable disorder, does not necessarily imply that the individual so affected may not at some period, die of phthisis. When a cure of atshma takes place, the system is in *statu quo*, so far as liability to phthisis is concerned. In the case above related, it is probable that the man's intemperate and debauched habits had so far weakened his system as to bring on contraction of the chest, from want of power in the muscles of inspiration to elevate the ribs,—new tuberculous deposits took place, or old ones liquefied, or perhaps both,—a cavity formed, and the disease terminated in death. I should here subjoin that the asthmatic state in the first instance was of very short duration. I find after a complete cure of asthma, that the return of the phthisical disease is rare.

CATARRH, or Bronchitis, symptomatic or idiopathic, in almost all its phases and varieties, is attended with more or less bronchial intumescence. By catarrh, I understand irritation of the mucous membrane of the air passages, in any part of their extent. It is either latent or manifest, mild or severe. In its mild or latent form it may happen to be unaccompanied by either cough or expectoration, and can only be detected by the ear. The easy, soft, downy murmur of natural respiration, degenerates into a course heavy breathing, with prolongation of the expiratory act. Between this and its aggravated forms, there are various gradations in the scale, but the tumefaction of latent catarrh, if of any considerable duration, is sufficient to antagonize phthisis.

Perhaps there is no morbid affection more common in this climate than catarrh, particularly in cold and damp weather. It is symptomatically present in most chronic diseases of the heart and lungs; in all febrile affections, and in numerous cases of impaired constitution. When irritation of the trachea takes place, or spasm of its posterior membranous portion, it is propagated downwards by continuous sympathy. But for the intervention of this complaint, the mortality from consumption in Great Britain, already so considerable, would be far more than doubled. Dr. Ramadge is, I believe, the first who taught that it is a preservative against consumption. Laennec, with all his acumen and experience, with the proofs daily staring him in the face, never alighted on this simple and important discovery. He combated, along with Bayle and others, the doctrine of the old schools, that it was one of the causes of phthisis, but most unaccountably overlooked its preservative influence. He has recorded cases of chronic catarrhal persons who lived to an advanced age; he had an opportunity of examining many of them after death, and observing the traces of old tuberculous disease, either cured or rendered quiescent, and yet never even so much as suspected the inherency of any preservative power in catarrh, thus verifying the old adage, '*non omnia possumus omnes*.'

One of the circumstances which contributed to the erroneous supposition that catarrh is one of the causes of phthisis is that the two are often found coincident. We are, however, more liable to set down a case of phthisis for catarrh than the latter for the former. Dr. Ramadge has shewn me many examples of this mistake, and says they are very common. He is constantly in the habit of noticing them to the medical gentlemen who attend the Infirmary. Where there are small incipient cavities, separated by healthy pulmonary tissue, or small disseminated tubercles beginning to form yellow points, the ear may not be able to detect any positive evidence of the morbid phthisical action commencing in the lungs, aye, even that of a practised auscultator. The best guide we have in this unsatisfactory state of things, is the absence or presence of successive nocturnal or matutine perspirations, and this will enable us to discriminate in all cases, excepting a few complicated with affections of the heart. When present, the patient is decidedly consumptive. Inattention to this symptom too often leads to a false diagnosis, even with some high authorities; the patient is pronounced catarrhal only, his apprehensions are disarmed, and he rests for a time in the enjoyment of a fatal security. This important symptom is overlooked or undervalued, because the auscultatory signs are either absent or obscure. Auscultation, under such circumstances, is purely speculative. The perspirations, though, with many a discarded symptom, will, as I have said, in almost all cases, alone, enable us to decide correctly.

Dr. Ramadge informs me that he is frequently applied to for advice in such cases, when it is too late to redeem the error, and all that is left him is the melancholy task of pronouncing on the real

character of the disease, and when permitted verifying, by autopsy, the correctness of his prognosis. In the latter stages of phthisis, catarrh is always present, arising, probably, from extension of the inflammatory action in the substance of the lungs to the lining bronchial membrane, but it occurs too late to arrest the disease.

Assuming, as I do, that general debility is the great chief cause of tuberculous deposit, I may be asked why convalescents from fever do not necessarily become consumptive. The answer is furnished by the coexistence of catarrh, either latent or manifest, defeating contraction of the chest, and its consequent deposit of tubercles.

Acute or inflammatory catarrh, independently of the direct danger to which it exposes the system, sometimes brings on a rapid and simultaneous liquefaction of pre-existent tubercles; and, though its own course may be arrested, the patient may die of galloping consumption. Influenza frequently proves fatal in this way, when severe. Like mercury, it quickly matures all crude tuberculous deposit, and if these be large and extensively distributed through the pulmonary tissue, their general and speedy solution is too much for the powers of nature, and the patient sinks. If, however, the deposit be small and partial, and the inflammatory affection moderate, the elimination of the morbid matter is often followed by a cure, more or less complete and lasting, but generally entailing a catarrh. We have been visited within the last few years with this epidemic, in a severe form. Dr. Ramadge informs me he has seen many persons, a long time subsequent to an attack, having cavities too large to be healed up by the bronchial disease, but with the pulmonary tissue everywhere else in a tolerably healthy state, in consequence of its inordinate exercise from the presence of the entailed catarrh.

It is of importance, in the interrogation of a patient, to ascertain at what season his phthisical symptoms first appeared. The chronicity of the disease depends much on the fortunate accident of its occurring in the winter season.

DISCIPULUS.

(To be Continued.)

TO CORRESPONDENTS.

Mr. Blythman is thanked for his obliging communication. We gladly accept his appreciated *offer.*

The Gentleman, *who is a licentiate of the Hall, and a member of the College of Surgeons, is of course eligible to all the medical appointments of the Poor Law Commissioners.*

A Poor Practitioner.—*We could little more, we are afraid, than extend our pity to this Correspondent. He, like many others, has had his small resources made less by the fluctuating and aimless policy of the College of Surgeons. When a few more similar instances of mis-government (authenticated) come before us we shall be better prepared to deal with the question. The demand of twelve months previous hospital practice is to be compared to the "examination of gentlemen practically on their merits."*

An Old Subscriber, *being a licentiate of the College, and a member of the College of Surgeons, has, therefore, a right to supply his own medicines,* and charge for them as an apothecary. *If he acted as an apothecary before 1815, the 55 of G. III. c. 194, protects him, as the practice. There is, however no chance of interference by the Society.*

Our review of Faraday's "Manipulations" has produced us a communication, from which we extract the following:—"*Here is an idea, unfortunately too prevalent, that all manual operations are somewhat derogatory; that to comprehend the theory of a science is quite enough, and that all manipulation should be delegated to assistants or menials. Now chemistry, justly proud as she is of her attractions, refuses to dispense the pleasure of her acquaintance to all who are too proud or too idle to become manipulators themselves. "We frequently see able and to follow all manner of handicraft, from the ladylike delicacies of glass-blowing to the mending of broken sauce-bottles! We had much pleasure too in acquainting all who aim at being chemists that they* must *do the same. Without such a facility, natural or acquired, the most splendid powers of mind, the most brilliant suggestions of genius, will be ineffectual. Now Faraday's '*Manipulations' *is not the best, but the only book, in this* or any *language, capable of yielding the required information; its object is, as the author expresses himself, 'to facilitate to the young chemist the acquirement of manipulation, and in consequence his progress in the science itself. It does not attempt to inculcate the principles of science, but the practice; neither does it claim to teach* a habit of reasoning, but has solely in view the art of experimenting.' *One great fascination possessed by this volume is, that it strives to remove the old prejudice in favour of an expensively appointed laboratory. Air pumps are supplied by cupping glasses—drinking tumblers are applied to uses innumerable, and as for the inexpensive glass tubes, they, by the blowpipe's aid, are metamorphosed into tens of thousands of useful forms. When it is remembered that such advice emanates from one who has the command of perhaps the most profusely appointed laboratories in Europe, we need not doubt its sincerity.*"

Aquarius *reminds us that in recent clauses in Water Works Acts, the river Thames water is specially required to be effectually purified by means of filtration, and asks whether filtration* can *effectually purify it? We have no hesitation in answering in the negative. Animal matter may be, and with regard to the Thames is, held in such infinitesimal tenuity, that no amount of filtration can achieve the work of defecation. We must add to this opinion our settled belief, that even much that might be done by filtration, in the way of making the metropolitan supply at least decent and cleanly, is omitted through a shabby and very mischievous economy by many of our Water-Work Companies. The Acts, we think, provide against this, if spirited individuals would but see them enforced.*

A number of other Correspondents will be answered next week.

THE MEDICAL TIMES.

SATURDAY, JANUARY 14, 1843.

Bad motives may have good points.—REYNOLDS.

RESERVING to a future occasion, any remarks we may wish to make on the state of our medical brethren in Austria (as given last week), we proceed, now, to present our readers with

THE MEDICAL ORGANIZATION OF PRUSSIA.

There are three grades of medical men—first, Doctors of Medicine and Surgery—secondly, First-Class Surgeons—thirdly, Second-Class Surgeons.

The "*Doctors*," before entering as medical students, must prove their possession of a liberal education, extending to a knowledge of natural and metaphysical philosophy. The studies extend through four years, and must be made in one of the five Universities of Berlin, Konigsberg, Griefswalde, Halle, or Bonn. On producing certificates of regular attendance, they are admitted to two rigorous examinations, one of which is conducted in Latin. The courses of lectures, which are half-yearly, are considered expensive—about a pound being paid for those occurring four times a-week; two, for those occurring daily. The diploma of Doctor of Medicine and Surgery, however, when acquired, gives no right to practice, which is only obtained by a further years' attendance at an hospital, or on the practice of some distinguished practitioner—and by practical proof of capability, as evidenced in the treatment of (at least) two patients, in one of the public hospitals. This, which is called the State examination, and which costs nothing, is presided over by a Commission composed of the University Medical Professors, and of the principal medical men either of the hospital or of the city. The examination can take place only at Berlin, except in special cases of sickness. Thus admitted, the Doctor may practice in every part of Prussia.

The *First-Class Surgeon* is not required to have studied philosophy, but must have acquired a good preliminary education in one of the State schools. After three years study of medicine and surgery, which costs him nothing, he is admitted to an examination, which is not severe, and for which he pays about £10. He is then allowed to practice anywhere in the country, or in towns not having more than 5000 inhabitants.

The *Second-Class Surgeons* differ from the preceding, in studying for only two years—in paying a pound less for their examination, in which they are obliged to show their knowledge of Latin. They may practice anywhere,—but if in cities, they are placed under the control of the Doctors and First-Class Surgeons. In cities, also, they are forbidden operations, and the practice of medicine, except under superior orders; and their numbers are limited in a certain proportion to the population. They frequently keep shops, and unite the trade of barber with surgery. In the country, they are in no way interfered with.

MILITARY MEDICINE assumes great importance, as might have been expected, in Prussia. The army doctors must all pass, whatever their previous acquisitions in medicine, through the "Frederick-William-Institute"—in which they receive lodging, food, and instruction, gratis, with a small pecuniary allowance. The course of studies is similar to that of the Doctors before given, up to the point of receiving the diploma, which is paid for. The candidates are then placed, as dressers, in the great Civil Hospital of Berlin, where they successively give two months exclusive attention to the different divisions of surgery,—Midwifery, Medicine, Diseases of the Eye, &c. They are then nominated, as Surgeons, to a company or battalion—and, after three years, they are frequently permitted to return to Berlin, to pass the second examination (for practice), and either establish themselves as Civil Physicians, or aspire to the desiderated post of medical attendant to the Great Military Hospital, which is always accessible to one in nine. The latter appointment gives a right to the next vacancy as Regimental Surgeon. Military service extends, in *rule*, to eight years—but, in practice, the Army Surgeons are allowed to retire much earlier, and have

the fullest permission to establish themselves in civil practice in any part of the Empire.

Candor dat viribus alas.

The recent occurrence of a contested election for the Coronership of Gloucestershire, in which (from political, or rather PARTY, considerations) a medical candidate sustained a defeat—and the expected approach of another, for the county of Durham, in which one legal and two medical candidates are reciprocally opposed to each other—the two circumstances occurring on the heels of each other—have recently drawn considerable attention to the question of the rival claims of Medicine and Law to these judicial appointments.

Before considering this interesting and very proper subject of enquiry, it is right to state—that medical men, in advancing their claims, stand (as a body) with clean hands before the public. The experiment of Mr. Wakley's coronership, if it has proved nothing further in the way of *ex-tranco's* weal, has certainly established the previously-unsuspected fact, that medical men have, as a body, a strong pecuniary interest in the preservation of *legal* coroners. To the extent of the number of coroners in the kingdom there are, we admit, individuals in our ranks who have a pecuniary interest in *excluding* legal candidates,—but, with the exception of those units, the whole thirty thousand of us are bound over to oppose an aspiring brother, in as many guineas as we are likely to have attendances on fatal accidents and sudden deaths. In one word, the MEDICAL coroner can do without us—the LEGAL cannot. Now, if we cannot, as we would wish, deduce from this circumstance any *certain* inference that, by medical coroners, there will be a reduction in the county rates proportionate to the medical body's losses—(our model coroner having, unfortunately, recorded on the Middlesex ledger one rather startling instance to the contrary)—we may, at least, thence fairly claim for our judgment the high value conferred by disinterestedness, if, after maturely weighing the subject, we prefer to the office those of the two who will be to us the source of the less emolument.

The best possible coroner would, undoubtedly, be one who was at once perfect lawyer and perfect doctor,—one who, in the first capacity, would rank with a Follett —and, in the second, occupy equality with an Arnott: but superlative excellence of this double kind can only be expected in such a man as the Admirable Crichton; or that still more admirable character of our own day, who, invested in his cerebral development with all the omnipotence of a very fortunate vanity, is at once an efficient M.P., a *laborious* journalist, an ardent coroner, and indefatigable—invalid!

We pass, then, to the second-best coroner —who, to our minds, is he who knows enough of law to keep him out of constant collisions with its legitimate expounders, and save him from a morbid fear of the reporters, and is sufficiently well acquainted with medicine to know where medical testimony is required, and how to estimate its value.

These two classes of candidates, however, rarely come before us,—and the practical question is between the mere lawyer and the mere doctor. Examined by our test of public good, the conclusion is soon reached. Life is of more consequence than law—health than technicalities —the prevention of crime, than the avoidance of verbal contentions,—and, in something like that proportion, is a MEDICAL of more value than a LEGAL coroner. Which would the poisoner more fear? Under which of them would he be most deterred from crime? The external aspects of men dying by apoplexy, heart diseases, poison, and rupture of the viscera by certain kinds of external violence, present no distinctive characters to non-medical mem. Various as are those causes of the same fatal result, they stamp no abnormal, certainly no prominently dissimilar, physical effect on the external frame; indeed, so slight are the outward distinctive traces, that the most they would probably effect for the most practised medical man—the ablest physiognomist of death (so to speak)—would be to awaken suspicion, and urge him to those further investigations which would tell, with something like certitude, the agents that have been in action. The existence of a difficulty of this kind—and of no common occurrence either—is shadowed out, and not darkly, to us, by the numerous verdicts of "Died by the visitation of God"—under which coroners and juries are accustomed, every day, to shield their ignorance of the specific causes of death. The legal man may have a better notion of verbal or documentary evidence,—may better estimate its worth—but he is at sea on all that regards the best and strongest of all the evidence offered — that presented by the corpse. The perpetrators of murder seek no witnesses,—apart, therefore, from corroborating circumstances, the main witness will always be the deceased; and it requires no great perspicacity to see that, when a coroner cannot attain the requisite evidence for himself, nor know how or when to ask the assistance of one who can, the criminal finds no greater friend—and guilt no greater coverer—than the judge whose office it is to detect the one and punish the other.

Thus hastily glancing at the question, we may shortly state that our arguments resolve themselves simply into this:—the office of the coroner being as much medical as legal, if he can only master one-half of his duties, that half should be (if there be any difference) the more important division,—which being evidently that which enables the coroner to make his office most preventive and detective of crime—we mean the medical division—it follows that in the cause of public health, public morality, and individual safety, the medical *(cæteris paribus)* should be supported, in preference to the legal candidate.

EXTRACTS FROM FOREIGN JOURNALS.

Muller's Archives, No. IV. 1842.

This number contains several papers of interest. The first is:

On Parasitical Fungi, developed by the Mucous Membrane of Dead, and Living Human Bodies. By Adolph. Hannover.

The author of this paper offers the result of his observations on a great number of subjects, healthy and diseased. It would seem that certain disorders (of which typhus is one) result from, or at all events, are coincident with the growth of peculiar fungi on certain mucous membranes, particularly of the œsophagus and other portions of the alimentary canal. An abstract of the paper, which is very long and accompanied with tables, shall appear in a future number of the Medical Times.

Contributions to the Anatomy of the Actinia. By Prof. Erdl, of Munich.

On the Development of the Asteroida By M. Sers.

Some Results of Examinations relative to the Anatomy of the Araneida. By Dr E. Grube.

Observations upon the Swimming Bladder of Fishes, with reference to some New Genera By J. Muller. Read in the Berlin Academy of Science, June 16th and 23d, 1842.

The subject matter of this paper is arranged under three separate heads:

1. On cellular swimming bladders and lungs.
2. On a springlike apparatus for increasing and diminishing the density of the air in the swimming bladder in certain genera of siluroides, and a similar structure in other fishes.
3. On a family of soft finned fishes possessing ossula auditus in connexion with the swimming bladder, with remarks on the system of soft finned fishes.

First.—The first division of the subject is thus commenced: "The older accounts of organs which served the purposes of lungs, or the cellular swimming bladders of fishes, offered by Severinus, Brodbelt, Schoepf, Broussonet, and others had not been confirmed, but Cuvier discovered, in the *lepisosteus* and *amia*, a true cellular swimming bladder, similar to the lungs of a reptile. I have discovered a similar structure in some other fishes, besides the genus *erythrinus Gronov.*, where I announced its existence some time ago."

Muller details the particulars of his discovery, and purposes to make the presence or absence of this cellular, or lung-like structure in the swimming bladder, a character of specific difference in the genera *erythrinus, macrodon*, and *calophysus.* Finally, he concludes the first division of his paper with this remark: "As certain as the swimming bladder of fishes is no lung, it is no less certain that the development of a true lung in fishes cannot be denied as impossible."

Second.—"The greater number of fishes," says the writer, "are not in a condition to rarify the air within their swimming bladders. The muscles of the latter are intended for the purpose of the air's *compression.* Quite different is a structure discovered by me in certain genera of river fishes, where the states of compression and rarefaction are placed under the control of two active and opponent forces, centred within the fish itself, in such a manner that the compression is continually active, and originates in the elasticity of a spring, whilst the rarefaction depends on permanently acting vital muscular powers, the force of which this spring can suspend at will. When the compressing agency of the latter is not in opera-

tion, such fish swim at a great depth, corresponding with the specific gravity of their bodies, as determined by the compressed air in their swimming bladders; but they rise to the surface through the agency of muscles—a condition different to that of most fishes."

Then follows an anatomical description of the spring like apparatus.

Third.—With respect to the third division of the subject, Muller states, that *Weber* discovered a connexion between the organs of hearing and the swimming bladder, by the intervention of *ossa auditus* in the genera *cyprinus, cobitis,* and *silurus,* This peculiar structure, the author has discovered to exist in many other genera of true *cyprinoids,* as well as every genus of siluroids, provided with a swimming bladder. The connexion of the swimming bladder without hearing bones, directly with the labyrinth through the intervention of air canals, as in the genus *clupea,* Muller discovers to exist in many other genera under Cuvier's *clupeides:* also in the *engraulis* and *notopterus.*

On the Anatomy of the Sepiola. By Dr. W. Peters, assistant in the Anatomical Museum of Berlin.

This gentleman states that he was engaged during a long residence in the Mediterranean Sea, in examining the structure and habits of various molluscous animals;—particularly the class cephalopoda. His attention was especially directed to the *Sepiola,* or cuttle-fish tribe, with the view of settling some anatomical discrepancies as to the real form and constitution of their ink-sacs. He thus commences his paper

"Grant described the ink-sac of *Sepiola* as a great, almost quadrangular sac, consisting of three flaps, of which the two lateral ones are reniform, and the front one possesses a thick glandular white partition. Owen has, however, observed in his 'Rossia Palpebralis,' (*Sepia palpebralis Gervaise et Vanbeneden*), a construction of the ink-sac altogether different from that just described, inasmuch as it possesses all the simple form common to other cephalopoda."

Dr. Peters proceeds to say, that he discovered considerable dissimilarities of this structure in sepiola not otherwise distinguishable from each other. Some possessed one simple sac, just like all mollusca of this class; in others, there were seen two black—synchronously pulsating organs, one on either side of the intestinal canal. The contractions followed each other at about the interval of a second between them. Peters at first imagined those organs to be accessory hearts; but further investigation satisfied him that they were devoid of any connexion with blood vessels, but communicated merely with the central sac.

He proceeds to say, —"This very different structure of the organs in the sepiola, appeared a circumstance of sufficient importance to warrant the assumption that there was a distinction of species, if not of genera, notwithstanding all other similitudes."

Further investigations, however, induced him to alter this opinion, and the examination of many specimens, caught at various periods of the year, proved, almost incontrovertibly, that the varieties of structure already alluded to were merely temporary. He is unable to assign a cause for this, but finds it quite independent of differences of sex, or the various phases of development of the sexual organs.

Finally, he concludes by saying, "I must also leave it in doubt whether this change occurs yearly or not; although the former appears probable, from the circumstance that out of many of these individuals caught late in the summer and in autumn, there were at least as many without as with the lateral organs; whilst amongst almost fifty caught in the months of April and May there was found only one which possessed the simple vascular organ."

The description of Grant is presumed to have been the result of an alteration in the physical appearance of parts, occasioned by their immersion in spirit,—under similar circumstances, Dr. Peters remarks, he should have come to the same conclusion. Dr. Grant's specimen, it would appear, was caught early in the year, and his description is correct *so far as it concerns the dead animal macerated in spirit.* Professor Owen's specimen would seem to have been taken late in summer, or in the autumn at least; judging from the researches of Peters, his description refers to the form of ink organs in that season.

CASE OF INTUSSUSCEPTIO.

By J. N. ASHWOOD, Esq., North M Ron.

Oct. 27th I was requested to visit Miss V., æt. 22, of full habit: she was then on a visit to some friends in this place. I was informed she had been in great pain for some hours. I found her suffering from enteritis; she complained of excessive continual pain in the lower part of the abdomen, just above the pubis especially, but diffused over the whole abdomen, with great tenderness on being pressed, constant sickness and vomiting, bowels not constipated, urine natural in colour and quantity, pulse 120, the usual pulse of enteritic inflammation, she could lie with her lower extremities extended without inconvenience. I immediately bled her ad syncop., gave her a full dose of opium, and as soon as hot water could be made ready, placed her in a hot bath, where she continued till she fainted: when placed in bed, fomentations and light poultices of bran were applied to the abdomen, calomel and ext. coloc. omni bihor, until free evacuations from the bowels were procured, The pain and sickness were much ameliorated after the bath, and in a few hours she became quite free from the inflammatory symptoms; the pulse under 90, fuller, and soft; the bowels freely moved - no tenderness or soreness of the abdomen on pressure. The next morning, the 28th, I found her comfortable, but in the afternoon I was sent for, as the inflammation had returned with the same violence as on the preceding day; the symptoms were as before, and the same measures were had recourse to with the same success. The next morning I was again called very early, when I found the disease returned; bleeding, &c. were again employed and with effect as before, she became quite easy. The next day, 30th, she was free from all symptoms of inflammation, but suffered from violent spasmodic pains in the abdomen (about the srobiculus cordis, and above the pubis), shooting through to the loins, the pulse not quickened; but this was soon relieved by a liberal dose of tinct. opii. I left her at night free from pain, the bowels had been relieved several times. On my morning visit of the 31st, I was much distressed to find the inflammation had returned, with, if possible, greater effect than before; I immediately bled her to syncope, and a bath being quickly got ready she was placed in it. At this time, her father having wished their family medical attendant to be called in with me—Mr. Flexman, of South Molton—he had been sent for, and arrived whilst she was in the bath. I mentioned to him my suspicion of intussusception, not from any diagnostic symptom being present, for there was none, but from the obstinate renewal of the inflammation, after appearing quite extinguished. He concurred with me in the necessity of again bleeding, for the last, although copious, had produced no relief; she was bled in the bath to a considerable quantity, but syncope was not produced, yet she was in a fainting state; when taken out of the bath a blister was applied over the whole abdomen. The symptoms gradually gave way; she had no return of the inflammation, but the following day she suffered from violent spasmodic pain in the right iliac region, with some fulness, but no definable tumour, with tenderness on pressure, no tenderness of the abdomen generally; the pain was relieved by occasional opiates, &c., when violent, together with fomentations, poultices, &c., but not removed. She now began and continued gradually to improve, yet the pain continued occasionally to harass her. She took no medicine after the sixth; on the 12th, she was removed to her father's house, when I lost sight of her. About three weeks after, Mr. Flexman requested I would call at his house, to see a portion of bowel and mesentery, which she had voided per anum the day before, and which her mother had sent to Mr. Flexman for examination, and which he considered a part of the colon. I called and found it as he had described, it was a portion of the entire canal of that bowel, about six inches in length, with its corresponding portion of mesentery attached; at the extremity of the mesenteric portion was a large artery, full the size of a goose-quill, with its open mouth as smoothly divided as though cut through with a scalpel, the mucous membrane of the bowel was of a dark chocolate colour, but the peritoneal appeared normal, the ends of the bowel appeared as though separated by the ulcerative process. The patient is at this time doing as well as might be expected, the only inconvenience she suffers is a difficulty of raising herself erect, with a sense of tightness near the seat of the cœcum. Mr. Flexman saw her but once after she returned to her home, previous to her passing the separated bowel—she took no medicine.

It is quite evident this was a case of intussusception, inflammatory adhesion of the invaginated portion, and separation by ulceration —there are many such cases on record, one where nearly a yard of intestine was separated, but in every case of intussusception I have read or seen, there were present unequivocal diagnostic symptoms of this affection. In this case, there was not the slightest symptom which could be regarded as diagnostic, unless the obstinate and frequent return of the disease might be so considered; there was nothing like stercoraceous vomiting, not the slightest appearance or smell of fæcal matters in what was vomited, but solely the contents of the stomach with bile, and the bowels were easily kept free (at first by calom. and ext. coloc. c. and enemas), through the whole course of the disease, from its commencement until the separation of the bowel: and after the termination of the inflammation, without the aid of medicine, her mouth was slightly affected about the fifth day. Before concluding, permit me to ask your readers, was not this life saved by the determined treatment? She was bled five times, each bleeding averaged at *least* twenty ounces Would not bleeding in clear cases of intussusception carried as far as is consistent with the preservation of life, be the means of bringing the patient safe through?

MR. ROBERT STEVENS'S DISCOVERY OF THE TRUE FUNCTION OF THE SPLEEN, AND ETYMOLOGY OF THE WORDS "SPLEEN" AND "MILT."

(To the Editor of the 'Medical Times.')

SIR,—A few of your readers may have seen an announcement in the *Lancet* of December 3, 1842, to the effect that Mr. Robert Stevens, of Kennington has discovered the true function of the spleen. The announcement states that the "discovery" has been made by means of *microscopical* examinations of the organ in a *live mouse*, and that the details and results of the *experiments* are at present before the *Royal Society*. The *Lancet* says, "We are not acquainted with them minutely, but believe that the facts at which Mr. Stevens has arrived, may be comprehended by a very brief exposition," and which the *Lancet* then gives as follows:—

"The circulation in the spleen of a live mouse may be easily shown, for the organ in that animal is fissured, and often divided. The blood corpuscles undergo no detention in it, and there is no intervening nondescript parenchyma between the capillaries of the organ. The blood undergoes no change in the spleen. In a dog which has been opened alive the contrast in colour between the blood in the splenic vein and the superior mesenteric will be plainly seen. The organ takes its name from *splen*, *splendeo*, and its vulgar name "*milt*" from *miltus*, vermillion. It is only some time after death that the spleen acquires its deep blue tint. But Mr. Stevens it is said, has proved, by direct experiment, that the addition of the splenic blood is necessary in the portal circulation, or, in other words, that an addition of arterial blood is necessary in the portal circulation, for such the blood really is. Now, were the arterial blood added direct, we should have the unprecedented instance of an *arterio-venous anastomosis*, which is contrary to the laws of general anatomy. The spleen is simply the necessary interposition of capillaries, betwixt the splenic artery (which is the largest of the cœliac axis) and the venous portal circulation. Such is the theory of Mr. Stevens."

The preceding exposition is perfectly clear and intelligible. There can be no mistake as to what Mr. Stevens means. He says, in fact, that the *use* of the spleen is simply to divert arterial blood into the portal vein, and that the organ itself is only the necessary interposition of capillaries between the splenic artery and the splenic vein. In answer I shall begin by simply stating that my object is to prove first, that the use of the spleen is *not* to divert arterial blood into the portal vein, but to propel the portal blood through the portal plexuses and hepatic veins into the right auricle; secondly, that the spleen is not simply a mere interposition of *capillaries* between the splenic artery and splenic vein, which nature has placed there in order to avoid infringing one of her own laws, or to obviate the occurrence of a direct arterio-venous anastomosis between the splenic artery and vein; but that the spleen consists chiefly and essentially of *venous radicles*, and that it is to be regarded *not as an isolated organ, but as the roots of an important vein*, THE SPLENO-HEPATIC VEIN, under which term is comprised the *spleen*, the *splenic vein*, the *portal trunk*, and its *ramifications* in the liver, to their terminations in the capillaries of the liver, the portal plexuses; and that the whole of this vein (roots, trunk, and branches, and of which vein the spleen is, as I have just said, simply the roots) possesses in an eminent degree the property of vital contractility, and is for the sole purpose of receiving the portal blood, and propelling it through the liver into the heart. I shall also show that neither the left ventricle, nor any other agent but the spleno-hepatic vein is capable of propelling the portal blood.

The case on both sides being stated, and made, I trust, perfectly intelligible, I shall now attempt to prove that the use of the spleen is NOT *to direct arterial blood into the portal vein*. I shall not begin by denying Mr. Stevens' statement that the splenic blood is arterial blood. I admit that it is an imperfectly carbonised blood; and it would be a mere dispute about words to disagree as to whether the blood in the spleen and splenic vein is *venous* or *arterial*. Upon this point we nearly agree. Mr. Stevens says the blood undergoes no change in the spleen. I, eight months ago, said, "the blood undergoes no change in passing through the spleen than it does by passing through most other organs"—and, that "there is as good reason to suppose that the venous plexus of the corpora cavernosa penis is for the purpose of sanguification or secretion (that is, for effecting a change in the blood), as the venous plexus of the spleen:" and the arguments which I then advanced to prove that the spleen is not for the purpose of effecting any change upon the blood, I shall now adduce, in opposition, to Mr. Stevens' theory that the use of the spleen is to divert arterial blood into the portal vein. Mr. Stevens remarks, that the splenic artery is the largest division of the cœliac: it is so in man only. In the quadruped the gastric and hepatic arteries are much larger than the splenic: and even in man, before birth, the splenic artery is smaller than the hepatic; because the spleen is then small, owing to the placenta, which is simply a temporary spleen being the chief—I had almost said, the *sole* agent in the portal circulation.

In quadrupeds, the splenic artery is smaller than the gastric and hepatic arteries, because the spleen bears a much less proportion to those organs in them than in man. In man, when the liver weighs more than *three pounds* the average weight of the spleen is about *eight ounces*; but in a pig (an animal which like man is omniverous, and the digestive organs of which bear no small resemblance to those of man) when the liver weighs *three pounds*, the spleen will weigh only *four ounces*. In the sheep and ox the relative size of the spleen to the liver is still less. Now, as in man, the spleen is in proportion to the liver as *one* is to *six*, and in the pig as *one* to *twelve*; it follows (as the spleen of the former is twice as large as the spleen of the latter—the liver in each being of the same weight) that the splenic artery of the pig will be only half the size of the splenic artery in the man, because the size of the splenic artery is proportionate to the size of the spleen, or to the quantity of venous radicles of which the spleen is composed; and therefore, as the spleen and splenic artery of the pig are only half the size of the spleen and splenic artery of the man, *the portal blood of the pig will have only half as much splenic blood, or arterial blood, or imperfectly carbonised blood, supplied to it as the portal blood of the man*. Now I ask Mr. Stevens why the portal blood of the man *requires* twice as much splenic blood as the portal blood of the pig? or why the portal blood of the pig *requires* only half as much splenic blood as the portal blood of the man? It is quite plain that it *is* so. As the spleen of the pig is only half the size of the spleen of the man, the liver in both being equal, it is clear that the portal blood in the former can receive only half as much splenic blood as the portal blood of the latter. There must be a *reason*, and a good reason too, why in man the spleen as compared with the liver, is more than twice as large as the spleen of the quadruped is, as compared with the liver of the quadruped; and I ask Mr. Stevens to give us that *reason*, to tell us, in accordance with the principles on which he rests his theory, *Why it is so?*

If Mr. Stevens theory is the *true* theory (and the Lancet *announces* it as such, and of course the Lancet ought to *know*) THEN THE SPLEEN OUGHT TO BEAR THE SAME PROPORTION TO THE LIVER IN ALL ANIMALS; AND OUGHT NOT TO BE TWICE AS LARGE IN MAN AS IT IS IN QUADRUPEDS. *That* is the objection I oppose to Mr. Stevens' theory; and that single objection will overthrow every false hypothesis concerning the spleen: and unless Mr. Stevens can show (which he cannot,) that the fact from which the objection is drawn squares with the theory, and the theory with it, as though the theory were made to explain the fact, and the fact to support the theory,—the theory must fall; and fall it will, for it is directly opposed to the fact; and is supported, not by *truth*, which alone can substantiate a theory—but *friendship*.

Having then shown that Mr. Stevens' theory is at variance with an important fact, I shall, in the next place, show that his view of the structure of the spleen is erroneous. He says the spleen is "*an interposition of capillaries between the splenic artery and vein.*" Now nothing can be more obvious than that this statement is incorrect, or that the spleen does not consist of *capillaries*, or minute canals intervening between the terminations of arterial ramifications, and the radicles of veins. The spleen consists chiefly and essentially of *venous radicles*, which are highly distensible, and as I shall subsequently show contractile; but who ever heard of *capillaries* being remarkable for their distensibility? If the spleen consists merely of *capillaries*, how happens it that sometimes it is distended, and at others contracted? If it consists of *capillaries*, how comes it to bear so close a resemblance to the corpora cavernosa in "texture and phenomena?" Is the calibre of capillaries subject to much variation, and if not, how can the spleen, if composed merely or chiefly of *capillaries*, vary so much in its degree of distension, as it is known to do at different times?

But no *argument* ought to be needed to disprove Mr. Stevens statement. The most superficial and cursory examination of the *organ* is sufficient; at least in any animal of larger dimensions than a *mouse*. Mr. Stevens knew when he was framing his hypothesis, that it was necessary the structure of the spleen should accord with his explanation of its use. Unfortunately, however, it did not; and therefore he immediately set about trying to make the structure square with the hypothesis, because the hypothesis would not square with the structure. In short, nothing but the necessity of bolstering up a sick theory could have caused Mr Stevens to take a plexus of venous radicles for capillaries: unless, indeed, it so happens, that his microscope diminishes instead of magnifying the apparent size of objects upon which it is employed.

As my letter has grown to a considerable length already, I shall reserve for a future communication the arguments which show that nothing else than the spleno-hepatic vein can propel the portal blood through the liver. I will therefore conclude with the following extract from a letter which I recently received from a friend, and which shows Mr. Stevens etymological "discoveries" are about on a par with his physiological.

"Mr. Stevens derives the Greek word *splen*, from the Latin *splendeo*, to shine; and the English word *milt*, from the Greek *miltos*, red

lead. Mr. Stevens may have heard of a certain Greek author named Hippocrates; nay, stretching probability a little further, he may have read his writings—in a translation; and if so, he may, perhaps, recollect that Hippocrates makes frequent use of the word *splen.* Now let this etymologist take up Lemprière's Classical Dictionary, edited by Barker, and turn to the head 'Hippocrates.' There he will find that Hippocrates died B. C. 390; and if he further turn to the article 'Rome,' he may read thus:—'B. C. 388, was a period when no Grecian writer knew aught of Rome—even by report, as a city actually in existence, since only two years previous (B. C. 390) it had been burned by the Gauls, and it was not till more than a century afterwards that the Romans became known to the Sicilian Greeks by the capture of Tarentum.' *Thus* (according to Mr. Stevens) *the Greeks* B. C. 391, *were daily using a word derived from a language utterly unknown to them till more than a century afterwards!* With regard to *milt*, it is a word current among all the children of the old Goths—among the low Dutch, Danes, Swedes, Icelanders, &c., &c. It was a household word in the mouths of their forefathers; those old pagan savages who roamed over the forests and wilds of Europe. Did these fierce idolaters, who neither knew nor cared for any language but their own guttural jargon, pay a visit to civilized Greece in order to learn that *miltos* was Greek for red lead, and adopt the word accordingly? Really the supposition that the word *milt* is derived from the Greek *miltos* is utterly preposterous and unworthy of refutation."

I am, Sir,
Your obedient servant
JOHN JACKSON.

6, Stonefield-street, Islington.
Jan. 6, 1843.

[We are informed that Mr. Stevens modestly disclaims the etymological brilliancies for which Mr. Jackson gives him credit, and that they are the exclusive property of the erudite and very ingenious editor of the Lancet—whom to rob of such rare gems in the way of *classical* research would be little short of the one unpardonable sin. Verily the readers of the Lancet must be a meek and most enduring race. How we pant for better acquaintance with such christian-like smite-bearers!—ED.]

PENCILLINGS OF FOREIGN MEDICAL MEN.

(Prepared from German sources for the 'Medical Times.')

DR. SAMUEL THOMAS VON SOEMMERING.

(Concluded from page 219.)

After order had been established at Mentz, he returned thither, but soon resigned his office, and removed to Frankfort in the midst of his family. Here he completed his work on the structure of the human body, and his assertion that the substance of the heart is devoid of nerves, which he supported by numerous reasons, created a great sensation. Soon after, he published a work on the seat of the soul, which he sought for in the vaporous fluid of the cavities of the brain, the walls of which never approach each other, and contain the commencing and terminating points of the nerves, which are continually moistened by it, and are acting again reciprocally on the fluid of these cavities. Then followed his "Tabula sceleti feminini juncta descriptione;" his very instructive figures of the human embryo; a series of figures of the human ovum from the earliest period up to the third month, and then the figures of the basis encephali, unsurpassed either in accuracy or elegance by any other work hitherto published.—After some short interval followed the figures of the human eye, which were succeeded by those of the other senses, which, by their high finish, are considered as patterns in anatomical literature. But besides these splendid specimens of human anatomy and physiology, Soemmering began to pay great attention to comparative anatomy, and examined and determined many fossil remains of the primeval world.

Thus several years were spent entirely between the circle of his family and close attention to science, and if he allowed himself some relaxation, it consisted in travelling, in which he extended the sphere of his knowledge, and that of his scientific friends. A son and daughter were born to him, of whom the latter is now an esteemed physician and oculist at Frankfort.

When the late King of Bavaria intended to revive the Academy of Sciences at Munich, and to constitute it as one of the leading features of the state, his attention was directed to the great services which Soemmering might render this Institution, who was, therefore, named in 1805, one of its first members. About this time he made the acquaintance of Cuvier, having, amongst others, rectified the opinion of the great French naturalist about the pterodactylus, (an antediluvian animal), which Cuvier had ranged with the reptiles, but which Soemmering proved to belong to the genus of bats (vide "Memoirs of the Academy of Munich," 1810.) They never could agree on that point, but remained friends notwithstanding. Cuvier described and figured in his great work on fossil bones, several specimens which he had obtained from Soemmering, and presented him, in exchange, with many rare palæatherium and anaplotherium bones, which are now deposited in the Senkenberg Collection at Frankfort.

His principal works of that epoch were "on the liquids absorbed by the nerves, as well in their healthy as morbid states, 1811." "On the crocodylus priscus."—"On the antediluvial lacerta gigantea, 1817." "On the tissue of vessels of the sclerotica of the eye, 1818." "Remarks on the stomach of men.

The favourable circumstances in which Soemmering had always fortunately lived, continued up to an advanced period of his life, and on the 7th of April, 1828, he celebrated the fiftieth anniversary of his doctorial promotion, on which occasion a medal was coined, having on one side the image of the professor, on the other a figure of the basis encephali, by which he had become chiefly known. He lived two years afterwards in the proud consciousness of having so powerfully advanced science. But having during the severe winter of 1829, occupied himself with observing the spots in the disc of the sun, he fell at once into a state of debility, and expired gently on the 2d of March, 1830. His death was severely felt through Germany, and even through Europe. The Royal Academy mourned this event in an extraordinary sitting, when Professor Dollinger pronounced a panegyric, from which especially the present memoir has been compiled.

An especial trait, which pervades all Soemmering's works is an unlimited love of truth, and the merits of others found in him the most perfect acknowledgment. His science he esteemed high, but searching, as he did, merely after truth, he did not extol any branch of it above another, and kept aloof from any partial one-sided predilection. It was repugnant to him if another expatiated on the excellence or preference to be given to certain parts of the human body, as if the others were coarser, less significative, less skilfully constructed, less worthy of our admiration. "As I can take to myself," says he, in the preface to the fifth vol. of his great anatomy, "some knowledge of the different parts which constitute the human body, I must confess that the hand seems to me as finely formed, as systematically combined, as worthy of admiration as the eye. I start from the axiom, hand is all, eye is all, and I warn any one from opposite one-sided prejudice." It can not be doubted that this enlarged mode of viewing the human body is the only one worthy of the real philosopher. We have before mentioned Soemmering's fondness for astronomy, and his last observations of spots of the sun, which were arranged by Professor Thilo, and published by the Senkenberg Society at Frankfort. Thus Soemmering, whilst he viewed everything from an elevated point of view, succeeded in inscribing his name even among the "*Stars Eorum laude Ingenium, Astra relant mori.*"

MESMERISM.

(To the Editor of the 'Medical Times.')

SIR,—You did me the favor to insert some time since in your really valuable Journal a short account of an operation performed in Jamaica during the mesmeric trance, and on which a kind of doubt was cast by me; at least I concluded my communication with saying that I was content to take it only on the authority of the editor of the *Jamaica Despatch.* I am now happy to say that the truth of such an operation having been performed is vouched for by the editor of the *Jamaica Standard,* a gentleman with whom I had the honor to be acquainted when in Jamaica, and whose word I would as soon take as his bond. I inclose the paper with this; but to save you trouble, I will copy the remark he appends to the insertion of the case: he says "we can assure the doctor, that all is right upon this head, and that many other experiments of *equal interest and importance* have since been made with precisely similar results."

You will perhaps allow me to add a mite to the vast accumulation of mesmeric facts which are every day forcing themselves upon the notice of the medical world. The first case is that of a lady who had a stiff neck. She complained very much of it, and I offered to mesmerize her. She consented, and I *succeeded in twenty-five minutes.* The second, was that of a man who had an extremely excruciating tooth-ache, and he was proceeding to a dentist to have it extracted, when he consulted me. I said I will remove it by mesmerism. He almost laughed at the idea; but, nothing daunted, I excited strong volition, and made the usual passes. In less than twenty minutes the tooth-ache was gone, and the poor fellow was actually about to run away, thinking that I possessed the power of an evil spirit! I quieted his apprehensions, and he has had no return of the pain, excepting a soreness.

I must add one other remark, because I wish for information on the subject—it is this:—Whenever I mesmerize—particularly my son, a boy of five years of age—I have, at the tips of my fingers, a feeling of clamminess, which is like *gluten.* Is this an invariable accompaniment? Mr. Brookes, who was in London last summer, told me it was, and that he always felt indisposed after mesmerizing. I can't say that I do; but in the case of the lady, I had shooting pains through my head—but they did not continue long. Dr. Elliotson assured me that he felt no inconvenience whatever from mesmerizing.

Your obedient Servant,
EDWARD BINNS, M.D.

Montague street, Portman Square,

AN INTERESTING CASE OF MIDWIFERY

By W. Thomas, Esq., Surgeon, Pembroke Dock.

Mrs. G., a young woman, pregnant with her first child, and near the period of her accouchment, stooping down for the purpose of relieving the bladder, "felt something," to use her own words, "suddenly crack across the lower part of the belly," and a large swelling of the right labium, was the immediate consequence. I was summoned on the moment to attend her, and found her lying on her back with her knees, of necessity, widely extended, to prevent the pain of pressure, and asserting "that the head of the child was actually in the world." On examination, however, I discovered that instead of a child's head, the swelling consisted of extravasated blood, enormously enlarging the right labium, as above mentioned, totally deranging all normal appearance of the external parts of generation; cold applications, with aperients and anodynes, were recommended. There being no reduction in the size of the tumour, a lancet was introduced, on the second day, and, by the aid of the finger, masses of coagula, mixed with detached cellular tissue, were, as it were, scooped out. Retention of urine occurred, and the bladder filling, passed out of the pelvis, forming a distinct

swelling, extending along the right iliac region, nearly as high as the umbilicus. The line of demarcation between the two viscera, viz., the bladder and the uterus, was accurately defined by a deep fissure, each viscus being of great size, and nearly parallel. Every effort to introduce the common female catheter proved ineffectual. A gum-elastic one being substituted, was, after considerable difficulty, introduced, and the bladder emptied of a quantity of urine, equal to four pints. When the instrument was withdrawn it had the twisted appearance of a corkscrew, and indicated an elongation of the urethra to an extent, far beyond the reach of the silver catheter. The operation had to be repeated only three or four times before labour came on, the same impediment existing on each occasion. Finding the pains for some time of little benefit, although severe as to suffering, I admininistered a dose of the ergot—an infusion of the unbruised grain—and before the period arrived for the second, it being my usual custom to give it in divided doses, the pains became expulsive, a living child was speedily delivered; the placenta quickly followed, and no bad symptom afterwards occurred. The artery ruptured on the occasion (the uterine, or some other branch of the internal iliac supplying the parts,) must, from the almost instantaneous extravasation, have been of considerable size, and probably but for this infiltration, instead of external escapement of the vital fluid, might have proved fatal. The bladder recovered its tone without difficulty, never requiring any further introduction of the catheter after the labour. My friend, Mr. Noot, Surgeon of the Royal Yatch stationed at this place, who kindly afforded me his valuable consultation and assistance, having, like myself, never met with a similar case, I have deemed it advisable to publish the particulars, which cannot fail to be interesting, and for which purpose I solicit a nook in the pages of your valuable periodical. The case is important to the obstetric physiologist in various particulars. For instance, the immense and immediate extent of the extravasation, totally destroying all normal appearances of the external organs of generation, the displacement and distention of the bladder, with the consequent elongation of the urethra, together with the efficacy of the ergot in producing expulsive efforts in the uterus.

EXTIRPATION OF OVARIAN TUMOURS.

(To the Editor of the 'Medical Times.')

SIR.—You will oblige me by allowing me space to reply to some observation of Dr. Clay in the report he has given of his very valuable cases of extirpation of diseased ovaria. It was never my intention to advise any simple operation for ovarian dropsy in cases of enlarged and diseased ovana as described by the doctor; but as my previous painful experience consisted of twenty fatal cases, occuring in my own and in the pr.ctice of others, I lost no time in making the members of the Provincial Medical Association acquainted with the facts of my first case by reading them a short paper on the subject at their next meeting, and which is published in the fifth volume of the Transactions: "Sherwood and Gilbert, London, and Deighton, Worcester." The subject of this case is now in good health, and has been pregnant three times since the operation, and given birth to three healthful children.

I have since witnessed a successful operation by Mr. King of Saxmundham, and another by my friend, Mr. Crisp, of Harleston, Norfolk. The lady, the subject of the last-mentioned case, had been 23 years suffering from the disease, and had been twice tapped. Three gallons of fluid were taken from the cyst, which was then removed without the slightest difficulty; indeed, I would always enlarge the wound, should difficulty occur at this period of the operation, rather than make use of violent traction, and, should the circumstances of the case require it, this simple operation might be converted into the formidable one recommended by Dr. Clay. This lady perfectly recovered, and has enjoyed several years of health since the operation. Mr. West, of Tonbridge has likewise published several successful cases: therefore I think Dr. Clay must be wrong in his estimate of the comparative success of the two operations.

I am, Sir,
Yours respectfully,
WILLIAM JEAFFRESON, Surgeon.

Framlingham, Nov. 7th, 1842.

MEDICAL NEWS.

PARIS ACADEMY OF SCIENCES, Dec. 26.—A paper was read on the experiments of M. Flourens on the bones of animals. This gentleman, acting upon the known fact, that if an animal be fed for a length of time upon food of a particular colour, that colour will be imparted to the bones, has made various experiments, with a view to ascertain the extent to which this absorption of colour can be carried, and how far it may serve to indicate the process of nature in the development of the osseous structure. After a long discussion, no other conclusion was come to, than that M. Flourens had, by his researches, rendered an important service to science.—An interesting paper from M. de Humboldt was then read. He informs the academy that the preparatory labours for cutting a canal across the isthmus of Panama are advancing rapidly. The commission appointed by the Government of New Grenada, for the construction of a canal to unite the two oceans, has terminated its examination of the localities, and has arrived at a result as fortunate as it was unexpected. The chain of the Cordilleras does not extend, as was supposed, across the isthmus, and, on the contrary, a valley very valuable to the operation has been discovered. The natural position of the waters is also favourable Three rivers, over which an easy control may be established, and which may be made partly navigable, would be connected with the canal. The excavations necessary would not extend to more than 12½ miles in length. The fall may be regulated by four double locks, 138 feet in length; and the total length of the canal will be 49 miles, with a width of 135 feet at the surface, and 55 feet at the base; the depth will be 20 feet The canal thus executed will be navigable by vessels of from 1,000 to 1,400 tons. According to the estimate of M. Morel, a French engineer, the total cost of this canal would be only 14,000,000 of francs, including the purchase of two steamers.—A report was made by M. Regnault upon some experiments by M. Poiseuille, respecting the laws which influence the flow of water through very small tubes, shewing that with a perfect equality in temperature, density, and pressure, the flow is in direct proportion with the length of the tubes. —An account was laid before the members, of the second journey of Messrs. d'Arnaud and Sabatier to the sources of the Nile, in 1841 and 1842, by the western branch, or White Nile.—A communication from M. Morisset, on the virtues of the decoction of oak bark in various diseases for which it has not hitherto been used, was next read. This gentleman states that this is a valuable remedy in cases of encysted dropsy, in œdematous affections of the limbs, and for the obliteration of the herniary sack in young persons.—M. Chuart, the inventor of a means of discovering the presence of any deleterious gas when mixed with common air, has addressed to the academy a paper on the accident which occurred lately in the mine of Terminy, near St. Etienne, for the purpose of showing that if his invention had been in use there, the presence of the deleterious gas which caused the explosion would have been ascertained in time for the use of the precautions by which the accident might have been avoided. It is known that an explosion from the admixture of carburetted hydrogen with atmospheric air can only take place when the former exists in a certain and known proportion. When the quantity has reached or exceeded this point, the contact of a light instantly causes an explosion. The instrument recently invented to shew the existence of danger, is exceedingly simple, ingenious, and effectual. Connected with a chemical solution is a kind of float, nicely graduated, and attached to a counterpoise. The solution is of such a nature that it undergoes a change when acted upon by the admixture of carburetted hydrogen, and when saturated to a certain point the flat changes its position, and, acting in its turn upon the counterpoise, a spring is let loose, and strikes upon a bell or drum, giving out a loud sound, and thus indicating the presence of danger.

Jan. 2.—M. Gasparin mentioned his discovery of a remedy for the disease in sheep called chronic pleurisy. A gentleman had a large flock of sheep, which, owing to the variations of temperature, were attacked by this disease. A great number had already died, and the remainder were regarded as incurable, when he was informed that a journeyman hatter had succeeded in curing the disease by means of arsenic in large doses. He tried the experiment on 20 sheep which were in a dying state. He administered to each 32 grammes (more than an ounce) of arsenic in powder, mixed with common salt. In a week two died, but the others were cured No ill consequences, he says, attended the administration of the arsenic. Some doubts seemed to be entertained by several members of the academy of the correctness of the facts cited by M. Gasparin, and, supposing them to be true, it was observed by others that, in the event of administering large doses of arsenic, it would be of the utmost importance to ascertain how long a period would elapse before the poison would be expelled from the system.—M. Elie de Beaumont laid before the academy a specimen of quartz rock containing diamonds. This was wanting in geological collections; for hitherto the diamond had not been found in its natural bed, but detached from it, and in alluvial soils. The researches of chemistry having led to the discovery that the diamond is only crystallised carbon, attempts upon attempts have been made to produce it artificially, but one of the greatest obstacles to success with chemists, was their ignorance as to the changes which the diamond undergoes from its first formation until it assumes the state in which it is found. This discovery of the gem in its natural bed, will perhaps enable chemists to add to their knowledge of the means by which the carbon of which it is composed becomes crystallised.—M. Bravais made a communication relative to barometrical and thermometrical changes in high latitudes in the absence of the sun, shewing that with a very feeble variation of the thermometer that of the barometer is considerable.—The report of a commission on the

candles called *bougie de l'etoile* was read. These candles are a composition of stearine made very hard, and reduced to a perfect whiteness. The wick requires no snuffing. An alarming paragraph, appearing in nearly all the papers, asserted that the quantity of arsenic contained in the candles was so great as to be seriously injurious to health, by inhaling an air impregnated with poison; but M. M. Danger and Flandin, who have analysed the *bougie de l'etoile*, report to the academy that they have not found in it the slightest trace of poison.

PERISCOPE OF THE WEEK.

On the Decussation of Fibres at the base of the Brain.—M. Foville points out, what all admit, that the extent of the decussation of fibres commonly demonstrated between the corpora pyramidalia is not sufficient to account for the completeness of the paralysis of one side of the body when the other side of the brain is impaired. "There is no proportion as to size, between their discussating fibres and their point of origin, the crura cerebri, or their termination, the anterior fasciculi of the spinal cord." He has succeeded, however, in demonstrating "a decussation at the commencement of the spinal cord, not through an extent of a few lines only, or by only a small number of filaments, but through the whole distance which separates the basis of the crura cerebri from the medulla spinalis properly so-called."—The anterior columns of the cord, when arrived at the medulla oblongata, separate from the middle line to give place to the corpora pyramidalia, and at the level of the tuber ascend and pass at right angles over the uppermost of its arcs. The posterior columns on the other hand pass outwards from the apex of the columns going to the crura cerebelli, and leave exposed the anterior fasciculi, which are then visible behind through the whole length of the floor of the fourth ventricle, and along the aquaeductus sylvii to the infundibulum.—The crura cerebri, for their part, form, from above downwards, a section of a cone, of which the fibres, instead of taking a straight direction, are turned spirally, and successively approach the median fissure into which they penetrate and plunge into the inner part of the anterior fasciculi of the medulla spinalis. The fibres from the right crus thus pass into the prolongation of the left anterior fasciculus, and *vice versa*. Along their course, the crura constantly giving off fibres which pass thus from one side to another, gradually grow thinner, and at their exit from the tuber they constitute only the base of the anterior pyramids. The same circumstances continuing they become finer and finer, till their very apices decussate at the boundary between the medulla spinalis and medulla oblongata. The transference of all the elements of the crura cerebri from one side to the other of the nervous axis is thus completed.—The mode of demonstrating this arrangement is to separate the two lateral portions of the nervous axis from the apex of the calamus to the infundibulum by separating the borders of the median grove. When this is done gently, each half may be seen to furnish an infinity of fibrous fasciculi of various size, which pass across the interlacing with each other.

Scarlatina.—Like rubeola and variola, scarlatina is a native of the East, first made known to us by the writers of the Saracenic school, and transmitted to Europe by the Crusaders. No recount, says Mr. E. Wilson, of a disease analogous to scarlet fever appears in the holy writings, whence we infer the non-existence of the disease in Syria and Egypt at the period which those writings describe, and its consequent origin at a posterior date. It is possible that the disease may have been prevalent in India previously to this time, and that its outbreak in Assyria may have resulted from the transporation of the infection by the winds. But, even if by this argument we shift our arena of inquiry to India, we must eventually arrive at the commonly received opinion, namely, the origin of the fever in a local and unknown cause. The infection of scarlatina is an acknowledged axiom, and the infecting distance is undoubtedly considerable, although not determined by observation. It is communicable by fomites of every description, hence the greatest caution is necessary to be employed in regard of articles of clothing which have been used by the infected person, and also of substances of different kinds which have remained for any time in the infected atmosphere of the sick-chamber. By want of caution in these particulars the spread of an infectious disease is greatly increased during the prevalence of an epidemy. Scarlet fever is sometimes conveyed from the chambers of the rich to the dwellings of the poor by such fomites; and, on the other hand, the clean linen of the laundress may be the means of transmitting the infectious poison to the persons of the sound. Scarlatina is infectious from the first moment of the existence of constitutional symptoms, for these are the workings of the poisonous ferment; and a conval scent is capable of communicating the disorder for at least three weeks after the decline of the eruption. Hence the necessity of secluding your patients, and preserving strictly that seclusion for a month after the close of the disorder, that is, if you wish to limit the propagation of the fever. In cities the body-clothes and bed-clothes of the patient should be immersed in cold water as soon as they are removed from the apartment, and afterwards fumigated in an empty room with chlorine; while, in the country, the clothes, after immersion in water, must be dried and thoroughly aired in the meadows, at a distance from habitations, or in such a situation as will enable the winds to convey the noxious poison away from the immediate seat of human residence. Willan has stated his belief that a nurse who had received the vapour of the lungs, the phlegm from the throat, or the discharge from the nostrils on her clothes or pocket handkerchief, is in a condition to infect a child whom she may afterwards attend or caress. Dr. Sims has remarked that the infection of scarlet fever has remained in the apartments of the house for several weeks after the family had recovered from the disease. And Dr. Robert Williams reports the statement of Dr. Cock, that he had traced the irruption of scarlet fever in St. Bartholomew, during the years 1829, 1830, to a direct importation of fomites: for a family who had suffered from the fever during their passage from America, landed at the island and communicated the disease to the persons who received them. Dr. Murray, in like manner, referring to the prevalence of an epidemy in Aberdeenshire, observes that he had seen several instances in which midwives conveyed the scarlet fever to the patients whom they attended.—The contagion of scarlatina has been illustrated by experiments made with a view to induce a milder form of disease than that which commonly prevails These experiments have been unsuccessful in their object, but have furnished proof of the transmissibility of the disease by the inoculation of the blood of the infected patient.

A New Method of Administering Quinine. Dr. Guastamacchia's method of avoiding the disgust which the bitterness of quinine always excites, is to dissolve eight grains of the sulphate in half an ounce of rectified spirit, and rub it, in two doses, with an interval of a quarter of an hour between them, along the spine. In intermittent fever this should be done at the beginning of the cold fit; and it very often prevented even a single recurrence of it.

The Relative Frequency of Tubercles in Various Organs.—The proportional frequency, says Dr. Engel, of Vienna, of the occurrence of tubercle in the lungs to that of tubercle in the cerebral membranes, the pleura, liver, and spleen is as 18 to 1; to that of tubercle in the brain and kidney as 18 to 2; and that of tubercle in the peritoneum and intestines as 18 to 3. This is the more remarkable, when compared with the relative frequency of cancer in the same organs. Cancer of the lungs occurs, in proportion to cancer of the liver, as 18 to 48; to cancer of the stomach, as 18 to 42; to cancer of the intestines and kidneys, as 18 to 12; and to cancer of the brain, spleen, peritoneum, and uterus, as 18 to 18.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members, on Monday, Jan. 6th, 1843:—

R. J. Mack, K. Kittoe, J. H. Wilmot, J. Virtue, L. Fowle, R. A. Varieas, C. R. Francis, W. H. Walker.

CLERICAL, MEDICAL, AND GENERAL LIFE ASSURANCE SOCIETY

INSTITUTED 1824.

A THIRD QUINQUENNIAL DIVISION OF PROFITS was made in JANUARY, 1842, and the BONUS then DIVIDED *amounted, on an average, to*

£28 PER CENT. ON THE PREMIUMS PAID.

BY COMPARING THE RATES OF PREMIUM (AS BELOW,) IT WILL BE SEEN THAT THEY ARE LOWER THAN THOSE OF MOST OTHER OFFICES,

PARTICULARLY FOR TERMS OF YEARS.

TABLE OF PREMIUMS FOR ASSURING £100 ON A HEALTHY LIFE.

AGENTS ARE REQUIRED WHERE NONE HAVE BEEN APPOINTED.

MANY MEMBERS OF THE MEDICAL PROFESSION ACT AS AGENTS TO THIS SOCIETY, TO WHOM THE USUAL COMMISSION IS ALLOWED.

Further particulars can be obtained of

GEO. H. PINCKARD, Actuary,

No. 78, GREAT RUSSELL STREET, BLOOMSBURY, LONDON.

*** *The Income of this Society, which is steadily increasing, now exceeds £97,000 per annum.*

Just Published, price 1s.

THERMAL COMFORT; or, POPULAR HINTS for PRESERVATION against COLDS, COUGHS, and CONSUMPTION. By Sir George LEFEVRE, M.D., late Physician to the British Embassy at the Court of St. Petersburgh.

JOHN CHURCHILL, Princes-street, Soho.

BRAITHWAITE'S RETROSPECT.

JUST Published, price 5s. 6d., Vol. VI., cloth lettered, of this Journal, containing a careful Digest of all the Practical Matter to be found in all other Medical Journals for the last six months, with a Retrospective Summary. Edited by W. BRAITHWAITE, Surgeon to the Leeds Eye and Ear Infirmary, and Lecturer on Obstetric Medicine in the Leeds School of Medicine.

London, SIMPKIN & Co.; Edinburgh, Oliver and Boyd; Dublin, Hodges and Smith; Leeds, Griffith Collingworth.

LONDON AND EDINBURGH MONTHLY JOURNAL ADVERTISER.

TO ADVERTISERS.—The LONDON and EDINBURGH MONTHLY JOURNAL OF MEDICAL SCIENCE is an admirable medium for advertising Medical and Scientific Publications, Works in General Literature, Medical Practices, Chemical Products, Pharmaceutical Preparations, and the Prospectuses of Life Insurance Societies, &c., &c. This Journal has, since its commencement, in January, 1840, enjoyed a very large, and steadily-increasing circulation in every part of Great Britain; and has now numerous subscribers in the colonies. It is taken in not only by private individuals, but by most of the Medical Societies and Reading Clubs in the United Kingdom, as well as by many of the General News Rooms in the large towns. Advertisements, therefore, inserted in this Journal, cannot fail to be perused by many thousand readers, a large proportion of whom must be of a select class.

Advertisements (which ought to be sent in by the 15th of the month), are received by John Churchill, Princes-street, Soho, London; Maclachlan, Stewart, and Co., Edinburgh; and by the Printers, Messrs. Balfour and Jack, Niddry-street, Edinburgh.

On Saturday, the 7th of June 1843, was published, price 4d. or Stamped 5d., No. 1 of a New Weekly Journal, to be entitled

THE ILLUSTRATED POLYTECHNIC REVIEW, and RECORD of SCIENCE, the FINE ARTS, and LITERATURE.

This Periodical will be devoted to the following subjects:—

SCIENCE, including ARTS and MANUFACTURES, with diagrams.

The FINE ARTS, viz., PAINTING, SCULPTURE, and ARCHITECTURE, with suitable illustrations.

LITERATURE, in which department will be included reviews and illustrations of new works of interest.

AGRICULTURE, MUSIC, and the DRAMA, RECORDS of SCIENTIFIC PROGRESS.

The most eminent writers and artists have been engaged to carry out the objects of this publication.

Each number will be enriched with many fine engravings.

Each volume will form a complete book of reference for some branch or branches of science. CHEMISTRY, in its application to the Arts, Manufactures, and to Agriculture, will be amongst the first subjects treated. A Series of Essays will be given, comprising all the known facts relating to this important section of science.

Books, Prints, and Works of Art for Review, Essays, Letters, &c., are to be addressed to the Editor, 143, Strand.

The ILLUSTRATED POLYTECHNIC REVIEW will be published every Saturday morning, by John Lumbird, 143, Strand.

The REVIEW will also be published in Monthly Parts, in an Ornamented Wrapper.

Subscription for Stamped Edition—£1 1s. 8d. Yearly; 10s. 10d. Half-yearly; 5s. 5d. Quarterly; to be paid in advance.

CURTIS ON DEAFNESS, &c.

This day is published, with plates, Third Edition, price 1s.

THE PRESENT STATE of AURAL SURGERY, with the most successful and improved modes of treatment, as employed at the principal hospitals of France and Germany, and at the Royal Dispensary for Diseases of the Ear. By John Harrison CURTIS, Esq., Director and Surgeon to the Institution.

London: JOHN CHURCHILL, Princes-street, Soho.

Of whom may be had, by the same Author,

1. A TREATISE on the DISEASES of the EAR, with cases and plates, sixth edition, price 7s. 6d.

2. An ESSAY on the DEAF and DUMB. Second edition, 10s. 6d.
"Mr. Curtis is entitled to the best thanks of the public."—Lancet.

3. A MAP of the ANATOMY of the EAR. Price 5s., coloured.
"We can recommend this map."—Medico-Chirurgical Review.

4. A CHART of the DISEASES of the EAR. Price 2s. 6d., small 1s.
"The chart will prove useful to the junior practitioner."—London Medical and Surgical Journal.

VAN BUTCHELL on FISTULA, &c.—The Sixth Edition. Just published, in 8vo., cloth boards, price 7s. 6d. (enlarged),

FACTS and OBSERVATIONS relative to a Successful Mode of TREATING PILES, Fistula, Hemorrhoidal Excrescences, Tumours, and Strictures, WITHOUT CUTTING or CONFINEMENT. Illustrated with numerous Cases. Being a familiar Exposition of the Practice of S. J. VAN BUTCHELL, Surgeon-Accoucheur.

"It is very rarely our practice to advert to books on professional subjects, but the 'Facts and Observations' appear, by their practical and unpretending character, to indicate so easy and prompt a relief from a large class of most painful and distressing diseases, that we believe this word of commendation from us, which we give with much sincerity, will not be thought misplaced or without its use."—Examiner.

Published by H. RENSHAW, Medical Bookseller, Strand; sold also by the Author, at his residence, 27, Baker-street, Portman-square.

IMPROVED PATENT PORTABLE WATER CLOSETS, warranted superior to every other, being more durable, more simple in their construction, and entirely free from smell, price £4 10s., painted cases; handsome mahogany ditto, £6; also, Chambers's newly invented water closet, to be fixed over any pipe, drain, or cesspool, combining, within the space of the ordinary seat, the cistern, and all other advantages of the regular water closet, at one half the expense. They are forwarded complete from the manufactory, so that they may be attached to the pipe by a workman on the spot. They are particularly recommended on account of their compactness and simplicity, and are to be obtained only of DANIEL CHAMBERS, inventor and sole manufacturer, 47, Carey-street, Lincoln's-inn.

FRESH IMPORTATION of GENUINE ARROW ROOT from the South Sea Islands, forwarded by Mr. Williams, son of the late lamented missionary, and consigned direct to A. S. PLUMBE, 3, ALIE PLACE, GREAT ALIE-STREET, WHITECHAPEL. This Arrow Root has been tested by the most eminent Physicians and Surgeons in London, and found to be greatly superior to any other. The jelly formed by it is stronger, thicker, and more transparent, and remains much longer in a [illegible] state than any other Arrow Root. It may be used for puddings, custard, blanc-mange, &c., recipes for which are printed on the wrappers. It is also an excellent aliment, and should be taken plentifully in cases of diarrhoea.

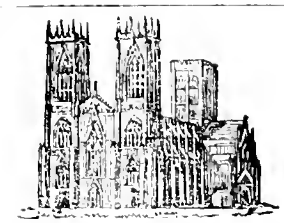
Sold by Chemists, Grocers, Druggists, &c., in one pound packets, considerable profit allowed to persons who sell the article. Particulars may be obtained of A. S. P., 3, Alie-place, Great Alie-street, Whitechapel.

ROYAL COLLEGE OF SURGEONS' AND APOTHECARIES' HALL.

DR. STEGGALL continues his Lectures and Examinations for the College and Hall, and all other Medical Boards. Dr. S. has removed from No. 17, Bloomsbury-square, and his Lecture and Class Room will be in future at his private residence, No. 2, Southampton-street, Bloomsbury-square.

HISTORICAL GROUP IN MAGNIFICENT ARMOUR.

THE Prince and Princess Royal in their Splendid Cot, the King of Prussia, Commissioner Lin and his Consort, modelled expressly by Lamqua of Canton, for this exhibition, with the Original Costumes worn by them. The gorgeous coronation robes of George IV., designed by himself at a cost of £18,000, with the room fitted up for the purpose, is acknowledged to be the most splendid sight ever seen by a British public. Admittance 1s. Open from 11 till dusk, and from 7 to 10.—Madame Tussaud and Son's Bazaar, Baker-street, Portman-square.



THE YORKSHIRE FIRE AND LIFE INSURANCE COMPANY.

Established at York, 1824, and Empowered by Act of Parliament.

London Agent for the Life Department, Mr. Edward Henwood, 46, Watling Street.

The attention of the Public is requested to the Terms of this Company for Life Insurances, and especially for Female Lives.

Fire Insurances are also effected by this Company on the most moderate terms.

Farming Stock insured without the average clause.

Prospectuses, with the Rates of Premium, and every information may be had at the Head Office, in York, or of any of the Agents.

London: Printed and Published by JAMES ANGUS [illegible] CARFRAE, 10, Essex Street, Strand, in the Parish of St. Clement's Danes, Westminster, in the County of Middlesex.—January 11th, 1843.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 171. Vol. VII. LONDON, SATURDAY, JANUARY 21, 1843. PRICE FOURPENCE. STAMPED EDITION, 5D.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazine. Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance) are received by any Bookseller or Newsman, or may be directed to [illegible], at the Medical Times Office, [illegible] London.

SUMMARY.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c. &c.

LECTURE IV., Delivered [December 9, 1842.]

(Continued from page 244.)

I must now allude to a case of water-stroke, which comes on sixteen days after the mildest cases of scarlatina. I am a little afraid of generalising too much, and I only tell you that I have observed this to be the case especially about this period of time after a mild case of scarlatina; that is to say, after that kind that least excites your [illegible] that the case would prove fatal. I never allow a case of scarlatina to escape from my observation, for when it has passed over—when this period has passed—you have the acute form of dropsy, which is fatal after sixteen days, or thereabouts. The child has all on a sudden a swollen state, the face is pallid; look at the ancles, you see that they are swollen, and if you examine the urine you will find it albuminous. When therefore in this state of things you have the inflammatory dropsy, one remedy I should give is the remedy of blood-letting. I just wish to make one remark or two on that character of dropsy generally preceding disease, for scarlatina is not totally of an inflammatory character. The case I take is one in which the disease had reached the character of a fever. If it is not inflammatory, it assumes the other form, and I need not tell you that this character is rather adynamic than inflammatory. Well then, under the influence of this disposition to dropsy, and this albuminous urine, you may have first of all the water-stroke, in the second place anasarca, and in the third place peritonitis. I was called a few years ago to a case of this kind at a school. The little boy was 13 years old, he had had a convulsion in the morning, and in the evening his face was swollen. When I got there I observed brandy and water on the table—with this particular object—I believe the symptoms before they got it were those of a collapse, or resembling a collapse; they thought the child would faint, and therefore they thought they would give it brandy and water. It is important to see the first change; this change is very different to the second or third. When I got there the child was in violent convulsions; the father and mother had just arrived, and the child was perfectly unconscious of them. We had one consultation, there were three medical men, and I said, "I know of nothing to relieve this child except blood-letting." I need not tell you that there was a little startled feeling at this proposition, because I found they were under the impression before of the necessity of brandy and water. I said "place the child upright, and open the jugular vein and let blood until an effect takes place." There was a little opposition from the father, but I said "I only recommend blood-letting, I only recommend what I believe to be the only remedy." He said we had been sent for in order to try our best efforts and therefore he would leave the child in our hands. We opened the jugular vein, and took 15oz. of blood, and there was no change at all. The child was raised upright, and kept in that position, and we determined not to go on any further, so the vein was tied up. I said "I am not satisfied; we will open a vein in the arm." We did so, and we took 25oz. of blood. At the time we took this the pupil of the eye, which had been excessively dilated, became natural; the child awoke from a dream, the convulsions ceased, and, strange to say, he never had a bad symptom, nor do I know that he wanted any other remedy. To cut the matter short, I believe he did not require any other remedy.

Now, in the first place I have just said that blood-letting is the only remedy; then in the second place I wanted to see to what an extent I could proceed, because that child was only 13 years of age. We see that the loss of 38oz. of blood—which is an extraordinary quantity—had the effect of subduing all the symptoms of the disease, and leaving the child perfectly well. I have only further to remark that there were none of the symptoms that usually follow the extreme loss of blood. I conclude with the remark that I have always formed, that when the disease is such as to require the patient to bear the loss of blood, there is no effect, except that which arises from the state of syncope, which comes on with the usual symptoms which we know to be the consequences.

I must now proceed rapidly [illegible] affections I alluded to in the first lecture, [illegible] to the hydrocephaloid diseases. You will be sometimes called to children who, slowly and gradually, glide into a state of hydrocephalus. I was called to such a case the other day. I applied leeches, and gave medicines; I thought the child was doing well, but I knew there was hydrocephalus, and I expected to see the usual symptoms, and certainly they were. The child was in a state of half-stupor—the eyelids were gaping—and there were all the slighter symptoms of hydrocephalus. But I observed the cheeks were exceedingly pale, and the lips perfectly bloodless; and I said to the practitioner, "do you not think this may be the opposite state to hydrocephalus, namely, the state of bloodlessness?" We found that the limbs were cold, and that the face was cold, and I strongly suspected that there was bronchitis or some preceding disease. There was a sort of exhaustion; on applying medicines, there was a second sort of exhaustion; and then there was extreme paralysis. I said, "He will recover if you let me just give remedies of an important nature." I said, "We must give brandy and water;" for I felt more and more persuaded that the case was one which rendered it important to give brandy and water. We gave the patient three drops of brandy and three drops of salvolatile every half hour. The child's eye no longer gaped; he went fast asleep, and when he awoke he was in a state of comparative health. We went on with the remedies, and in a few days he was perfectly well.

What, then, I have further to say in concluding this subject is, if you are called to these cases you inquire whether there are tuberculous diseases in the family, especially a disposition to hydrocephalus; and you must watch the symptoms. You must inquire as to preceding disease; for if there has been bronchitis, leeches applying, and purgative medicines daily, you may hope that there may be a state of exhaustion. The cheeks are pale and cold, and the hands and feet are cold. It is by observing the state of the hands and feet, and the frequency of the pulse, and connecting these symptoms not with the symptoms of the existing disease, but with the preceding disease, that you form your diagnosis. You may, therefore, proceed with brandy and salvolatile.

My next subject is that of spasmodic action in children. You will observe, I have already got to the fourth lecture, and the number allotted to me is 10 or 11, so I can, therefore, only touch on this subject; especially as they are more concerned with children than adults, I ought to touch on them very briefly. Now, with regard to spasmodic affections in children. They may be either *centric* or *eccentric*, that is to say, they may be connected with some disease of the brain. For instance, they may occur in hydrocephalus; in the course of hydrocephalus there may be large tubercles or tumor within the brain, and of course I need hardly tell you that the diagnosis is most important, but by far the greatest number of spasmodic diseases are of an eccentric character, and depend on the irritation of three parts of the system. First there is the state of teething; in the second place indigestible matter in the stomach, and in the third place morbid matters in the large intestine. One part of the disease in children I take to be the mild form of convulsive affection. One of the most common effects is that the thumb is drawn into the centre of the hand, the toe is drawn into the sole of the foot, and there is a little grinding of the teeth. Very often I have seen these symptoms and nothing else. I have seen nothing but a contraction of the thumb and the toe, and a little strabismus, and nothing else; I have seen a grinding of the teeth and nothing else; (with regard to the crowing inspiration, I want you to observe the physiology here.) It is nothing but a disposition to close the larynx, when there is [illegible] inspiration. Suppose this state of [illegible] to go on—what happens? A very violent kind of convulsions; this state is always characterised by violent convulsions. What are the essential differences between this crowing? They are only these,—where there is a partial closing of the larynx, and where the aperture of the larynx is absolutely closed, and whatever the effort made, there is no power of inspiration or expiration. You then see the patient in a state of struggling, something like being strangled; the countenance is flushed, and you may be sure that state is indicated by the countenance. You have, first of all, in spasmodic affection, the closure of the thumb in the palm of the hand, and the contraction of the toe in the sole of the foot. These symptoms are but evanescent. You observe another thing—a state of instant strabismus, and you must catch the first symptoms. When the child is affected with strabismus, you see there is a disposition to it, so that a little thing will excite it, and in a moment it vanishes away. The same may be said with regard to some of the other affections, but there is nothing more interesting than the grinding of the teeth; that takes place at another moment, and is altogether peculiar. I have found that out of 12 such cases 11 the have taken place during sleep; in another case crowing inspiration comes on, in 19 out of 20 cases during sleep. The reason of this I do not know; but that the disease predisposes to spasmodic affection is a fact I am perfectly confident of. You are very often called to a case of crowing inspiration, and before you get there, the child has awoke, and you find that all you have to do is to watch the phenomena.

I have said nothing in this description about the state of the brain, but I have this one remark to make, and that is, whereas in hydrocephaloid diseases the first symptoms are cerebral, and the second spinal; so in this case the first are spinal, and the second cerebral. For what happens? This thing happens:—before we had convulsions, now we have congestion, and with that

congestion of the brain. You have probably effusion into the ventricles of the brain, and then you have the second stage of hydrocephalus. It comes on under peculiar circumstances, and is not tuberculous. If you are called in under these circumstances, and you do not hear the history of the case, you may be uncertain whether the convulsive affection is primary or secondary. Nothing is more important to notice than, whether the symptoms be primary or secondary. The affection of the brain may be what is observed in hydrocephalus, but it is a secondary case. You will inquire particularly as to these phenomena, whether there was affection of the head, and then spasmodic affection, whether the affection of the head came on first, and then the spasmodic action. In some cases of congestion of the brain I see no reason why blood-letting should not save the patient from a state of jeopardy.

I now come to speak respecting the morbid anatomy. Here you see very little of the morbid anatomy. The only thing you observe is the state of the blood vessels, and the effusion in the cavities of the brain, on the surface of the brain, and at the basis of the brain. The most important object, just now, is the treatment. It is so for various reasons; in the first place, because I think the treatment some years ago was diametrically opposite to what it ought to be, and because I think the treatment I should propose to you is in the early stages of the disease only calomel. The time was when all these cases were treated with calomel. You will see in the work of Abercrombie, on the diseases of children, that in the crowing respiration and similar affections of the respiratory organs and some cerebral diseases the treatment was calomel. There is a treatise on the subject by the late Dr. Davy. The truth is, that the doctrine of the reflex function did not then exist, and, therefore, the disease could hardly be said to be understood. I invariably observe this done, namely,—in one case, freely lancing the gums; in another case, freely evacuating the stomach; and in a third case, freely evacuating the intestines. I have known a neglected state of the teeth to lead to these convulsive affections; also morbid crudities in the stomach, and a morbid state of the intestines.

I have been endeavouring simply to point out the causes of these affections, to which remedies may be applied. My remedy invariably is one that has never failed, and I have, therefore, been confirmed by subsequent experience in the truth of what I am now saying. What I would do is this: the gums should be lanced every day. Now there has been a good deal of contention about this; but I will give you an idea why I propose to lance the gums. It is not that the teeth may come through, because the teeth may not very often come through, but I am persuaded from what I have observed that there is a state you can only compare to slight inflammatory action in the gums during the whole time of teething. You have never perhaps happened to place your hand on the epegastrium; if you do, and find an indication of the heat of the blood itself, the idea is that there is a sudden state of inflammation, and I suppose something of the sort takes place in the case in which the teeth are growing in the gums. Now I am persuaded in another case that the lancing of the gums has done good. And why do I think it has done good in these cases? I have found inflammation in a state of dentition, I have repeatedly ordered the gums to be lanced, and I am perfectly sure that it has had a good effect; but long before the teeth have come through, there is no question, if you lance the gums, particularly it you first of all relieve the teeth, and then you let a little blood, but that you relieve that state of overaction in which that inflammation exists. That is the reason why you should lance the gums every day. The next thing to be attended to is the state of the stomach. You should give a few grains of ipecacuanha in order to produce vomiting. You should pass fluids through the stomach first, as it is desirable to have an abundance of fluids through the stomach, and then apply the ipecacuanha, in order to produce excessive vomiting. In order to lose no time the next thing is to have the intestines washed out with warm water. This is one of the simplest remedies, and the most natural. I do not say you should trust to this, but I think it is important it should be done. Another reason why I think this an important remedy is, that warm water removes the morbid contents of the intestines, and when they are relieved, further medicines are unnecessary. The next thing to attend to is the diet. You should give that most adapted to the age of the patient. I generally, if the patient is young, recommend asses' or cows' milk diluted, and I would recommend the thickening of it with barley, or something of that sort. I would give one remedy, because, if you give several, they may not agree with the stomach of the patient. If you imitate nature, you are most likely to supply the stomach with food suited to it, and you should only give that, and nothing more. Unless you pay proper attention to the stomach in this way, you may not be able to determine what is suited to it. This thing should be done day after day. Another important thing to attend to is this:—It is known that the crowing inspiration is produced by the prevalence of the north-east winds; what does this lead you to do? To be exceedingly careful not to expose the child to the impression of the north-east winds, and to adopt those measures of prevention which would render it safe from any fresh attack from that cause. This should be continued for a considerable time, as a child in the case of the crowing inspiration, is exceedingly liable to have it again. I must mention another point, that is, clothing. The change of air is most important, and I have known a child taken to a different atmosphere, cease to have the crowing inspiration. This has been frequently the case; and when the child has returned home again, there has been a return of the convulsions. There is a most interesting case detailed by Mr. Henry Marsh, of Dublin, in which the child had the crowing inspirations; it was taken out, and it got well, but when it was brought home, the crowing inspiration returned. I have just one final remark to make. I told you that hydrocephalus was a family disease, and, strange to say, this is a family disease. There is more danger of receiving it after the child has had the crowing inspiration. In some it has gone on to violent convulsions, and, in several instances, these convulsions have proved fatal. One of the most important results is the great expansion of the chest, and the enlargement of the thyroid gland. Now, the first thing to remark, is the effect on the countenance and on the brain produced by violent convulsions. I do not imagine that it produces the effect we see on the countenance, congestion of the brain and enlargement of the thyroid gland at the same time. But I imagine the thyroid gland becomes enlarged from the effect of the convulsions, just as the brain is affected. It is important to have this in view; for if strangulation is the result—if it tends to this effect—you must come to the conclusion, that little can be done for it. I say I have never yet seen any one of these cases, in which I have not early in the disease, ordered the gums to be lanced daily, the stomach evacuated, and then given doses of medicine. The most important thing is, that the bowels should be kept in a proper state daily with warm water, and the little child protected from the north-east winds. I must not go on with the subject of diseases in children, because I mentioned just now, that I have a given number of lectures to give on the subject in general, and therefore it may be better to begin forthwith with the diseases of the brain in adults.

Prophylactic Treatment against Hydrophobia.—At a recent meeting of the Sheffield Medical Society, Mr. W. Jackson suggested the propriety of subjecting every person who had been bitten by a rabid animal to a long though mild course of mercury. He would keep up a mercurial action for at least three months, in the hope that the mercury having thus obtained possession of the system first, would prevent the occurrence of hydrophobia.

PRACTICAL OBSERVATIONS ON THE NATURE, PECULIARITIES, AND TREATMENT, OF SOME OF THE MOST PREVALENT DISEASES, &c. CONNECTED WITH THE POPULATION OF NORTH CHESHIRE, AND SOUTH LANCASHIRE, EMPLOYED IN COTTON FACTORIES.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Manchester.

CHAPTER III. FROM THE FIFTEENTH, TO THE TWENTIETH, OR TWENTY-FIRST YEAR.

Although the space of time herein-named is short, it is nevertheless quite sufficient to present the enquirer with as numerous a list of diseases as any other epoch of life, though of much longer duration. It is at this time, many fatal diseases, which commenced their attack in earlier years, progress towards a fatal conclusion; and, it is at this time, also, more than at any other, that we are compelled to acknowledge the baneful effects of this peculiar employment on many constitutions that are exposed to it; whilst the high temperature, in which they are confined, causes numbers of blanched faces and weak constitutions from oft repeated attacks of menorrhagia. The constant and sudden changes from heat to cold, and from moist to dry, induce an equally numerous class of suppressed catamenial secretions; many cases of menorrhagia, are to a surprising extent; indeed, it is difficult to account for their being able to follow their employment in some cases, from the extent of the discharge, but the dictates of necessity are stern and uncompromising. In treating menorrhagia, it is almost useless to prescribe, without, at the same time, insisting on a cessation of employment; by the simple accomplishment of which, many cases are immediately checked. As many cases of suppressed menstruation are evidently from debility, I have succeeded best in restoring the normal appearances by the exhibition of tonics, such as the tr. ferri. mur., but more particularly the nitrate of silver. Perspiration, another secretion (or rather exudation), suffers materially; when carried to excess, it at once reduces the system rapidly, cough and free expectoration follow, and the case ends in consumption; otherwise the skin is unnaturally dry, the mesenteric glandstake on disease, obstinate constipation, and indigestion follow—the sure forerunners of fatal atrophy. In these latter cases, tonics are again indicated, combined with the peculiar action of preparations of iodine very carefully given, and closely watched; and occasional soreness of the gums, produced by giving very small doses of calomel in rapid succession.

There is a strong analogy between the cases of adult atrophy and those of marasmoid children; and as the tepid bath, with a small quantity of ol. terebinth. in it, has a magical effect on the latter, I have been induced to try it on the adult; and, although the trials have not been very numerous, they have been very successful. Phthisis is extensively prevalent, and there are but few exposed to its attacks who recover. After long observation, I feel certain that there is a strong connexion between this disease and scrofula; as most of the cases of phthisis (particularly the fatal ones) can often be satisfactorily traced to have had extensive scrofulous disease, in early years. Much has been said of late on the "Curability of Consumption." If, by such is meant confirmed phthisis, a wider field for practice cannot present itself, than in the manufacturing districts, to make good any such doctrine, or to furnish sufficient means to prove it a fallacy. At this period of life, scrofula is not so much seen as in earlier years; it having given way, or terminated in some other disease. In common cases of constipation of the bowels, much may be attributed to the articles of diet, such as cheese of very inferior quality, baker's bread, containing alum, and common tea and coffee, much adulterated, forming the chief articles of consumption; so that if the bowels are not otherwise predisposed to disease, they are almost certain to be much confined. Hæmoptysis, hæmatemesis, and epistaxis, occur frequently; the

two former connected with other diseases of longer standing—the latter as a substitute for menstruation. Simple chronic debility can scarcely be considered as specifically attacking any one portion of these individuals, but is, in reality, the features of the whole factory community. I may just observe, in reference to it, that females are subject to syncope, often of an alarming character. Leucorrheal discharges are very common, and very difficult to arrest (if not impossible) during the continuance of the occupation. Zinc washes, with tonics, are most effective. Fevers are very prevalent, particularly the typhus, often produced by neglected attacks of the simpler forms of fever. In the treatment of typhus, venesection (that vaunted *sine qua non* of many) is, with these constitutions, so employed, and in such locality, almost inadmissible; very few, indeed, can bear the lancet; and whoever patronizes it (under such circumstances), will have good reason to regret its use. The result of the bleeding practice is evidently more fatal than the sudorific, or other simple treatment. The stamina of this class will not bear the lancet, and persons seldom recover when bled in typhus. Some local affections are prevalent, such as bronchocele, morbus coxæ, spinal curvature, ophthalmia, &c. Diseases of the skin are not so frequent, as in earlier life; and less so, in females, than in males—probably, from their being more careful in guarding against eruptions of a contagious nature. Inflammatory attacks are common, often the consequence of checked perspiration: the most common are hepatitis and enteritis—the latter often followed by long and obstinate diarrhœas. I have already (in the last chapter) spoken of early conception, the effects of which are observable at this period, making the females look old before their time. The facilities of child-bearing, although strictly in connection with this chapter, will be considered in the next.

CHAPTER IV. ADULT FEMALES.

We now come to consider the effects of this employment on females, at the adult period of life; the diseases to which they have been, and are at present, subject: and here, if any doubts existed as to the injurious effects of factory employment, they would be entirely dissipated, by the numerous circumstances that now are too evident to be mistaken. The debilitating influence is here fully exemplified, by the frequency of abortion, menorrhagia, floodings, excessive leuchorrheal discharges, anasarcous legs, varicose veins, hæmorrhoids, prolapsus ani and uteri, diarrhœas, general debility, and easy parturient efforts. With regard to the last item, it is a remarkable fact, that difficult labours are (comparatively with other classes) *extremely rare.* For this, two reasons may be assigned—1st, The females marry when very young; 2nd, Their constitutions have a laxity of muscular fibre about them, that evidently tends to facilitate labour; and perhaps two more may be added, their labours are often premature, and even when at the full period of gestation, the children are generally smaller than the average size. To this numerous list of maladies, others might be added, which arise from the debilitating effects of those diseases already enumerated; such as flatulency, anorexia, acute and chronic rheumatism, fevers, ascites, &c. &c. Puerperal fever is by no means rare, and more or less fatal in proportion to the use of the *Lancet*; I have invariably found bleeding injurious with this class of females. In all forms of rheumatism, I have found the free use of the sulph. lotum, with carb. sodæ most effectual, as recommended in my paper, supporting the views of Dr. Munk on Angina Pectoris (see *Lancet*, vol. 2nd, 1839-40, page 783; and vol. 1st, 1840-41, page 417).

For relief in prolapsus uteri, so prevalent here, I was anxious to contrive an instrument to support the uterus, without stretching the vaginal canal beyond its normal dimensions (the fault of all the old tribes of pessaries, which increase the evil sought to be remedied (see my paper read before the British Association, published in the Medical Times, 1842, Vol. 6, page 188); and, although I succeeded beyond my most sanguine expectations, I still regret being unable to bring it within the reach of the working classes, as to price, being compelled to have the whole pessary made of either pure or German silver. From the prevalence of varicose veins of the legs, I was desirous of affording some relief of a more permanent nature than is generally practised in such cases; and, I resolved to try the plan of operation by Vienna paste, as proposed by M. Laugier of Paris, which operation I had the honour of first introducing into English surgery in 1839 (see *Lancet*, fivepapers during 1839-40-41-42). After the most decided success in no less than fifty operations (and one which failed), I am convinced that it is the most effective means of curing these obstinate cases, and may be practised (more generally than it is) with advantage. In this same class, from the effects of debilitating employment, I have witnessed a greater disposition to uterine hæmorrhage after parturition, than in any other; but it has been much more rare, since the introduction of the Ergot of Rye into medical practice. The character of leucorrheal discharges is often extremely virulent, accompanied with extensive excoriation, vaginal relaxation, and protrusion of the uterine mass; these persons so affected drag on a miserable existence, not being able to relinquish their employment for a sufficient time to establish a cure, and procure means necessary for the correction of the diseased functions. Indigestion in all its forms is observed extensively; to which their bad habits, and inattention to diet and domestic comforts, contribute an equal quota, with their confinement and employment. During the period of suckling, mothers are very liable to inflammatory attacks of the mammæ, in consequence of the milk being pent up so many hours, and the frequent exposure to sudden and extreme changes of temperature. In the adult period, bronchocele becomes more apparent, probably from less precaution to hide it. It is, however, decidedly more frequent in hilly districts, and more properly attributable to the water of the neighbourhood and atmosphere, than employment. Asthmatic affections are frequent among that class of factory workers termed card-room hands. The general characteristic appearances of this class, are, pale, sallow, thin faces, bloodless lips, and emaciated bodies, looking at least ten years older than they really are; and having had no opportunity of learning domestic management from their early introduction into the mills, they are generally very bad economists, bad managers, and make very indifferent wives for working men.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

In accordance with our sketch of operations given in the last lecture, the first ponderable body we shall bring before your notice is oxygen, which was discovered by Priestley, or at least distinguished from other bodies, on the 1st of August, 1774. He termed it dephlogisticated air, on account of some imaginary property in regard to the much spoken of but imaginary principle, phlogiston. Scheele subsequently termed Aempyreal air, and Condorcet, vital air, because he remarked its property of supporting animal life. The term oxygen, as I have already remarked, was given to it by Lavoisier, and the other French chemical revolutionists, a term derived from two Greek words signifying *acid*, and *to generate*. When this name was first proposed, philosophers imagined that the substance under consideration necessarily existed in every acid, being in fact the acidifying principle. It is hardly possible to recognise at a glance the numerous fallacies in chemical nomenclature, which derived their origin primarily from a belief in the universal acidifying properties of oxygen; to change this nomenclature however, would be now impossible: therefore, we must be content to accept such terms as that under notice, with all due and necessary limitations. Oxygen, if we regard it in a simple and a compound state, may assume the form of solid, liquid, or gas. As a solid, we find it in combination with metals, forming a class of bodies termed by chemists metallic oxides, and which in common language we designate by the terms *tarnish*, or *rust*, also in numberless other instances. As a liquid we find it in the well known fluid, water, besides a multitude of other compounds. Gaseous compounds containing oxygen are just as innumerable; carbonic acid, or soda water gas may be mentioned as an example. Although we find this substance then, in each of the three adhesive states yet in its most simple or uncombined form, oxygen can only be obtained as a gas, the processes for obtaining which we will mention hereafter.

Of all the fifty-five simple bodies, oxygen enters most largely into the composition of this world and its inhabitants, animal and vegetable, a fact which cannot fail to awaken feelings of wonder and admiration at the remarkable power of chemical agencies to alter the conditions which characterise certain bodies in their simple or undecompounded state. These speculations, however, you will be the better enabled to enter upon, when you shall have learned the properties of oxygen. We will now proceed to demonstrate roughly the amount of oxygen entering into the composition of this globe. First of all, then, let us take cognizance of the water; at least three-fourths of the surface of the earth is covered with this fluid, the average depth of which has been so variously estimated, that I shall content myself with observing that it may probably amount to three miles, now every eight parts out of nine by weight of water, are oxygen. The crust of the globe, according to De la Beche, consists of 45 per cent. of silicic acid, a substance which contains half its weight of oxygen, and the remaining fifty-five per cent. is made up for the most part of substances rich in oxygen also; therefore on the lowest possible calculation, we cannot reckon the quantity of this substance in the crust of the globe at less than one-third. Again, every 23-100ths of the atmosphere are oxygen and every 8-9ths of atmospheric vapour. We last of all come to the inhabitants of this globe, both animal and vegetable, all of which contain oxygen, both as a constituent of their own proper tissues, and of the water which is always united with them, and which is necessary to the very existence of life. Now the result of the lowest possible calculation from these data is, that at least three-fourths of this globe, with all belonging to it, are oxygen in one form or another, a fact which demonstrates pretty clearly the important functions which it has in many ways to perform.

Oxygen may be obtained in many ways, not however with equal facility or equally pure. For delicate chemical experiments, it is usually prepared from the chlorate of potash, by distillation, or from distilled water by the agency of galvanism. In order to obtain it from the chlorate of potash, a little of this salt should be placed in a flask, or retort made either of Bohemian white, or English green glass; English white or flint glass does not answer for this purpose, being too easily fusible. English green glass, that is to say green glass containing no oxide of lead, is remarkably infusible, and therefore becomes applicable to this, as well as many other similar purposes; but it is exceedingly difficult to work, and therefore there has been of late found in the shops a green glass certainly, but merely common white glass, coloured green by some easily fusible material; this latter kind may be easily known by the ease with which it is scratched by a file. The chlorate of potash being inserted as described, join on a bent tube, and cork it if a flask be employed; if the contrary, immerse at once the beak of the retort under water in a pneumatic apparatus, the flame of an argand, or of a spirit lamp being applied to the salt, will liberate oxygen in abundance; of course the first portions of gas in this as well as in every other case of distillation, should be rejected, because it is necessarily contaminated with atmospheric air.

The theory of this decomposition is very easily understood. Chlorate of potash is composed of chloric acid, and potash; chloric acid of five equivalents oxygen, united with one chlorine, and potash is made up of one oxygen and one potassium. On applying heat, all the oxygen is given off, and chlorine united with potassium, or *chloride of potassium* remains. In chemical symbols this decomposition may be thus represented;—$Cl\ O^5$

yield $Cl K + O_6$. Oxygen gas may also be obtained from nitrate of potash by the same process, and substituting nitrogen for chlorine, the theory of the decomposition will be intelligible. When oxygen gas is required in large quantities, with only a moderate degree of purity, it is usually obtained by heating the binoxide of manganese in an iron retort; a gun barrel answers the purpose very well, or a wrought-iron mercury bottle for larger quantities; the binoxide may be purchased either in the state of impalpable powder or minute fragments—either answers equally well for preparing oxygen. By this process the gas is rendered in very large quantities, but of greater or less impurity; still, however, it will answer for the majority of purposes to which this gas is applied in the arts. The theory of the decomposition here taking place is very simple; there are four compounds of oxygen with manganese, devoid of acidity. They stand thus:—

	Mn.		Ox.
Protoxide	1	+	1
Sesquioxide	1	+	1½ or 2 to 3.
Binoxide	1	+	2
Red Oxide	3	+	4

Now, on heating the binoxide to redness, in the process just described, half an equivalent of oxygen is given off, and the sesquioxide remains. Inasmuch as this process requires an iron bottle, conducting tubes, and other heavy and expensive apparatus, other processes for obtaining oxygen may sometimes be desirable. It may be eliminated from the same oxide of manganese, by mixing the latter with sulphuric acid to the consistence of a soft magma, and heating the mixture in a glass retort. This plan, however, does not yield the gas with facility (although such would be indicated by theory), and it is altogether inconvenient. The theory of the process, however, is interesting, and throws some light upon an important class of chemical decompositions; binoxide of manganese is incapable of uniting with sulphuric acid, protoxide of manganese, however, unites readily. The mutual influences, then, of sulphuric acid and binoxide of manganese are such, that the latter is decomposed,—one equivalent of oxygen being eliminated, and protoxide of manganese being produced, which immediately unites with sulphuric acid, to form protosulphate of manganese. In symbols this decomposition is thus indicated:—

$$MnO_2 + SO_3 \text{ yield } (MnO + SO_3) + O$$

The difficulty experienced in obtaining oxygen by this last process, renders some other plan highly desirable. Mr. [illegible], of Woolwich, recommends a mixture of equal parts, by weight, of binoxide of manganese and chlorate of potash, which, being put into a glass retort or Florence flask, will yield oxygen in abundance on the application of heat from a spirit lamp or other source of equal power. Mr. Balmain, of Liverpool, has mentioned another plan; he says, a mixture of three parts bichromate of potash with four parts of common sulphuric acid, contained in a capacious retort, will, on the application of a moderate heat (a common spirit lamp), yield pure oxygen with a rapidity entirely at the command of the operator. This process has for some time been employed in the laboratory of the Royal Institution, and I believe was discovered by Dr. Faraday. The results of this decomposition are sesquioxide of chrome, sulphate of potash, and oxygen.

$$KO + 2(CrO_3) + 4(SO_3, HO)$$
$$\text{yield } (SO_3 + KO) + (Cr_2O_3 \ [illegible]) \text{ and } 3O$$

There may be enumerated several other processes for obtaining oxygen, but I have mentioned those which are chiefly had recourse to. Let us now proceed to investigate the properties of this gas.

It is insipid, colourless, and inodorous, permanently elastic under all pressures and temperatures. Its specific gravity is 1.111, that of atmospheric air being unity. It is 16 times heavier than hydrogen. At a pressure of 30 inches of mercury, and at a temperature of 60 deg. F., 100 cubic inches of oxygen weigh 34 grains. Dulong and Berzelius, however, estimate the weight of 100 cubic inches at 34.193 grains, and consequently its specific gravity at 1.1026. According to Davy's its specific gravity is 1.127. Its refractive power for light, when compared with atmospheric air, is as 0.830 to 1000. It is evolved by electrolytic action from the positive pole or anode, therefore the reason of its standing amongst the anions is obvious, as also the reason of its being formerly termed an electro-negative body. It is absorbed very sparingly by water—100 cubic inches of this fluid only taking up 3.5 cubic inches of it. It exerts no action upon litmus, nor upon turmeric paper, neither does it whiten lime water.

The most striking property of oxygen is that of its supporting combustion with great vigour, and of rendering certain substances capable of burning which are usually regarded as incombustible. Then may be remarked the wide range of its combinations, and its property of acids; lastly its power of supporting animal life.

In order to demonstrate the remarkable property oxygen gas possesses, of supporting combustion, I immerse into a bottle full of it, a taper, the flame of which has been extinguished, the wick merely remaining red hot; immediately the taper becomes re-lighted, and burns with remarkable brilliancy.

Next I immerse a piece of charcoal also in the state of dull ignition, but no sooner does it touch the oxygen gas than it becomes brilliantly incandescent, and throws out sparks in every direction.

Phosphorus and sulphur also when immersed in oxygen gas during their combustion burn with a rapidity increased to an extraordinary extent, particularly the former substance. Nay; even certain bodies usually regarded incombustible, as iron for instance, are capable of burning in this gas. In performing this latter experiment, the iron wire should be twisted into a spiral form, and immersed into the jar containing oxygen, with a bit of ignited match fastened to one extremity of the coil: combustion proceeds with great rapidity, and small particles [illegible] of melted iron, fly off in every direction, whilst one large globule, generally, remains attached to the end of the helical turns. This experiment is connected with a remarkable dispute relative to the theory of combustion.

In all these instances of combustion, an union has taken place between oxygen and the substance burned, nothing has been destroyed, no not the minutest particle; to a casual observer, such may seem to be the case, but a chemist, instead of destruction merely sees the production of colourless gases. It would be out of place for me to enter upon the consideration of all the substances formed in these experiments; I must content myself with saying that phosphorus, charcoal, and sulphur, form, by union with oxygen, substances which are sour, which redden litmus, and which, by uniting with another class of substances termed *bases*, form salts; now these are the characters of an acid. Iron, however, by uniting with oxygen, does not yield a compound endowed with these properties, consequently the union together with others of a similar class, is denominated an oxide. So remarkable is the part which oxygen takes in the chief phenomena of combustion, that it has been said to be the only supporter of combustion; and the phenomenon has been defined "the rapid union of bodies with oxygen," a definition which cannot be retained in the present day without violating our most early received ideas; for example, we should be led into the absurdity of admitting that combustion might occur without fire, and that there might be fire without combustion. The best definition for this phenomenon seems to be rapid chemical action, attended with the evolution of light and heat. I cannot conclude the subject of oxygen, without adverting to the experiment of burning iron wire, which experiment I stated to have a remarkable connexion with the theory of combustion. Stahl and his associates referred the phenomenon of combustion to a peculiar principle, which they termed phlogiston; this phlogiston they imagined to be present in all combustible bodies, and that its escape caused combustion. This theory was countenanced by the appearances which occurred in most cases of combustion; for pneumatic chemistry was unknown in those days, and if a substance were converted into a gas, it was presumed to be altogether lost. Now there are a few cases in which a body is increased in weight after being burned: iron, when burned in oxygen, is one—consequently this fact was no sooner discovered, than the theory of Stahl was discovered to be erroneous, in one instance at least; and just afterwards, pneumatic chemistry sprung up, and the downfall of the phlogistic theory was complete. Lavoisier in imagining that oxygen gas was the universal supporter of combustion, assumed that the *gaseous* oxygen was compounded of actual oxygen and light and heat—the two latter being evolved whenever the actual oxygen united with a combustible body; but the amount of both heat and light depend as well on the nature of the body burned as the quantity of oxygen consumed; indeed, there are many other objections to this theory, and in the present day all admit that it is incorrect, as must be every other theory which assumes oxygen to be the only gas concerned in supporting combustion. The very terms combustible and supporter of combustion are unphilosophical; such distinctions being dependent altogether on secondary circumstances.

ERRATUM.—In latter part of last lecture for "[illegible]" read "*exponent*."

CURABILITY OF CONSUMPTION.

(Continued from page [illegible].)

(To the Editor of the 'Medical Times.')

SIR.—In proceeding with the subject of catarrhal affections in their sanative relation to phthisis, I am tempted to animadvert upon the culpable negligence, chargeable to most of the medical officers of our public institutions, in their examinations of the history of disease, particularly that of Catarrh. To this, as much as to any other single cause, would I attribute the mistaken views entertained and propagated on the incurability of consumption. I have attended six general hospitals and am unable to call to mind one instance in which the history of chronic catarrh was traced back to its commencement, and subjected to careful and scientific analysis. We should not content ourselves with merely ascertaining the state of our patients a few months, or a few years back, but if their cases be of long standing—as ancient as 20, or 30 years (and there are many such),—it will prove advantageous to collect as much information as possible, relative to the circumstances connected with the first stage or stages of development. It will be ascertained, in numerous instances, that unequivocal signs of the existence of pulmonary consumption preceded the catarrhal invasion. The most distinguished members of the auscultatory school are either decided advocates of the curability of phthisis, or exhibit a strong leaning that way; and there is no class of phenomena,—physical, constitutional, or pathological, that seems to have influenced their deductions more than that now under consideration; and yet they have all overlooked nature's method of cure. If I could be led by mere authority on these points, that of Dr. Ramadge would no doubt operate strongly; he has had the rare advantage of more than twenty years large experience in consumption, his patients in the infirmary alone averaging 100 a week; has watched numbers of them from the commencement through the intermediate time; has received them in a state of phthisis, and traced its gradual or rapid succumbence to catarrh at an earlier or later period; seen them die of disease, non-phthisical, and examined their lungs, &c., after death; but—

'*Nullius addictus jurare in verba magistri.*'

I have seen and judged for myself. In company with my fellow pupils, I have had many a weary walk from one part of London to another, attending him in his [illegible] journeys of investigation. On one occasion we had not fewer than six cases in succession, of persons who had been labouring under chronic catarrh, but died not of it, —all of which showed one or more of the ordinary signs of pre-existing, or co-existing, tubercular disease, such as adhesion of the summits of the lungs to the adjacent ribs from the proximity of tubercles; semicartilaginous, puckerings

of thickenings of the pleura pulmonalis; disseminated black pulmonary matter; cicatrizations; pasty tubercles; and black oval discolourations marking the site of tubercles absorbed or softened and eliminated, &c. &c. These spots in some cases, when a section of the lung was made, were seen standing out in relief from the incised surface passed over by the edge of the scalpel; in others the absorption was incomplete, and they were partially occupied with tuberculous matter; or various modifications presented themselves from the almost indistinct trace to the indurated quiescent tubercle. It would be tiresome to describe the numerous anatomical minutiæ seen on these dissections. Holiday pathologists may overlook, but cannot avoid confessing them when demonstrated to their senses. The compatibility of chronic catarrh, with long life and tolerable general health is a matter of every day observation, but the very large proportion of cases, wherein the lungs are or have been tuberculated, cannot even be suspected, unless by persons who have frequent opportunities of autopsy, and direct their attention carefully to the subject.

The occurrence of catarrh at an early period in the winter, renders its own persistence probable, but its power over phthisis more decided; when in early spring, and the latter disease is incipient, or moderately manifest, time enough may remain to overcome it, and the bronchial irritation may be quite removed or reduced to a latent form by the genial temperature of the summer. Many patients escape in this way.

Old catarrhal asthmatics hardly ever suffer tuberculous disease of the bowels, and its consequence—diarrhœa. When catarrh arrives too late to stay the course of consumption, if it proceed to the length of bringing on emphysema, it has the effect of preventing the diarrhœa, which so often prostrates and cuts off the patient rapidly, and, as it were, prematurely.

Polypi, or any mucous intumescence in the nasal fossæ, obstruct the free egress of air in expiration, and produce effects similar to those already described. A chronic thickening of the membrane of the nose may frequently be observed in children of a strumous habit, and the amount of obstruction from this cause or from catarrh, though apparently insignificant, rarely fails to operate as a check on the progress of phthisis. The mechanical impediments presented by the presence of polypi are sometimes so considerable as almost to preclude the possibility of breathing through the nostrils, and rarely so slight as not to embarrass it in some degree. Persons who sleep with their lips closed, labouring at the same time under contraction of the posterior nares, or in whom the uvula or soft palate is preternaturally enlarged, necessarily make prolonged expirations, which, in consumption, cannot fail to have a beneficial tendency. I need not do more than allude in this place to the other morbid conditions of this vestibulary portion of the respiratory apparatus, and its adjacent structures, such as lupus, ozena, disease of the antrum, congenital malformation, &c., which will all be found reducible to the same principle; they at times narrow the passages, and prevent the easy exit of the inspired air.

Uterine hæmorrhage, *and profuse or too frequent bleedings from any part of the body*, exercise—intermediately, through the disordered state of the heart's-functions, or the structural alterations they superinduce,—a greater or less control over the progress of consumption. Hemorrhoids and sanguineous fluxes from any part of the Portal system, menorrhagia, epistaxis, hematemesis, and immoderate loss of blood from venesection or accidental injury, are all followed by disturbance of the circulation at its centre, and tumefaction of the mucous bronchial membrane. Hemorrhages from the lungs,—the result of lesion in that organ, and, when profuse, indicative of an alarming state of pulmonary disease,—often form an exception to this rule: yet I have no doubt they may, under favourable circumstances, and when very moderate, if accompanied by blood-letting in small quantities often repeated, to lessen the vis a tergo, be either devoid of danger or contribute, to a slight extent, towards modifying the character of the tuberculous progress or manifestation. Dr. Ramadge, I should here mention, is averse to the practice of venesection under such circumstances, as, indeed, are many of the most eminent practitioners of the day. I shall return to this question, in discussing the treatment of phthisis, as I regard it by no means of secondary importance. I would here observe, that excessive venesection, or extensive loss of blood, from any cause, is in itself an evil of no common magnitude. The heart, like every other muscular part, gives way, and, as Corvisart expresses it, falls into a state of passive aneurism. Great care should be taken not to reduce it to a state of debility. We may purchase benefits too dearly. The extreme to which venesection was formerly carried in some of our hospitals, multiplied, not a little, cases of derangement in the circulation. I recollect, among many others, two remarkable instances of this in the London Hospital, under the treatment of the late Dr. Robinson. Though very unsuccessful, no individual could be kinder, or more attentive, to his poor patients; but unfortunately he was always suspecting the existence of dangerous affections of the heart, and frequent, sometimes copious, bleeding was his panacea. Susan Thomas, aged 30, of 11, Back Lane, St. George's-in-the-East, was bled 50 times, whilst under his care. Elizabeth Good, aged 22, Queen Street, Tower Hill, was, by his direction, bled 57 times in the course of four years, had 150 leeches applied, and was repeatedly cupped. They both previously exhibited the symptoms of phthisis, which the derangement of the cardiac functions had removed, but from the great loss of blood, they became excessively plethoric; a state of cerebral congestion, with frequent hemorrhage from the nose, stomach, bowels, and other parts, were the consequences of this treatment. He fell into Charybdis in the endeavour to avoid Scylla. He had been surgeon in a local militia regiment, and seemed to forget, that bold military practice was not exactly applicable to civil life,—a fact I have verified by my own experience.

I beg to subjoin the description of a case of uterine hemorrhage complicated with phthisis as given by Dr. Ramadge in a letter to Mr. Keddell of Sheerness, who had sent the patient to town to have the benefit of his opinion. "There is old phthisical disease in the summit of both lungs. The want of clearness in the respiratory murmur is most obvious in the infra clavicular region of the right side. The right lung is more affected than the left. There is chronic disease of the left lung where it is in contact with the pericardium. Though the physical signs of phthisis are evident to me, yet the general or constitutional symptoms have never been well marked, owing to uterine hemorrhage three years ago, which was exceedingly profuse. Dilatation of the heart followed, as well as a tumefied state of the bronchial mucous membrane. Owing to the imprisonment of the air which always follows such a change, the lower lobes have been preserved from contraction, and are in a state unfavorable for any new tuberculous deposit. The parts of the chest which require attention are the trachea, the summits of both lungs, and the region of the heart. The complaint which affects Mrs. H. is of a triple kind. There is consumption—masked and interrupted by bronchial disease, and dilatation of the right side of the heart."

The foregoing opinion was given many months since, yet the lady has improved to the satisfaction of all parties.

DISCIPULUS.

(To be Continued.)

The Major Counterbalanced by the Minor.—The late Dr. Babington remarked, "That medical men in general were too careless as to the vehicles with which they combined active medicines; and that he had known many cases of affections of the brain and nervous system made worse by medical men ordering camphor mixture in place of plain water, with other medicines which might have done good. The camphor mixture had acted as a stimulant, and thereby prevented sleep and rest, which were the objects most desired."

PENCILLINGS OF LIVING MEDICAL MEN.

Dr. Chambers.

An apology is perhaps due from us to this eminent physician for having hitherto omitted to introduce him in our pages. But our omission has arisen not from any depreciation of his merits, but simply because, however conspicuous be his professional position, he presents comparatively few points for remark. No one who ever held a rank so high in the profession, and enjoys a practice so extensive, can afford less scope for a sketcher while living, or can leave fewer materials for a biographer when dead. He is not one of those whose abilities, now shrouded by neglect, or repressed by misfortune, will be rewarded ultimately by time, and receive from a grateful posterity that recompense which envious or malignant contemporaries withhold. His is the present hour, and he has little to expect from the future. *Carpe diem* may be, as indeed it is, his motto, for the morrow will know him not. With an extensive field for research, he has written no work, enjoying ample opportunities for imparting information, he has implanted in no pupil's breast any record of his fame. Appreciated as an accomplished physician now, and rewarded by the most extensive practice of the day, he will leave no memorial behind him, and have as little claim to posthumous recollection. His career will resemble that of yesterday's sun, which threw out light and warmth in its transit, but to-day presents no shadow of its course.

But to descend from speculation to narrative—from contemplative anticipations to the prosing affairs of life—the subject of this sketch is, we believe, the son of a medical man, who not only enjoyed a competent practice, but succeeded in bequeathing the greater part of it to his descendant. The facility with which practices are thus handed down from father to son, forms one of the great inducements for a medical man to settle in the metropolis. In the provinces a practitioner has little difficulty in finding immediate employment, he may even amass a considerable fortune, and this he may secure to his offspring, but not his practice. His village rival or some obscure stranger, will step between his son and the desired inheritance, a consequence of the passion for novelty which generally prevails in rural districts. But the metropolis—a field so immense that a man, however great his abilities and exertions—is doomed, if a stranger, to pass the prime of his life in neglect, his whole existence may be spent in anxious inaction, and he may descend unknown and impoverished to the tomb. The cause? The public hospitals are closed to him unless he be possessed of claims by nepotism, sycophancy, or corruption! If he succeed in entering *their* portals, his practice is established, and his son in most cases is sure of the eleemosynary succession.

This sort of entailment is of course open to all the objections that may be urged against hereditary peerages and hereditary barbers; for though it follows not that the son of an able man must be an ass, it would be as vain to expect a budding peer to wag his tongue, or an incipient barber to wield his razor, with all the practised ease and dexterity of his progenitor, as to anticipate that the ability of the father will be inherent in the offspring; and by this kind of inheritance it is that the public hospitals are blocked up by the abortions that now so frequently disfigure them.

Chambers is also indebted for his success to a number of those fortunate accidents which are often more conducive to success in life than the most consummate abilities. His relation (a nephew we believe) to the late Charles Grant was eminently serviceable to him before the sleepy days of Lord Glenelg, and the death of old Dr. Warren, who lived in the same street, was one of those unmerited God-sends which occur to a few favoured individuals, and which give sunshine and ease to the rest of life's voyages. A residence in the neighbourhood of some fashionable hotels has also been of use to him, Mivart's alone, it is said, having sent to him as many patients as St. George's Hospital, of which he sometime ago resigned the physicianship. His practice is reported to be very lucrative.

Chambers, it is said, made a fortunate appeal to the apothecaries at the West End by the charms of his table. No prayers were necessary, cant was uncalled for; even grace itself, perhaps, wasdispensed with: he had only to assemble a dozen or a score of these worthies at his board twice or thrice a week, ply them heartily with wine, and *presto*, in their estimation, he at once became the prince of physicians. Esculapius himself, had he descended upon earth, and trusted exclusively to the strength of his powers, would have had no chance with him in so far as were concerned those worthy men who thus expected and received a good dinner to-day and a good dinner "the morn." They of course, in return, puffed the giver of these good things; for though the vulgar proverb declares that men's sympathies must be assailed through their heads or their hearts, wiser philosophers are of opinion that they may be more immediately enlisted by an appeal to their stomachs. The secret of charity-dinners lies solely in this; without the previous feed not a solitary sovereign would be forked out for "the sacred cause of charity:" and Chambers shewed his profound knowledge of the inner man by at once lighting upon the expedient. Nor let it be supposed that while alluding to the practice we are condemning the man. Justice compels us to state that their recommendation was just, and that amongst all the fashionable physicians of the day it would be difficult to find one more competent for his post. His practice, though by no means profound, evinces a simplicity and a science which others of the profession would do well to imitate.

His appointment as physician to St. George's Hospital (for which, we understand, he was indebted to Brodie, or Sir Benjamin's uncle, Everard Home,) also exerted no inconsiderable influence on Chambers's fortune, as it took place at a time when office in this aristocratic institution was a passport to fashionable practice. That it is so no longer, the miserable brigade of sucking surgeons, and struggling physicians, who now, with the exception of Keate, form the staff of the establishment, can painfully testify. But in the palmy days of nepotism it was otherwise. The Highlandmen's cry of "Shouther to shouther" (shoulder to shoulder), was never more strikingly illustrated at Waterloo—they never stuck more closely together than did the St. George's men of these days. It was in short a real family compact: Chambers cried up Brodie; Brodie extolled Chambers; the satellites and retainers of each caught up the echo, and not a man within a mile of Hyde-park corner had a chance of practice, unless he belonged to the clique. The whole practice at the West End has thus been reduced to a sort of family affair. "Scratch me, and I'll scratch you," is the universal maxim, and in so far as Brodie and Chambers are concerned it is maintained resolutely as ever. They have each left St. George's, but the inferior adherents who remain would no more think of taking a fee without calling them in, than they would of refusing one from the unlucky wight that falls into their hands. Hence the extensive employment of Brodie and Chambers as consulting practitioners, and though the men may be good, the system is bad. It in fact reduces an honourable profession to the condition of a mercenary *trade*.

If called upon to give a stamp of individuality to Dr. Chambers as a member of the medical profession, we should experience some difficulty. Of a man who has never written, or publicly spoken of a science, it is no easy matter to form an estimate, except in a general way; and yet our readers, as well as the public in general, may be desirous of knowing to what peculiar qualification it is that the subject of this sketch owes his commanding and fortunate position. They will also be anxious to know if he presents any feature that strikingly separates him from the common herd. But in truth it is difficult to gratify their curiosity. In his private capacity he stands aloof in striking if not stately isolation from his professional brethren: no hospital now witnesses his presence, no medical society or club is honoured by his attendance; at professional *conversaziones* he is mute, if not absent; and the object being gained, the means are forgot, the elevation being reached, the ladder is cast off. The apothecaries who formerly sat at his board enshrine themselves there no longer; and while physician at St. George's, he passed with such silent rapidity through the wards, that it would puzzle the most assiduous student to remember a word that he uttered, or—when assisted by the Hospital journals—an act that he did. Not that Chambers is a gloomy misanthrope, or an idler His appearance, his character, and his habits utterly belie the supposition; not that he is naturally or professionally incompetent; his language, his aspect, his full-developed forehead show that his mind is masculine, though not so gigantic as his body; and the facility with which he shines in those lighter branches of classic literature which were wont to form (and probably still do form) so large a share in the system of education adopted at our fashionable schools and universities, indicates that his powers have not been uncultivated, though many perhaps will concur in the opinion that, applied to such trivial, if elegant, purposes, they have been woefully misdirected. However, *chacun a son gout*, it is Chambers' pride and pleasure so to excel; and he probably rejoices more in the late Marquis of Wellesley's apostrophe,—who in a short Latin poem written a few days before his recent decease, addressed him as classic "Camerarius,"—than if he had indited Hippocrates, sent forth the works of Cullen, or rivalled Hunter or Harvey in fame.

In personal appearance Dr. Chambers is a stalwart healthy man, bearing a greater resemblance to a veteran life-guardsman than to a fashionable physician. He is, however, of agreeable manners, and, so far as physicians can be, of feeling disposition. As already mentioned he has written no work, though he is reported to be an elegant classical scholar, and to possess considerable dexterity in writing Latin verse, an accomplishment in the nonsense department of which Sir Henry Halford also excels.

PHILO-PROBE.

EXTRACTS FROM FOREIGN JOURNALS.

(From the Berlin Medicinische Zeitung, for the 'Medical Times.')

GERMAN.—*On Fractures by Dr. Schlesier.*—The object of Dr. Schlesier in this paper is to shew the advantages of Seutin's starch bandage in fractures, and especially for children, as he considers that with its greater firmnesss it is more simple and lighter than the common bandages, &c., and therefore controuls the fracture and its coaptation much better. He gives three cases of fractures in children.

Cure of Two Preternatural Joints in the same Individual, by C. G. Gunther, Surgeon.—A labourer being at work in a coal mine, a large mass of coal fell upon him, by which, besides other injuries, the left arm and leg were fractured, the tibia obliquely, the fibula across, in the forearm both bones. The fracture apparatus was of the writer's own contrivance. In six weeks the ulna was consolidated, but the radius was quite moveable, and crepitated strongly. On the 49th day, he first remarked the growing of the toe nails of the fractured leg, shewing that the consolidation of the fracture had commenced.* It went on to the 61st day, when both fractures of the leg were found disunited. The writer attributes the failure of union to the very poor living of the patient. Through nourishing diet, with a good allowance of beer, the fractures of the arm were quite consolidated in twenty weeks, but the tibia formed a preternatural joint. At the end of 145 days he caused the patient to walk about his chamber, supported by a person on each side, as from weakness of the left arm he could not hold the crutch. After some days the arm and leg became stronger, and he was able to walk alone. In some months from the accident he was able to labour.

* This remarkable physiological phenomenon, which teaches how economically nature proceeds in the employment of organic materials, I (M. Giunthur) have observed in several instances during nine years. In 1832, a very observant young man, who had a fractured leg, perceived that the toe-nails of the foot did not grow like those of the sound one, for they continued in the same state as at the time of the accident. He had cut them the day before the accident. This circumstance appearing to me to be in connection with the healing process, I paid much attention to the further condition of the nails; and on the 50th day I first perceived a renewed growth of the least toe-nail, in a few days the three others, and after a week the great toe-nail. Repeated observations have given me certainty that the restrained growth of the toe-nails is a constant phenomenon with fractured limbs.

Cure of Artificial Joint, by M. Wiefel, Surg.—A healthy man, a servant, æt. 26, had fractured both bones of the forearm more than a year before he applied to the writer for advice. The arm might have been bent in any direction, and in moving it, the ends of the bones might have been heard rubbing against each other; they were apparently held together by a kind of capsular ligament, thus forming a false joint. On consideration, he thought it might be cured by producing an artificial anchylosis; with this view he inserted two long needles between the fractured ends of the ulna, so that they passed quite through the artificial joint from one side to the other, letting the needles remain. On the first day they caused much pain, on the second but little, on the third the pain was again violent, on the fourth much increased, and extending to the whole arm and shoulder, with swelling of the forearm; on the fifth it extended farther, even to the head, with violence: as the punctures now began to suppurate, the needles were withdrawn; cold applications to the arm, which in two days relieved the pain. The place of the fracture after fourteen days remained swollen and hard. Fourteen days after the first operation, three needles were inserted in like manner between the broken ends of the radius; during the first five days the same effects were produced as with the ulna, but the subsequent inflammation of the place of fracture was later and stronger. The arm remained four weeks in one position, and six weeks after the acupuncture, the bones were completely united, but that of the radius yet remained tumefied and painful.

Reunion of a Divided Finger.—A cannoneer of the 8th brigade of artillery, severed completely with an axe the last phalanx of the left middle forefinger, close to the joint. After an hour, when received into the lazaret, the cut off end of the finger was placed in its proper situation, and retained by plaisters and bandages, it became completely united by "prima reunio."

THE WAR (MESMERIC) IN THE NORTH.

To the Editor of the 'Medical Times.'

SIR,—You seem completetely to have overlooked the mesmeric war now raging in the north, between Mr. Squire Ward, Mr. Wilson, and Mr. Wood, relative to the late operation at Wellow. Permit me to send you an outline of one of the engagements. Mr. Wilson commenced the attack in *column*, by discharging a Marshall's (Hall's) baton, in the shape of the excito-motory system, by which he hoped to put his adversaries completely *hors de combat*: but unfortunately, in the onslaught, he went too far—*id est*, he proved too much. *Videlicet*, after a flourish (of trumpets?) about the said Marshall's (Hall's) wonderful discoveries—discoveries I suppose he calls them, because the said Marshall, in a foraging expedition, *picked them up* in Prochaska, Whytt, and

Albert Haller—he continued to harass his enemies thus:—

"Its action (*the excito-mot.*) is so entirely independent of *sensati n* and *voluntary agency*, that it is best manifested when these are temporarily suspended. For instance, a person is asleep, you gently touch the eye-lashes; the impression is conveyed by the incident nerves to the spinal marrow; a corresponding impression travels thence to the muscle surrounding the eye-lids, and these are closely pressed together. Or, you tickle the soles of the feet—THAT LEG, and, MOST PROBABLY, the OTHER (!) also, are retracted."

After a prodigious effusion of—ink, he knocks his adversary on the head thus:—

"The only alternative is, that the patient *felt all* that was inflicted (?) on him, and that he had made up his mind to bear it without flinching, and did so (!). This is the solution of the whole mystery. Let mesmerists take the hint—(READ THIS, YE OUTER BARBARIANS, AND TREMBLE! The Governor Lin!)—and before another case of 'amputation without the knowledge of the patient' is got up, let them get up the discoveries"—(that is the foraging discoveries)—in the nervous system "of Doctor (Field) Marshall Hall."

Bow! wow! wow! "Let no dog bark!"—*Governor Lin, passim.*

Did ever Christian, Pagan, or man hear such stuff? The fool who fancied he played upon the organ, when he only blew the bellows, *was* a sage to Mr. Wilson. But let Mr. Squire Ward advance:—

"According to Mr. W.'s *law*, I presume, that on touching the eyelashes of *one* eye the orbicularis muscle of *both eyes* ought to be contracted at the same moment, but he does not say so, *nor is it so invariably*. Again, by tickling the sole of one foot, so as to produce an effect upon the nerves, and consequent retraction of the leg, BOTH LEGS ought thus to be *simultaneously and invariably* retracted—but Mr. W. does not say so—*nor is it so invariably*.

"Now we will hear Dr. M. Hall," continues Mr. Ward, "in the *Lancet*."

(What! Monsieur Tonson come again! I thought he had committed suicide; at any rate, I know he went to CHURCH-*ill*, looking *werry*—*vide* Boz, for this elegant, monosyllable—pale, desperate, and determined to *do* or die). To resume:—

In the *Lancet* of the 3rd Dec., this gentlemen is reported to have said at the meeting of the Royal Medico-Chirurgical Society that the case 'proved too much.' It was said (*the* Marshall *loquitur*) 'that whilst one limb was undergoing amputation, the other remained perfectly motionless. Now unless man differed from all other animals *this could not be*. Even when the head* which is the organ of sensation, was *removed*, the *laceration, incision*, or puncture of *one limb*' (WHAT HAS BECOME OF THE SOCIETY FOR THE PREVENTION OF CRUELTY TO ANIMALS?) induced muscular actions in the other. Was the source of these movements as well as sensation annihilated? Certainly not; for the patient breathed perfectly, swallowed brandy and water, &c. This is Dr. Hall's *oral* statement,' continues Mr. Ward, 'now mark his PRINTED one. A horse is struck with a pole-axe over the anterior lobes of the brain. It fell instantly, as if struck with a thunder-bolt; it was convulsed, and then remained motionless. It shortly began to breathe, and continued to breathe freely by the diaphragm. *When lacerated* by a sharp or pointed instrument on any part of the surface of the body, it was TOTALLY MOTIONLESS, manifesting no evidence of *sensation* or *volition*. Here is a discrepancy which I cannot reconcile, viz., that in an animal, whose *head has been cut off*, muscular actions are induced in both limbs by pricking or lacerating one, while in the animal which has *only been stunned* by a pole-axe, the same prickings and lacerations fail to produce the same effects—and in spite of the animal remains "totally motionless."

* Dr. Hall has discovered that the head *contains* the brains.—*Vide his lectures in the Medical Times*:—

But we cannot follow Mr. Ward further in his very crushing exposé of Dr. Marshall Hall. Let us see what Mr. Wood says. After stating that he was unwilling to say anything of "the luminous discoveries of Dr. Hall, because he would be compelled to quote Prochaska for them, he thus continues:—

"I will content myself with mentioning a case in which this *distinguished* physician was concerned, and in which it might have been supposed that he would have availed himself of some of that knowledge which Mr. Wilson seems to think he possesses, to alleviate the distressing sufferings of his patient. A few weeks since I was accidentally introduced to a family, in which the only daughter had been suffering for TEN YEARS from a severe form of St. Vitus's dance. Every thing had been tried in vain; no expense whatever had been spared in the attempt to relieve her sufferings. Amongst other physicians who had been consulted, this Dr. Marshall Hall, who was known to have cut up a vast number of animals, and was supposed, in consequence, to know something about nervous diseases, was unfortunately trusted for 12 months with the case. At the end of this time the patient so far from being in the slightest degree improved, was worse than ever; and, in addition to her distressing malady, had her shoulders disfigured by cupping, and her teeth and gums destroyed by mercury, which had also ruined her digestion. When I saw her I thought if she could not be cured, she might at least be greatly improved by mesmerism, and offered to try it. My offer was at once accepted, and, for the last five weeks, I have had the satisfaction of seeing in her a steady and decided improvement. The change has caused no less delight to her family and numerous friends, and from the decided, and I may say rapid improvement that has taken place, I think we may reasonably hope that it will continue, and that she will be perfectly restored."

To offer any remarks upon evidence so conclusive of what Dr. Hall himself means, would be "gilding refined gold." Mr. Wilson, by way of "taking in" the clodpoles of the north, fulminates the great London physician Dr. Marshall Hall, of West Middlesex Assurance notoriety, against them, and mark the results,—he has proved himself ignorant of that to which he pretended, and has exhibited the *great* physician as a wretched pilferer, a poor creature that does not know, to-day, what his opinion was yesterday.

Yours, &c.

BETA.

9th January, 1845.

ROYAL MEDICO-BOTANICAL SOCIETY.

January 11th.—Dr. Farre in the chair; Mr. Rodgers delivered a Lecture on the Proximate Principles of Opium.

He observed that:—Of all the products of the vegetable kingdom, there is, perhaps, not a more complicated one than that which is obtained from the papaver somniferum. This alone is an object of much physiological and chemical importance; but there are special matters connected with opium, which make it of great interest to the chemist; for it was during the examination of this substance, that morphia was discovered—a discovery which has given rise to investigations that have already produced the most important results, not only in organic, but inorganic chemistry.

Mulder analysed five specimens of opium from Smyrna, and the following is the average of his results:—

Narcotine	7·713	Caoutchouc	4·338
Morphia	6·228	Resin	2·753
Codeia	0·767	Gummy extract	25·370
Narceia	9·000	Gum	1·706
Meconia	0·790	Mucus	18·733
Meconic acid	6·121	Water	12·108
Fat	2·209		
		Making altogether	97·836

The existence of other principles in opium, besides the above, has been supposed by other observers; of these, I may mention Thebaia and pseudomorphia. The former is described by Couerbe, as existing in a small proportion, and the latter by Pelletier, as occasionally occurring.

Narcotine is readily obtained from opium, by the action of boiling water, and is preserved in crystals, as the ethereal solution cools: other methods are occasionally adopted, but the above is the readiest mode of preparing it.

Morphia can be obtained from opium by many processes, one of the best is that proposed by Drs. Gregory and Robertson, a modification of which is adopted in the present pharmacopœia.

The tests for morphia in the pure state are very decisive. The following are the best:—

Nitric acid, when dropped on morphia or its salts, produces a red colour, which soon becomes yellow.—Neutral perchloride of iron produces a blue colour.—Iodic acid, when added to morphia, is deprived of its oxygen, the free iodine can then be detected by starch.—The salts of morphia are more soluble than itself.

CODEIA was discovered by Robiquet, 1832, and Pelletier states, that he obtained 6 ounces from 100 lbs. of Turkey Opium. It differs from morphia in being more soluble in water, and by not being reddened by nitric acid or blued by perchloride of iron.

NARCEIA was discovered by Pelletier, in 1833 It is obtained from opium by a very complicated process. It is, when pure, in white silky crystals, very sparingly soluble in cold water, soluble in alcohol, but not in ether. The action of acids is peculiar; when strong, they decompose it, but when diluted they gradually combine with it, producing at first a blue colour, which passes into purple and red, and finally disappears.

MECONIA was discovered by Dublanc and Couerbe. It exists in very small proportion, and its properties require examination.

THEBAIA was also discovered by Couerbe, and described by him to possess very strong alterative properties.

MECONIC ACID is peculiar to opium, and forms salts with various bases. It undergoes peculiar changes by the action of heat, and produces two new acids, viz., the metameconic and pyromeconic.

This acid produces with the persalts, a red colour. Much has been said about the tests for opium; it is one of the few organic poisons which admit of decisive detection; for if we can obtain proof of the presence of morphia by the tests already enumerated, and the red colour, by the action of the persalts of iron, on meconic acid, from a suspected solution by the means recommended in various toxicological works, there is no doubt of the existence of opium.

At the next meeting, Dr. Sigmond will deliver a lecture on the effects of some medicinal plants and their preparations, in the treatment of asthma, more especially during the paroxysm.

CHANCES OF CURE FOR HARE-LIP.—M. Roux has now operated for this deformity above 100 times. In cases of "division simple," that is, we presume, when the division extends no further than the lip, success has attended the operation about twice in three times; but in complicated divisions, or when the fissure has extended to the palate, &c., only one-third of the operations have been thoroughly successful.

TO CORRESPONDENTS.

The Pharmaceutical Journal.—*A correspondent, in whose eyes the Pharmaceutical body finds little favour, sends us a paper in which the scalpel is very freely used on that periodical, but occasionally not in suited, subject, the "Pharmaceutical Journal." If the hilarious correspondents in excuse for heaving wits, had been similarly remunerated for their duped unity in —poor editors—our correspondent would have been less exacting in his requisitions, and have probably written with something less of severity; as it is, we must content ourselves with giving the concluding portion of his observations* in extenso. *"Some Correspondents are evidently indulging, at this hilarious season, in a little gentle hoaxing of the discriminating editor. One sends up a specimen of what he thinks fictitious ammonio—chloride of iron. The editor announces that it "possesses none of the characters of that substance, and appears to be hydrochlorate of ammonia, bruised, and slightly tinged, probably with tincture of sesquichloride of iron." Another 'Correspondent' informs us that a dealer in cream of tartar called on him a short time ago, to inquire the effect of plaster of Paris on the system, as he had sold a quantity of cream of tartar at a price at which it was impossible to furnish it genuine, and which did not admit of its adulteration with so expensive a substance as above.—Too bad. L. E. Y. and H. P. S. are informed that the 'Council has not yet instituted an examination for honours.'—We suppose the above gentlemen are in haste. A Country Associate is informed that 'fermentation is a necessary process in making cyder.' Another Associate is informed that the editor has 'no evidence of the fact, that water with a spare diet tends to make people stout. It is not probable that the elements of water are assimilated in the formation of fat.' 'A Chemist and Druggist' is responded to that 'we know of no chemical agency practically available, by which thick flint glass might be decomposed, so as to obtain perforations of determinate dimensions through it.'—This is exquisite! 'Amicus' is informed that 'the prohibition against pirating the diploma of the society is general, admitting of no exception.'—'Spoke like an oracle!' 'The* Closing of Shops,' *saith the editor to many correspondents, 'is a subject that has had our most mature consideration, not only at the present time, but also long before the establishment of the Pharmaceutical Society. The facts mentioned by several of our correspondents tend to confirm the opinion which we had previously formed, from observation and experience, viz., that'—prepare yourself, good reader—'the question is one of extreme difficulty.' If Mr. Bell alludes here, as his words imply, to the mere shutting up of the shop, we think he and his correspondents are making a pother about a matter which a stout shop-boy would soon settle; but if the 'extreme difficulty' be in the question—the* vexata questio—*of the hour for the general closing of chemists' shops, then we appreciate his good sense in not, editorially, attempting to 'bell that cat,' without the cordial co-operation of* all *his 'intelligent correspondents.' So much 'for light pharmaceutical reading.'"*

Mr. Brookes *writes to us to say, that Dr. Ennis, from his note in our last number, seems to have misunderstood him. He says, the "tingling of lameness at the tips of the fingers" whilst Mesmerising, is certainly not an invariable accompaniment, and is observable only in some cases, of severe neuroses, and invariably at the hands passing over particular parts, and is always an indication of the abnormal condition of those parts. He "could wish also Dr. Ennis had been more accurate in his recollection of his observations as to 'feeling indisposed after mesmerising.' The operation, doubtless, produces much greater exhaustion than could result from the mere muscular exercise, and that is the only inconvenience he has* generally *experienced, but in a few epileptic, and other cases, where much uneasiness has existed, he has occasionally experienced considerable indisposition after."*

Serres's Lecture on Organogeny—Dr. Williams on the Practice of Physic—*our brilliant friend* Probe *on the St. Thomas's Lecturers—the Editor on Foreign Medical Government, next week.*

Mr. Craig sends us an account of some phrenomesmeric experiments performed by him at York, and published in the "York Courant Gazette," from the report of a medical witness. We need only allude to one fact in the statement, viz., that an incredulous medical assistant, whose name is not given, was mesmerised on the first essay; and on having his organ of combativeness excited, "started up—gave Mr. Craig a blow on the face, which cut his lip, and afterwards struck him violently on the breast, so as to render him sick;" a pretty good proof, we should think, of the absence of collusion or the presence of more love of martyrdom in the cause of a hoax than we should be disposed to exhibit. The anecdote reminds us of a phrenological lecturer who, on being knocked down by an examined young man, who had been just told by him that he had the organ of destructiveness very badly developed, got up with great joy beaming in his countenance, and exclaimed,—"There, ladies and gentlemen, the most satisfactory *proof of the truth of phrenology I ever met with in the course of my life." We have also received notices of the Lectures of Mr. Brookes at Maidstone, and Mr. Spencer Hall in Yorkshire. They are interesting, but* space *is wanting.*

Letters have been received signed J. Selkirk and H. N. We have been sent also Mr. Smith's case of gonorrhœa. We have some doubts about the accuracy of the nomenclature. Can they be removed?

A Correspondent writes.—A case of Spina Bifida terminated fatally here a few weeks ago. The circumference of the tumor, a few days previous to death, was about 20 *inches, and embraced, at least, three of the dorsal, and two of the lumbar vertebræ. The age at death was six years and two months. Will any of your readers favor the Medical Times with a brief statement relative to any similar case of the same extent? Hydrocephalus was combined with disease of the spine.—R. A.*

Empirical Assassination.—*We have been sent the following narrative, published in the "Banbury Guardian," with a letter containing further explanations from a Gentleman living in the district.*—"At the village of Warmington, but in the Poor-law Union of Banbury, an aged pauper met with his death under peculiar circumstances. The inquest was taken by a Jury, before George Cattel Greenaway, Esq., on the 31st. ultimo. John Coleman, proved that at four o'clock in the morning of Tuesday, the 20th of December, he found the deceased under deceased's bed room window, much hurt; the window was twelve feet from the ground, and deceased had fallen from it. The witness applied to Mr. Wyatt, the overseer, who recommended that Mr. Wise, a surgeon of Banbury, should be sent for, but witness did not think it necessary, and the following day Mr. Wise called. The witness was not aware the deceased had sustained a fracture of the thigh, until informed of it by Mr. Wise. Mr. Robert Stanton Wise, the surgeon referred to stated, that hearing of the accident, witness called on the deceased, when he found his left thigh considerably swollen, and broken about the middle (the fracture being a simple one) and he had sustained various other injuries on the leg and body, but there was no external wound on the thigh. The witness placed the limb in a proper position, and ordered the patient to be kept quiet. Witness visited the patient on Friday morning, the 23rd instant. In reply to a question from the coroner, enquiring why Mr. Wise had not visited his patient on Thursday, he explained that he did not consider it necessary and thought him in no immediate danger. Mr. Wise went on to state, that on attending on Friday morning at the house of the patient, with splints, bandages, &c., he was informed by one of the farmers of the parish, that there had been a meeting of the parish that morning, and that they had determined to place the patient under the "Bone-setter." Hannah Coleman, on stating that Mr. Matthews, the "Bone-setter," first saw the patient on Saturday, the 24th of December, and he saw him almost daily until his death; he directed the limb to be poulticed. A wound first appeared on the front of the thigh on Sunday, the 25th, and the bone first protruded through the wound on Tuesday, the 27th; the patient gradually sunk, and died on Thursday evening, the 29th. After Mr. Wise had, in such a manner, been informed that the parish had employed the bone-setter, he retired, and did not again attend. In answer to questions from the coroner, as to the cause of death, Mr. Wise, judging from what he had seen and heard, distinctly stated the man's death was occasioned by the fall from the window, accelerated by the simple fracture being converted into a compound fracture, from the want of proper surgical treatment and attendance, and which would not have been the case had he been under the care of a regularly educated and qualified surgeon. The jury, after a brief charge from the coroner, returned a verdict of Accidental Death, (a very convenient verdict!—*It appears that the bone-setter occupies his position by hereditary right, on the maternal side, his mother, Susan Matthews, having* acquired *a very flattering distinction in the treatment of broken bones.—(and the reception of broken victuals?)—long before her remarkable successful son had stepped into the inheritance. But what shall we say of the "farmers," the "committee," the parochial functionaries, and, we may reasonably suppose, the poor-law guardians, who, by a deliberate vote, placed this unfortunate patient under an illiterate and singularly stupid quack, inviting him—a mere rustic—from his agricultural labours to murder this wretched stipendiary of theirs. Within their own knowledge there were several dislocations of the hip and shoulder going about the parish for years, unreduced, through this fellow's intrepid ignorance, and yet they ordered him another victim! The commissioners cannot, of course, have had their attention directed to this very wicked violation of their recently-published orders. The verdict was what* might have *been expected in a neighbourhood so highly enlightened*—accidental death—*which is only true, or nearly true, in the supposition that the jury meant that the death was caused by the* "accident" *of the guardians choosing a quack surgeon for their pauper's benefit!*

THE MEDICAL TIMES.

Saturday, January 21, 1843.

Aut bene aut nulla lege.

At a time when the best, and in *some* circumstances, perhaps, the *only* barrier against the misleadings of interest or revenge—faith in the sanctions of a revealed religion—is being undermined, or thrown down in the minds of so many eager and anxiously-striving individuals, the office of Coroner, which we were considering last week, presents itself to us as one of immeasurable importance. The history of Rome, under her Emperors—when Paganism, from being the disbelieved of philosophers, had become the laughing-stock of the multitude—the description of the same city under the Borgias, when every man of influence was in practice what their contemporary and famed instructor, Machiavelli, was in theory—and the assize intelligence of our own country, in our own days, which reveal so many of the *more* clumsy attempts of our poorer countrymen to rid themselves, by poison, of some troublesome or hated obstacle to better fortune,—all these speak with fearful import of what some specimens of humanity are capable of doing under certain circumstances of temptation—and point, with no unmeaning finger, to the wisdom of Society's giving to their criminal intents the smallest possible fragment of probable impunity. The more watchful the vigilance, and the more successful the justice of the law, the greater, of course, will be the security, and the higher that best of civic blessings—the

confidence of the individual: and it is no mean boast of the distinguishing wisdom of our ancestors, that, at a comparatively dark era, they established throughout the kingdom, a magistracy whose almost exclusive functions being the investigation of sudden or suspicious death, made unpunished murder almost impossible. Noble however as is essentially this truly venerable institution—effective as was its operation at its origin—perfect as it should be in this day of improved legislation, when, for a thousand reasons, its best utilities are infinitely more required, we are yet obliged to declare, in the fullest conviction of our mind, that, in its present condition and working, it is little better than a costly national nuisance. Which of our readers has not, in perusing or watching the proceedings of our innumerable inquests, asked himself, with us, the *cui bono* of all the bustle, loss of time, and expenditure of money, ending every day in those most lame and impotent conclusions,—"Accidental Death," "Found Drowned," "Died by Apoplexy," or, by "the Visitation of God,"—conclusions which, if true, are truisms that needed no jury's decision, and if false, are crime-hiders. A carpenter falls from a scaffold, and dies—a carter tumbles from his shaft, and is killed—a sailor is found washed on the shore, in the last stage of decomposition—a young lady's dress catches fire, and she is burnt to death—these are the common subject-matters of our Coroners' expensive Inquests; and what is there in them, or in any circumstance connected with them, to call for so absolute a waste of men's money, that cannot be spared,—and of men's time, that cannot be recalled? Let us grant th at without some care,crimes may become confounded with accidents,—nay, let us admit that, if there were no other way of avoiding such a misfortune, the prevention of one such act of confusion would justify ten thousand otherwise fruitless acts: but, first, what crime, in recent times, have a Coroner and Jury detected, that was not detected beford their sitting? Paying the greatest attention to the subject, we yet remember no one case where anything has been done for detecting crime with them, which would not have been done quite as effectually without them. We can far more easily imagine suspicion lulled, and enquiry stifled, by the usual and stereotyped verdicts so flippantly given, in general, by ignorant juries—and so welcomely received by impatient Coroners. Secondly, there *are* other means,—less troublesome, less expensive, and equally sure means,—of dealing with such casualties. Let the medical man attending the case, be required to send, to the nearest magistrate, a written statement of the nature of the accident, with the other circumstances of the death; and let it rest with the magistrate to say whether the case calls for the further investigation of a Coroner and his jury. Of course, this discretionary power might be variously modified and restricted,so as to remedy,if not exclude, abuse. How many hours, by a simple plan of this sort, would be annually spared to men, to whom the time wasted in an inquest-room, would be gold in their business, or happiness in their homes? How much expense would be spared to cities and counties? And what a boon would it be to the character of our judicature, to have the country rid of the useless, the burdensome, the ridiculous caricature on judicial enquiries, commonly presented by our Coroners,with their dozen good men and true—enquiring about what was plain as light at noon-day, and announcing, after great trouble and expense, what everybody knew before!

But while Coroners' juries, under present arrangements, are thus so ridiculously active, so uselessly busy, in most cases of accident; they are scarcely more efficient in those cases of maltreatment or murder, the detection of which is the main object of their institution. Where have we a guarantee that a "sudden death" is the result of "heart disease," or "apoplexy," or a "visitation of God," when no autopsy takes place? What can the hasty—the *timid*, the *partial glance* at the corpse, effect in the way of giving information to a non-medical Coroner and a half-instructed jury? We say deliberately, that the present system of holding inquests is utterly useless in every case where the perpetration of crime has not been of the clumsiest possible character. It can, indeed, only be tolerated in the supposition thst the law has no wish to discover or terrify crafty and adroit criminals—for it excludes the possibility of detection in every case where the wrong-doing has not been of the clumsiest description. But the object of the inquest is at once to deter and to punish—to make detection as certain as crime, and by making *right* the interest,and *wrong* the ruin of individuals, maintain their safety and preserve the confidence of society. Now we are bold to affirm that nothing but a *post-mortem* examination, including an analysis of the contents of the stomach in every case of sudden, as distinguished from accidental death, can secure in full integrity the objects of the Coroner's Inquest. Any thing short of this is, but a stifling of enquiry and a covering of crime under the very mantle of the law. Of course there would, with the searching scrutiny we recommend, be thousands of cases where nothing would be discovered but the operation of natural causes—but the scrutiny would not, therefore, in any of these cases be useless. Its uniform enforcement would spare the feelings of the survivors that wound so frequently dealt by the present irregular and capricious mode of investigation; no one would feel that because the remains of his deceased friend were examined, he was himself, *therefore*, suspected; the invidiousness of selection would be removed. Secondly,science might be largely benefitted.—We know of few things more required in the Profession, or which would prove of more value to the living, than an accurate knowledge of the statistics of the causes of sudden death. The *prevention* of such distressing visitations is the only service in the power of our Profession—and how prevent what we cannot foresee—or foresee what is not within the sphere of our experience? In truth, we have only to suppose careful reports of every *post mortem* examination, sent to a central office (say, the Registrar-General's), where the cases would be properly classified, and their results made known periodically,and who does not see that the advantage to science of such an arrangement, would, in itself, be worth the whole expenditure incurred in sustaining the improved mode of holding inquests?

But the great, the paramount advantage, would be the safety it would give, and the sense of safety it would inspire. The detection of crime, if not certain, would be made sufficiently probable to make its perpetration an egregious *impolicy*; the only argument that can tell with effect on the unprincipled. As was proved by Louis the Twelfth's astrologer-physician, who had his life saved and attended to, because his master's life was thought to be dependant on it, we are never safer than when others' interests are identified in our safety.

We call, then, for a Reform in our Coronership. Its present administration is one of the most trying spectacles a man of sense can gaze on. Changed from what it was at its origin, it is only the less fitted for the changed circumstances of the time. The ends of its existence are unanswered: it is neither detective nor preventive of crime. Where it is useless it is active; where it is required it is inert—in everything imperfect. We ask a change. We ask, that whenever jurymen are summoned, and constables and coroners are paid, that all this shall be done to some purpose. Once met, let them not separate till they have put the cause of death beyond dispute. If we may trust blindly, in all cases, to each others' virtue—let us have *no* inquests; if we cannot, let coroners' inquests give us the security they were intended, and are able to give. If this be not done, a thousand times better to leave every case of sudden death to the public's care—to the common sense of the neighbours. Crime, if it will ooze out under the present system, will assuredly ooze out without it. Without the coroner there would be suspicions; without him accusations; without him, charges before magistrates willing to act in any case justifying interference.

Thus superseded in its present mode of action, thus ridiculously useless, common sense impatiently asks that the office should be at once either amended or abolished? We say AMEND IT.

NEW MEDICAL INSTRUMENT.—The Echometer of Dr. Aldis is, we think, well adapted for the purpose of percussion. It may be seen at Savigny's, &c. It is not only ingenious but likely to prove useful especially to young auscultators.

REVIEW.

The Physical Diagnosis of Diseases of the Lungs. By Walter Hayle Walshe, M.D. Professor of Pathological Anatomy in University College, London; Physician to the Hospital for Consumption and Diseases of the Chest; Member of the Medical Society of Observation of Paris, &c.

We can recommend this volume as a useful guide on almost every point connected with the physical diagnosis of the diseases of the respiratory organs. Our author has studied his subject with great care, and given in the small volume before us the result of his observations in a very condensed form; yet so as they may be consulted with pleasure and profit, both in the closet, and at the bed-side of the patient. The book displays, in a very striking manner, the resources of art in the detection and distinguishing of respiratory diseases. We can remember the time when the physical signs of such diseases were almost entirely overlooked. The medical man, at the time to which we refer, was satisfied with an examination of the pulse, the breathing, the expectoration, the degree of pain, and the quantity and quality of the various evacuations. His diagnosis regarding even the seat and nature of respiratory affections were, consequently, seldom correct, and never correct to the minutest particulars. By attending to the physical signs, however, of these diseases, a door is opened to a more thorough knowledge, and a more philosophical treatment of all such affections. The methods at present employed in observing the physical signs of internal diseases are, according to our author, of seven kinds, viz.;—I. *Inspection;* II. *Application of the Hand;* III. *Mensuration;* IV. *Percussion;* V. *Auscultation;* VI. *Succussion;* VII. *Determination of the Situation of surrounding Parts and Organs.* The subject generally of which our author treats, is arranged into three parts. In part first, a description is given of the above seven methods of physical diagnosis. Part second consists of two sections, the first of which is thrown into a tabular form, and places before us a notification of the causes and seats of the various physical signs as well as the names of the diseases in which the signs are observed, and in the second section, we have a well digested synopsis of the physical signs of the diseases appertaining exclusively to the lungs. The third part of the work consists of a critical commentary on points both of theory and practice, connected with his subject. We shall make a few remarks on each of these sub-divisions of the work; and first of the methods employed in the detection of internal diseases. We have no means of investigating the physical signs of disease but by the senses; and why should we restrict the investigation to any one sense:—to the eye or to the sense of touch? Wherever abnormal *sounds* exist, the ear is the proper organ, obviously, for appreciating these, and where peculiarities of *smell* or *taste* exist, or are evolved during disease, it is as clear that the senses of smell and taste are the only organs that can be depended upon in the investigation of such peculiarities. By the proper application and training of three of the senses, medical science has already been much benefitted; and were the senses of smell and taste also pressed into the service, it is probable that still greater triumphs would be made. We ourselves have long been in the practice of distinguishing the proper gonorrheal discharge from the other discharges of the urethra by the sense of smell. We have also frequently been able to predict, previous to examination with the hand, the existence of cancer of the uterus, by the peculiar odour of the secretion, and all know how easy it is to discover the existence of diabetes mellitus by the sense of taste alone. To the methods then adduced by our author, we would add those of OLFACTION and GUSTATION, and would strongly recommend to our readers and contributers to enter without delay upon the investigation of this hitherto unexplored field of medical research. Our author has given many short but excellent directions for the practical application of the different methods at present in use, and shows no overweening partiality for any one method. It is not all auscultation with him, but while he concedes to each method its true value and place, he inculcates the propriety of employing all the methods, when this is practicable, as one method tends to confirm or rectify the conclusions drawn from another. Our limits will not permit us to follow our author more closely in this part of his subject. The following directions in the use of the stethoscope may be given, however, as a favourable specimen of our author's style and manner of treating this part of his subject.

In performing auscultation several precautions, affecting the observer and the observed, are to be attended to. 1.—The chest should be uncovered, or, if such exposure be inadmissible, as thin a layer of clothes as possible allowed to remain between its surface and the stethoscope. 2.—All friction between the stethoscope and the patient's or the observer's clothes should be carefully prevented. 3.—The position of the patient should be regulated in the same manner as for the performance of inspection; an unconstrained state of the muscles being particularly necessary, in order to ensure free entry of air into the lungs. The sitting posture is, everything considered, the most conducive to perfect investigation, provided the chair employed have a tolerably high seat. While the front of the chest is submitted to examination, the patient should sit not exactly erect, but with the trunk sloping a little backwards, the arms being allowed to hang loosely at the sides. When the observer proceeds to examine the lateral regions, the patient may be directed to clasp his hands on the top of the head, in other respects, retaining his former posture; and lastly, when the posterior regions are examined, sit upon the chair astraddle, with his back to the observer, his arms crossed, and his head bent somewhat forwards. *Mutatis mutandis*, the same precautions are to be taken when the patient stands, lies, or sits up in bed.—4. It is of importance to apply the stethoscope firmly but not forcibly to the surface: too slight or too strong pressure interferes with the accurate transmission, or alters the character, of the sounds. Besides, persons with tender skins, or in a state of extreme emaciation, cannot endure rough application of the instrument.—5. Great care must be takan to ensure accuracy of contact between the skin and every point of the circumference of the end of the stethoscope; as a necessary condition for this, the instrument must be held perpendicularly to the surface.—6. The position of the observer should be free from all constraint; he should apply his ear to the stethoscope in the same manner as the instrument to the chest; concentrate his attention upon the sound examined; and, unless a most experienced auscultator, proceed (as far as is compatible with the patient's safety) slowly with his examination.'—The motto *festina lente*, is a good one for the beginner in the study of physical diagnosis. 7. It is advisable to commence the auscultation of patients, while they breathe in the manner to which they are naturally inclined; because it is important to ascertain the precise natural condition of the respiration, and besides, directions for the regulation of the act often puzzle. Some individuals, however, absolutely require guidance, as the moment they perceive the instrument applied to their chest, they throw the muscles of the trunk into violent and unnatural motions, which of course materially impede the entry of air into the lungs. The readiest way of making such persons breathe in an efficient manner is, to perform several quick *noiseless* respirations before them, and desire them to imitate these. This method will, however, occasionally fail; our object may then be gained by desiring them to sigh, to speak, or to cough. The deep inspiration required for the performance of these acts, will at once enable the observer to ascertain the condition of the murmurs; and indeed there are many states of the lung in which, quite irrespectively of the patient's manner of breathing, much information may be gained by a single cough. 8. Certain sounds produced in the pharynx are liable to be confounded with the true pulmonary sounds of respiration; the error may be avoided by directing the patient to open the mouth, if it have been previously shut, and *vice versa.* If the sounds heard have their seat in the lungs, they will suffer no change from this opening or closing of the mouth; if in the pharynx, they will be more or less modified in character. 9. Both sides of the chest must be submitted to precisely in the same way,—as already explained in reference to percussion.—10. Auscultation should never be considered complete until the entire chest has been examined; it is often in some or other situation, where the symptoms would least have taught us to look for disease, that auscultation proves its existence.—11. In acute affections, auscultation should be repeated twice, at least, in the twenty-four hours.

As the first part of our author's treatise is confined to an explanation of the methods employed in discovering the physical signs of the diseases of the respiratory organs in the second part, the signs themselves naturally come to be investigated, and from the tabular form which our author has here adopted, a vast amount of information is condensed into a small space. The signs discoverable by the seven methods of investigation, above referred to, are given in succession, and the table is so constructed as to give under each method,—1st., the name of the sign; 2nd, the physical cause of the sign; 3rd, the ordinary seat of the sign, and 4th, the diseases in which the sign is observable. Besides the valuable tabular view above referred to, this part of the work includes a synopsis of the diseases of the *lungs*, in which the signs of the diseases of this most important organ are given in a more connected and systematic manner than a tabular view could impart. As a favourable specimen, we select the description of pneumonia, which will reward the attentive study of our readers.

ACUTE PNEUMONIA.

a. *Of a considerable Mass of the Lung.*

The question whether the existence of pneumonic inflammation can be detected by physical signs, before the stage of engorgement has supervened, and if so, what those signs are, is elsewhere examined; the three admitted stages only of the disease, together with the phenomena of resolution, will be considered here.

First Stage—Engorgement.

Inspection. Diminution of motions of expansion and elevation (if severe pain be present.)

Percussion. Sound less clear than natural, resistance slightly increased.

Auscultation. Respiratory murmurs weak, suppressed or masked by rhonchus in the affected parts; exaggerated in those at some distance from it and in the opposite lung; true crepitant rhonchus; vocal resonance somewhat increased; some degree of bronchial cough.

Second Stage—Red Hepatization.

Inspection.—Expansion of the affected side; bulging of the infra-clavicular sub-region in pneumonia of the upper lobe; diminution of the motions of expansion and elevation; motion of expansion diminished in proportion to that of elevation.

Application of the Hand.—Increased vocal and tussive vibration; pulsatile vibration?

Mensuration.—Increase in the semicircular measurement of the side; deficient increase in semicircular width in inspiration.

Percussion.—Sound diminished in clearness, until completely dull, decreased in duration, sense of resistance very much increased, under certain

circumstances of locality of the inflammation, character of the sound tubular.

Auscultation.—Respiration bronchial, or blowing, of either the diffused or tubular varieties; weak in the immediate vicinity of the inflamed part (Grisolle;) exaggerated in more distant parts and in opposite lung; bronchophony, or, under certain circumstances, broncho-ægophony; bronchial cough; intensity of transmission of heart's sounds increased.

Third Stage.—Grey Hepatization, or Interstitial Suppuration.

The signs in this stage are the same as in the preceding one; facts observed of late years tend to render it probable that the occurrence of a peculiar form of mucous rhoncus, in addition to the signs of the second, may announce the supervention of the third, stage.

Stage of Resolution.

Inspection.—Retraction or depression of the affected side.

Mensuration.—Diminution of semicircular width.

Percussion.—Dulness of sound less marked than previously, and gradually decreasing in amount, with a return of the natural elasticity; the alteration of sound is long, however, in being perfectly removed.

Auscultation.—Respiratory murmurs weak and harsh; redux crepitant, or sub-crepitant rhonchus; still some bronchophony gradually disappearing.

b. *Lobular Pneumonia.*

[The pneumonia of infancy, and in a particular form that preceding the formation of secondary abscesses in the lungs from the circulation of pus with the blood.]

Inspection, Application of the Hand, Mensuration, and Percussion, give merely negative results in true lobular pneumonia.

Auscultation.—Respiration exaggerated in some points; harsh, bronchial, or even slightly blowing sometimes in others; occasionally a few cracklings of an imperfect crepitant rhonchus; in children, the dry or humid rhonchi of bronchitis.

Chronic Consolidation of the Lung.

Chronic Pneumonia.

Inspection.—Depression, especially visible in the infra-clavicular region; diminished freedom of costal movements, while the general motions are not perceptibly affected.

Application of the Hand.—Increased vocal and tussive vibration.

Mensuration.—Antero-posterior diameter in the infra-clavicular region diminished; semi-circular measurement of the side sometimes diminished.

Percussion.—Sound diminished in clearness and duration, resistance increased; tendency to the wooden or to the tubular character sometimes manifested.

Auscultation.—Respiratory murmurs weak in the affected spot, harsh, bronchial, or having the diffused blowing character to a slight amount; exaggerated in the neighbouring parts; bronchophony; bronchial cough; heart's sounds transmitted with undue intensity; irregular subcrepitant rhonchus in small quantity, occasionally, at the very earliest period of the lapse of the disease into the chronic state.

The third or last sub-division of the work before us consists of explanatory and critical notes, touching the various points of doctrine and practice referred to in the first and second parts of the work. We consider this a very valuable sub-division of the work, but being thrown at the end of the volume, it is stripped of some of its interest. We think the preceding parts of the volume would have been rendered less dry and heavy, had the notes been brought in juxta position with the subjects to which they refer. They would be more likely to be read than when thrown together, without any bond of union, save that of the subject to which they refer. Be this as it may, the notes themselves are valuable, and show that our author has not only studied the subject in all its details, but likewise acquired acquaintance with the opinions of all the authorities upon the subject of which he treats. Our author is neither a slavish follower, nor a blind adviser of the opinions of others, and with the liberality and good feeling characteristic of the ingenuous mind, he uniformly displays judgment and discrimination. In compiling this work, Dr. Walsh has done the profession some service. We wish him the success which this work proves him to deserve.

DEATH FROM STARVATION.

APOPLEXY.—By J. Nottingham, Esq., Surgeon.

I was requested this morning, Jan. 12th 1843 to examine the body of a poor woman, aged 33, the mother of a large family, who died suddenly on Tuesday evening. She was the wife of a labourer, who, during the last three months has earned little or nothing; and for the same length of time, himself, his wife, and six children, as might easily be supposed, have had exceedingly low fare;—the youngest child is twenty-two months old, and this child the mother suckled up to the time of her death—although she herself, to use the words of one of her neighbours, "lived only on potatoes and now and then a half-pennyworth of coffee, which she mixed with a little boiling water, and then drank it."

Formerly the poor woman enjoyed good health; she was low in stature, active and industrious in her habits, and anxious for the education and welfare of her children; of late, however, she had had occasional attacks of fainting, and had complained of sick-headaches, but always evinced a disposition to bear up against every suffering, difficulty, and distress.

On Tuesday evening she carried two buckets of slop, one in each hand, to feed a couple of pigs, by the future sale of which she hoped to obtain some little gain which might help her with her family during the remainder of the winter:—arriving at the place to which she carried this weight—she dropped down dead.

On examination, we found the different organs in the chest and belly in a tolerably healthy state, the stomach was empty, save a few remains of undigested potato, and the bowels much distended by wind; having examined these parts with care, we proceeded to open the head.

The top of the skull being removed, the membranes covering the brain were examined, and found healthy; but through their semi-transparent layers on the right side, we saw blood which was evidently out of its proper vessels, and upon the surface of the brain.

The membranes were cut open, and the brain taken out,—when the right hemisphere was found to be what we may call broken at a point corresponding to the middle of the temples, and from this break a clot of blood projected, which was traced into the body of the right lateral ventricle of the brain; it would perhaps have weighed two ounces, it was of a pear-shape, the smaller end extending into the hollow or body of the ventricle:—This was the only clot of blood met with, but the parts of the brain projecting into the ventricle were softer than natural,—as was also all that part of the cerebral mass corresponding to the surface of the effused blood.

It need not be said that this was a case of death from apoplexy,—but it would be interesting to trace the operation of causes which are at work in such cases as this.

Had the protracted suckling of the child anything to do with the fatal event, or might we say that it was the result of starvation alone?—Doubtless, we should be correct in combining the effects of the two, for being, more or less, alike in their effect, we may easily understand their common tendency.

All mental operations are carried on with more or less pain and difficulty, when the system is suffering from extreme want of food, which is one proof that the great organ of the mind is especially dependent on an adequate nutrition of the body;—and the blood vessels of the brain, like every other part of the human organisation, lose more or less of their tone and resistance when affected by causes such as those to which we now allude;—thus weakened and irritable it is not surprising that when any unusual effort is made such as the carrying of heavy weights or whatever else it may be,—they should give way under the sudden shock of an increased circulation, and thus put an end to a life of misery by a death which that misery has caused. We can hardly consider that Horace told the truth in his ode,—"Ad L. Sextium Consularem."

"Pallida mors æquo pulsat pede pauperum tabernas
Regumque turres.

for death in his travels turns often to the abode of the poor, for reasons which do not take him to the dwellings of the rich, although to the latter, another and an opposite class of causes may bring him, thus helping to straighten the beam of the balance.

About three years ago, I met with a case of sanguineous apoplexy in a little girl, eleven years of age, under somewhat similar circumstances. After several weeks of exceedingly low diet, she one day died suddenly while grinding coffee in the mill in a grocer's shop.—In another instance—which I examined a few years ago—a very poor woman died suddenly, being three months advanced in pregnancy;—she had for some time been in a state of extreme wretchedness, but in her case there was a considerable quantity of serous effusion into the ventricles of the brain, but no extravasated blood.

This paper cannot be farther extended by pathological details,—but moral considerations of the highest importance belong to the history of death, when its cause is not such as ought to occur in the ordinary course of nature. This is not the first, or the second, or the third case of death from starvation which I have had occasion to attend to, and it has often occurred to me that medical men might often be well employed in observing and reporting on the physical condition of the poor in those almost inaccessible districts and streets in many towns which are so little visited—saving by the clergy and by medical practitioners—for it might be said, without fear of contradiction, that the richer inhabitants of most of our large and populous cities, have little notion of the extreme smallness of the means with which their poorer neighbours—to use a vulgar, but expressive phrase—keep body and soul together.

Such cases we have here noticed, stand in good contrast with all that belongs to the "Merry homes of England;" for although there be much in the beauty of England's excellency, which might have vied with Tyre or Babylon of old—she certainly is loaded in the opposite extreme, with an amount of wretchedness,—perhaps greater than that which is observed in any other, equally civilised, country. The why, the wherefore, and the remedy, are neither so easily discovered, nor so readily applied, as the philanthropist, or the moralist might desire,—but this appears to me to be true,—that an investigation into the influences exerted by peculiar physical conditions, on the moral movements of the poorer classes of the community, would amply repay the labour of the most pains-taking inquiry, but could only be made by men who are, at the same time, good physiological and moral observers; and that physiological and moral science are intimately connected, and should be studied and pursued

together,—we will not take pains to prove, but will close this communication with a quotation,—perhaps somewhat pedantic, from the Roman philosopher, who was not inattentive to such matters

Omnes artes quæ ad humanitatem pertinent habent quoddam commune vinculum, et quasi cognitione quadam inter se continentur.

AGRICULTURAL CHEMISTRY.

Caution to Practical Chemists.

The agriculturists are at length aroused, over the United Kingdom, to the important assistance they may derive from chemistry, and much as we respect the intelligent and respectable of this class, we can hardly forbear suspecting, that the generous reliance of our men of science is, at present, somewhat in danger of being but scurvily responded to on this side the Tweed, at least. But we shall allow the reader to judge for himself.

At a meeting of subscribers to the fund for obtaining the services of an agricultural chemist, held at Edinburgh, on the 9th current, Mr. Milne, younger, of Milngraden, Advocate, is reported (see *Edinburgh Evening Courant*) to have spoken to the following effect:—

The report stated, that the Interim Committee had circulated in the different counties, copies of the minutes relative to the appointment of an agricultural chemist. The Directors of the Highland Society had offered not only to afford the subscribers, and their committees, accommodation in their Museum, but to contribute £50 yearly, for five years, on condition, that £350 should be forthcoming from other sources, and among other *items*, it was proposed, that the chemist should be entitled to charge, for analyses, sums varying from *One Shilling to Seven Shillings and Sixpence!* As no definite mention is made of the amount of salary to be enjoyed by the forementioned chemist, we are thus so far left in the dark, as to whether the salary, and the fees for analyses, are to be in corresponding proportion.

Dr. M'Donald said, if the amount of salary was reduced, and the fees for analyses raised, (as became the dignity of the science,) the meeting would succeed in getting a man eminently qualified. The idea of soil being analysed for a shilling, or for seven shillings and sixpence was one which, he was sure, no one would have suggested that had witnessed analyses, and to expect that a man would, for such a remuneration, give the result of labors, which (when minute?) occupied him ten days, or a fortnight, was perfectly absurd.

A gentleman stated, that he had been informed by chemical gentlemen, that thirty or forty analyses might be carried on at the same time, which would lessen the expense and trouble to the operator.

We are inclined to believe, with Dr. M'Donald, that neither the first speaker, who, by the way, belongs to a learned profession, or the gentleman who followed him, can have witnessed analyses, saving, perhaps, in their rudest mechanical form, as practised by itinerent lecturers of inferior grade. The original report, as given by the first speaker, savours too much, unless we mistake, of *driving a bargain*. Let, therefore, chemists beware! Overstocked, as medicine and its collateral branches are, she has it, at least, in her power to assert her dignity. If she fail in this, she will amply deserve the crumbs, which ignorance and cupidity may have laid aside as her portion.

AMICUS.

[illegible],
January 11th, 1843.

THE MEDICAL SOCIETY OF BORDEAUX.

(To the Editor of the "Medical Times.")

Sir,—I have been requested to forward to you the accompanying "Programme" from the Medical Society of Bordeaux, who desire to make known their intention of awarding a gold medal of the value of 600f. (£24,) to the author of the best reply to the following question:—

"What is the influence of Penitentiary systems, and of solitary confinement in particular, on the health of prisoners, both in a physical and moral point of view?"

Papers to be written in the Latin, French, Italian, English, or German language, and sent (post free) to the Secretary, Mons. Burguet, No. 67, Rue Fondandege, Bordeaux, before the 15th June, 1843.

I am, Sir,
Your obedient Servant,
C. H. HOLLAND, M.D.

16, Queen Street, May-fair,
Jan. 12, 1843.

PHRENOLOGICAL SOCIETY.

On Monday the above society held a meeting at Exeter Hall, which was most numerously attended. We observed there many gentlemen of science, and the assembly was honoured with the presence of many elegantly attired ladies, who evinced great interest in the proceedings of the evening. Mr. Ewens commenced by detailing a series of experiments in mesmerophrenology, which he had performed upon a highly respectable married lady, a patient of his (under his care), and which entirely confirmed similar preceding experiments, and showed in a clear and beautiful manner the curious and interesting phenomena of mesmerophrenology. He mesmerized her in a few minutes; on exciting the organs, precisely the same results occurred as detailed in former instances, but in still fuller development. When philoprogenitiveness was excited she said she was nursing infants, and assumed a corresponding attitude; upon destructiveness being pointed at, she threw them away, declaring "she could kill the little devils." Benevolence being touched she appeared to recognise many old friends; and combativeness following she began to square a la Cribb; when music was touched she sung "O woodman spare that tree!" In conscientiousness she appeared absorbed in reflection; and when changed to veneration, she placed herself in a more beautiful posture of prayer than was ever simulated on the stage. At the end of the sitting she said she had enjoyed two hours tranquil rest; she had no recollection of what had occurred—she was quite ignorant that any experiments had been performed on her, and has not yet been told of the circumstance, the operator wishing to avoid all possibility for the least suspicion of deceit or collusion. The second sitting elicited the same results; when music was excited she regretted she could not sing well but "her husband, she said, intended to send her to Exeter Hall to learn the Hullah-baloo!" The third sitting was much the same. The organs of size, colour, ideality, &c., when mesmerized, brought up appropriate images in connection one with another, the transition being as quick as the movement of the operator's hand. There appeared to be little or no sympathy between the operator and patient. The report which was highly interesting and creditable to its ingenious author, and which we regret we cannot give at greater length, was corroborated by Mr. Josephs, who witnessed the experiments.

Mr. Atkinson, F.G.S. delivered an address on the history of phrenology more particularly of mesmero-phrenology, remarking that in his opinion the new discovery would rival, if not eclipse those of the immortal Harvey, that *they* did most honour to Harvey's memory, who, instead of reviling what they did not, or would not understand, and following the example of his ignoble compeers, in heaping obloquy on what was above their comprehension, devoted their time and serious attention to the investigation of nature, the unerring guide to truth. After some conversation between Dr Elliotson, Mr. Ewens, Mr. Symes, and others, the president observed upon the interesting topics in the report of Mr. Ewens. He ridiculed the futile opposition made against the science by many members of his profession; and said, as no man is a prophet in his own country, time alone would shew that in this as in other instances, magna est veritas et prevalebit. The Duke of Marlborough informed him—the president,—in a letter from Ireland that whilst at the Marquis of Ely's seat in that country, and strolling out in the morning, he came upon a very ferocious dog, chained in a farm-yard. His grace durst not approach this brute, but standing at a respectful distance, mesmerized him, and going up actually embraced the sleeping brute. The dog remained in the sleep for thirty minutes.

The meeting separated much instructed and amused.

ENLARGED TONSILS AFFECTING THE VOICE AND PRODUCING DEAFNESS.

[illegible] WILLIAM THORNTON, Army Surgeon, M.R.C.L.S.

A young gentleman, residing in London, of strumous constitution, nine years of age, was brought to me, delicate and pale. He complained of distressing symptoms, such as confirmed tonsillary disease can alone produce. His hearing defective, the voice thick and nasal, and the articulation so indistinct, as to be almost unintelligible to strangers. The difficulty of swallowing, induced his friends to consult me. Upon examination of the fauces, I found that the tonsils were very much enlarged, were hard and scabrous to the touch, and extending so far towards each other as to be within a line or two of touching. The *mucous membrane* in a state of chronic inflammation. I prescribed friction of the ointment of Iodide of mercury upon the external fauces, and small doses of Iodide of potassium dissolved in dect. sarsæ. concent., internally, also a rhubarb aperient, administered twice a week. A tonic powder, composed of carbonate of soda, rhubarb, and columba, given alternately, with the hydriodate of *potash*. The topical treatment to the tonsils were argentum Nitratum applied by a pencil-brush three times a week. In the course of a week, the *tonsils* felt quite soft, and began to diminish very rapidly, they were reduced to their natural size. I was anxious to give these remedies a fair trial before I had recourse to *excision*. The effects of the combined treatment were most gratifying, and all the impeded functions were gradually restored, and the general health improved and *cured* in the course of a month. The persevering medical treatment and *dietetic* restrictions are of paramount importance in the management of enlarged tonsils, especially when they occur in youth. When these remedies fail, it is only then necessary to resort to the operation which is safe and painless.

ON OVARIAN EXTIRPATION.

In answer to W. Jeaffreson, Esq., Surgeon, Framlingham, Suffolk.

Sir,—In answer to the observations made by you in the Medical Times of last week, I have to acknowledge, that when writing the articles in question, I was actively engaged in the treatment of the cases; consequently, in my limited time for search, some recorded cases may have escaped notice: indeed, I have since been made aware of this, through the kindness of Professor Simpson, and shall avail myself of every information, to place both operations on their proper footing, statistically, when I publish my additional cases. *I have also been made aware of unsuccessful cases, of the minor operation, which have not been recorded.*

I can assure you, Sir, I have no wish to depreciate the merits of the operation, by the minor incision. On the contrary, I consider the medical profession much indebted to you, for the novelty and boldness of your operation,

certainly a great improvement at the time, but as the profession of medicine, (like other sciences) is progressing, any endeavours to advance it should not be misconstrued.

My opinion, respecting the minor incision, remains the same, as the cases in which it would be advisable, are so extremely rare, viz: *a large single cyst, perfectly free from any adhesions, except the pedicle.* But the difficulty of diagnosing to such nicety!—even the dragging of the pedicle, a circumstance which cannot be avoided, would be a serious objection. I believe, many might be induced to prefer your operation, from its apparently less formidable character; but if any adhesions existed, they would find themselves under a difficulty *from which the larger incision alone could extricate them;* and experience tells us, that few and far between are the cases without adhesions (See Dr. Seymour's Work.)

You *admit the necessity of enlarging the incision, when adhesions exist.* I think it far safer to make the incision large enough at first, to prevent any serious displacement, or injury, to the viscera by the dragging of adhesions.

Since the publication of my cases, I have been highly honoured by the favourable opinions of very many men of the highest standing in the profession, relative to the operation as practised by me.

I shall be obliged to you, or any other gentlemen, who can refer me to cases, successful or otherwise, whether published or not, that I may be able to give the operations their proper standing when compared with each other.

I have the honour to be, Sir,
Yours very respectfully,
CHAS. CLAY, M D

Piccadilly, Manchester, June 11 184

PERISCOPE OF THE WEEK.

Causes of Sudden Death.—By a careful selection of statistical accounts from the foreign as well as British journals, we may, after a lapse of time, arrive at the means of making a tolerable approach to a calculation of the relative frequency of diseases. Of 26 sudden deaths occurring at Strasbourg, 1 was found on post-mortem examination, to be occasioned by cerebral hæmorrhage, and 1 by apoplexy; by cerebral congestion, 4; cerebral and pulmonary congestion, 1; hæmoptysis, 1; foreign bodies in the bronchi, 2; pulmonary congestion, 13; syncope, 1; perforation of the intestines, 2,—Total 26. We advise those interested in the progress of medical science to watch narrowly after similar statistical *facts.*

Treatment of Phthisis by Proto Ioduret of Iron. M. G. Boissiere, a pupil of M. Dupasquier at the Hotel Dieu, Lyons, has lately founded a memoir on 27 cases of phthisis, under the care of the last-named practitioner, and treated by the above medical agent. Of the 27 patients, 7 died before the remedy had had time to exhibit any very marked effect on the system, and only one case was discharged cured; though the improved condition of the remaining cases appeared striking enough to M. Boissiere to warrant him in declaring "that the proto-ioduret of iron is the most efficacious remedy to which the physician can resort in the cure of phthisis.' M. Boissiére has noted the symptoms produced on himself - a person in health—by the remedy. "Before taking the proto-ioduret" he says, "I examined the pulse carefully on three occasions, at intervals of ten minutes, and found that it beat regularly 75 times per minute. After a quarter of an hour from taking a dose of 25 drops of M Dupasquier's proto-ioduret (which differs materially from the inferior preparation formerly in use under that name) the pulse had risen to 8, and I felt some headache; after an hour the mouth was cool, and there was slight dryness in the throat; the pulse had now fallen to 80, but the headache remained." When the remedy is administered in small but gradually increased doses for eight or ten days, the sensations just noticed are felt in a permanent manner; after this the organs become accustomed to the irritation which is then little felt The mouth and pharynx may be the seat of burning pain with tumefaction of the mucous membrane, which is red and often covered by a small papular eruption; this state is often attended by loss of appetite, thirst, and a remarkable change in the sense of taste. In some cases mastication is completely prevented by the pain arising from the contact of food. This local inflammation is, however, rare; it occurred only four times in the 27 cases.—In one half of the cases, the patients suffered from nausea and vomiting on the first or second day of treatment, but seldom longer depending rather on irritation of the velum palati and uvula than of the stomach in general. The first impression of the ioduret on the digestive organs is slightly irritant; but tolerance of the remedy is soon established, and it then acts as a tonic.—The vascular excitement appears to be proportionate to the weakened condition of the patient.—In a fortnight or three weeks, the pulse becomes more full and strong, and less frequent; the heat of skin subsides, and the patient is better able to resist atmospheric changes than he had been The patient's countenance becomes slightly florid the muscles and flesh get firm, and in some cases symptoms of plethora set in, accompanied, sometimes, by signs of local congestion in the lungs, the head, &c. In three cases the remedy gave rise to an affection of the skin—viz., urticaria, eczema, and lichen. During the first days of the administration of the remedy, the dyspnœa and frequency of respiration are increased; but after the first or second week they gradually decrease, and finally disappear. The frequency of the respiratory act diminishes much more rapidly than the dyspnœa; the latter often remains when the frequency of the respiration has been re-

duced to its normal standard. Still the difficulty of breathing is always removed, if we are enabled to continue the remedy sufficiently long to dissipate the congestion and effusion which surround the tubercular deposits.—The ioduret sometimes determines slight discharge of blood from the lungs, during the first few days of its administration; but this rarely occurs, and when it does happen the hæmoptysis is slight, and disappears as soon as the tonic influence of the remedy is felt. In two patients admitted into M. Dupasquier's wards with hæmoptysis the hæmorrhage was promptly arrested by the ioduret; and this symptom was of much rarer occurrence in the wards of M. Dupasquier than amongst other patients who were not treated with the ioduret of iron. During the first few days of the administration of the ioduret, the cough is somewhat more frequent, the expectoration more abundant, but easier; on the fourth or fifth day these symptoms diminish in intensity. The quantity of matter expectorated is likewise considerably diminished; in a month it is often reduced by one-half, three-quarters, or even seven-eighths. In six of M. Dupasquier's cases, both the cough and expectoration disappeared entirely; in four the expectoration ceased after forty days; in the other two after the fifteenth day. The sputa, while diminishing in quantity became more viscid, and expectoration was accordingly more difficult; but they gradually lost their purulent character. M. Dupasquier has observed the pains peculiar to consumptive patients in the interscapular region or walls of the thorax, yield within three weeks or a month; but the ioduret of iron never seemed to have any influence on pleuritic pains, or on those seated in the walls of a cavern.—*Tubercles.*—The physical signs of the presence of tubercles in the pulmonary tissue are—bronchophony, intense and prolonged expiratory sound, bronchial souffle, roughness of the vesicular murmur, dulness on percussion, and thoracic *fremissement.* It is evident that if all these signs disappear completely after the administration of the ioduret of iron for a sufficient time, we are entitled to conclude that the tubercles have disappeared, and that diminished intensity or extent of the physical signs indicates a proportionate diminution of extent or intensity in the tubercular deposit. M. Boissiere says, " I have seen only six cases, in M. Dupasquier's wards, of crude tubercle, without caverns; in no case did I witness complete removal of all the signs above indicated, even on one side of the chest. In one case no diminution of the physical signs occurred; but in the other five I detected some remarkable changes. Thus, in two patients the expiratory sound and the bronchial souffle completely disappeared, and the respiratory murmur was restored to its natural state; the other signs had not disappeared, but they had diminished more than one half in one of the cases at the end of two months, and in the other at the end of fifteen days. In three cases the intensity of the bronchophony had diminished one half at least; and the dullness of sound and *fremissement* were equally diminished. I remarked that the diminution of the extent over which the physical signs were observable generally kept pace with the diminution of intensity, and that it always took place from below upwards, commencing at the limits between the diseased and healthy tissues, and being more rapid in the lung which was least affected."—*General Symptoms.*—The most important of these are the *gradual emaciation* and loss of appetite, the gradual loss of strength, night sweats, and the evening exacerbations. In three of the six cases of phthisis in its first stage, already noticed, the night sweats and evening fever were absent; in two of the remaining three cases the nocturnal perspirations persisted for three months, but during that time they gradually diminished, and are now scarcely perceptible; in the third case they disappeared entirely at the end of a fortnight. The ioduret of iron then exercises a beneficial influence on the cutaneous exhalation from phthisical patients in certain cases at least. But its influence on digestion and nutrition is much more evident. Every one of the patients (in a period varying from eight to fifty days) recovered their appetite: the weight over the epigastrium and febrile paroxysm during digestion ceased; the face lost its earthly hue, and assumed a good color; the emaciation, in some cases, ceased altogether; the softness and flaccidity of the flesh disappeared; and the muscular strength was restored. Several patients who had been admitted in such a degree of weakness as to be unable to stand upright or walk, were after some time enabled not only to walk about for half the day, but to take fatiguing exercise. M. Dupasquier's opinion is, that the ioduret of iron is most efficacious in the third period of phthisis, or, at least, that its action is then most evident, and more so in the second stage than in the first. Constitutional is much more susceptible of benefit from the ioduret of iron, than accidental phthisis. In three cases of the latter, M. Dupasquier saw no good effect result from the use of the remedy. The chief auxiliary medicines employed by M. Dupasquier, with the ioduret of iron, are, Hoffmann's elixir, bark and the bitters, effervescing draughts, opiates, some vegetable astringents, and the pectoral drinks commonly employed to allay the bronchial irritation. The regimen which he enjoins is almost exclusively animal; he makes the patients clothe themselves warmly, and take as much exercise as their strength will permit.

Inversion of the Uterus.—Dr. Humphreys Storer was in attendance upon a woman in labour, parturition taking place naturally. The cord was not touched, except to divide it, and remove the child. On putting his hand under the clothes to take away, as he supposed, the placenta, he found that he had hold of the uterus with the placenta attached. He removed the placenta and then returned the uterus without the slightest difficulty. There was a little hæmorrhage when the afterbirth was detached, but none after the prolapsus had been reduced. The patient was very much prostrated, and for an hour appeared to be dying; she, however, revived, and ultimately did well.

The placenta was very large, and Dr. Storer states that, had he made any attempt to return it, in accordance with the advice of Burns, Dewees, and Gooch, he would have met with difficulty, from its mere bulk. This case proves that inversion may take place without the interference of the practitioner; no traction was made on the cord, which was of the usual length, and not encircling the child.—*New England Journal of Medicine and Surgery,* July, 1842.

MEDICAL NEWS.

Irish Medical Charities Bill.—Lord Elliot has announced that this Bill is to be postponed for another session. One cause is the almost unanimous opposition of the medical profession, which has shewn very great and very persevering zeal in resisting it. Another, is the opposition of the political party agreeing generally in opinion with the government, who are fearful that the new Bill might lessen country gentlemen's local influence. A third reason is the admitted failure of the present Poor Law system in Ireland: the consequent want of confidence felt in its head administrators is supposed (and we think with good reason) to disqualify them for the additional responsibilities contemplated for them in the new act. It is said, however, that some member of the House, unconnected with the government, is pledged to introduce a bill which, it is hoped, will settle the question.

Lunatic Asylums.—The Lord Chancellor of Ireland, on Jan. 12, adjudicated on a most atrocious case of mal-treatment of a lunatic. The following is Sir Edward Sugden's narrative as given in court:—" I could hardly have believed that such an outrage on humanity, as is disclosed by the affidavits in this case, could have been perpetrated at the present day. A gentleman, of a highly respectable family, who is afflicted with insanity, was put under the care of a committee of his person, Afterwards one of his brothers was appointed committee, and he placed the lunatic in a house in Cork; and, after having done this, he neglected all that personal practical attention to the circumstances of the lunatic which he was bound to have afforded. Now the jurisdiction in such cases, which I have derived from the Crown—it may be delegated to any one, and I now exercise it on the part of the Crown—makes it the duty of the Court at all times to exercise parental care over persons in the situation of lunatics, and immediately to interfere in cases of the kind. This unfortunate lunatic was found by two gentlemen, who are magistrates in the county, and they immediately exerted themselves on his behalf; they, however, instead of entering into a correspondence with the committee, should have immediately communicated with me, and the business would have been promptly settled. So far from blaming them, however, for not acting according to the strict letter of the law, I am anxious now publicly, as I have already done privately, to express the obligations which I feel to them for their humane conduct. The lunatic was found by those gentlemen in an out-house belonging to the man with whom he had been placed, and from the state of the roof there was access for the weather and the rain; and, though it was in the latter part of the year, he was stark naked, his legs chained and clenched together, and fastened by a chain not more than two feet in length, without even straw, and not able, on account of his chains, to lie down in such a way as to rest himself, and without power to move beyond the limit of the narrow circle which the chain would describe. Such were the circumstances in which, through the inattention, to say the least of it, of his brother, the lunatic lived. If ever there is a moment when the care of one man for another should be anxiously exercised, it is when the other's power over his own actions is extinguished through his mental incapacity. A disregard for the comfort of those who are in this unhappy state, to falling into which we are all exposed, is most inhuman, and while we are free from it—thank God for being so—it is our duty to watch over those who are less fortunate. I believe it to be one of the first duties of every one as a subject to see that matters of this kind are investigated, as it is of the utmost importance to the country, in respect of the state of feeling existing in it, that regard should be had to the condition of persons in the situation of lunatics." We shall give, in an early number, an abstract of the recent act (5 and 6, Victoria c. 123) for the regulation of Lunatics.

MARGATE.—It is now said that the late Sir Thomas Preece made his will three years ago, and bequeathed the whole of his property to St. George's Hospital, in London.—*Kentish Observer.*

ROYAL MEDICO-BOTANICAL SOCIETY.—At the Anniversary Meeting, held January 16th, the following gentlemen were elected officers for the ensuing year:—President, Earl Stanhope; Treasurer, Henry Cope, Esq., Jun.; Secretaries, John Foote, Esq., Joseph Houlton, M.D.; Librarian, Edwin Saunders, Esq.; Conservator, Frederick John Farre, M.D.; Professor of Botany, office vacant; Professor of Chemistry, J. G. D. Rogers, Esq.; Professor of Materia Medica, George G. Sigmond, M.D.; Professor of Toxicology, John Charles Cooke, M.D.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, January 13th, 1843:—H. H. Corbould, F. D. Howell, J. I. Atkinson, R. E. Davies, B. H. Hutchinson, F. O. Barker, H. W. Reynolds, F. J. Burrge, T. F. Mc'Ganran, R. E. Lutley, R. Rudall, A. Featherstonhaugh.

London: Printed and Published by JAMES [illegible] CAMPBELL, [illegible], Essex Street, Strand, in the Parish of St. Clement's Danes, Westminster, in the County of Middlesex. January 21st, 1843.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 175. Vol. VII. LONDON, SATURDAY, JANUARY 28, 1843. PRICE FOURPENCE, STAMPED EDITION, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

(LECTURE V., Delivered December 12, 1842.)

Gentlemen,—In our last lecture we were considering the subject of nervous diseases in children, and I have now to call your attention to the subject of inflammation within the cranium; and I am well assured, that in private practice, inflammation within the cranium is not properly considered as the cause of disease. It arises in the first place from blows; in the second place, from a sudden stroke; and it may also arise from excessive mental application. The lamented death of Henry Kirke White arose from a cause of this kind. It arises from other circumstances, and it is generally considered to come on from suppressed menstruation; and it comes on in those cases in which the urine is albuminous. There is a fact detailed by Delamotte in a case of operation on the face; the auxiliary plexus of the nose was tied, and the consequence was inflammation of the posterior and the opposite hemisphere of the brain. You see from this enumeration of the causes of inflammation within the cranium that that subject is very obscure; and connected with the fact I have related to you, (for the case is not common) you will see that it will require the utmost attention to detect this disease early in its course. There is another fact which makes it still more difficult to detect, that is, it is very often a very low kind of disease; a very insidious disease. For instance, a very interesting case came under the notice of Cruvelhier, in which the patient scarcely appeared to have any sense at all of disease. The young man would get up and sit near the fire, until at last the symptoms came on much more prominently, and the case appeared ultimately to be one of the most distinct cases of inflammation of the brain.

The first symptom of inflammation of the brain, is pain, in which case it is like arachnitis, which is more acute than inflammation of the substance of the brain itself. Having mentioned these two cases, arachnitis, and inflammation of the substance of the brain, it is important to state that we have no diagnostic from which to determine when it is one case and when the other, and it is much more frequently that we find the two exist simultaneously. With inflammation of the membranes of the brain which affects the whole surface of the brain, there is inflammation of the substance of the brain, and this involves all the nerves within the skull which are more or less impaired; as these cases occur in the way I have noticed, I shall describe them together. Then we find that, sometimes, diseases will arise from inflammation of the membranes of the brain as in arachnitis, and also from inflammation of the substance of the brain. Then pain is the first symptom of it, but it is not of an excruciating kind; it is rather dull. With pain there are other symptoms, such as intolerance of light, or intolerance of noise, and other symptoms denoting an augmented state of the faculties of the brain; in one word, it will give you an idea of the first stage of arachnitis or inflammation of the substance of the brain. And the symptom of the utmost importance,—because it is exceedingly diagnostic,—is that of sleep. The patient does not sleep in the night, or is aroused by dreams and by starting. During the day there is no sleep, or if there is any sleep at all, it is merely a little dozing. No point is more important to notice in connection with disease of the brain. The next symptoms which come on, are those of the spinal marrow, and this I noticed in the former lecture, speaking of inflammation within the cranium in infants. Very often we find a little spasmodic action, perhaps a little strabismus, which accompanies a little spasmodic action of an arm or one leg, or both arms and legs. It very often happens that in the midst of this state of things you have delirium. Now, where the delirium is violent the case is that of arachnitis generally. Much later it is not violent. It often happens in a state of false delirium, and in a state of half sleep, that there is coma vita, and the eye gapes, and the eye stares. Now it is almost certain, in this case, that the power of the orbicularis palpebrarum is overcome by the power of the levator palpebræ, and this being almost solely a voluntary muscle, the contraction of the eyelid is overcome by the voluntary action of this single muscle of the body. This I noticed when speaking of the excito-motor power. I cannot enter into that subject but very briefly, just to bring a fact before you. Very often we conceive that the levator palpebræ is one of the muscles under the influence of this power. Now with regard to the orbicularis we can easily imagine, as we know it is a muscle of voluntary contraction, that its action is produced through the medium of the spinal marrow. It is on this account the eye is closed. Now, supposing it to act in an inverse manner, and that during sleep the eye is not closed, it is probable that the levator has some connection with the spinal marrow, as it is the only voluntary nerve in the brain. The gaping eye, as contradistinguished to the closed eye will be diagnostic of a state of half sleep, which is one of the symptoms indicating diseases of the membranes of the brain.

You must have been struck with one circumstance in listening to this detail of the symptoms of inflammation in the brain, and that is, they are all of an exceedingly low order, and are not at all calculated to strike the eye of the observer; on the contrary, they are not to be detected but by the utmost application of a spirit of observation to them. I believe I have stated three cases which I have observed at the early period of the disease, when the diagnosis is most important.

I just now want to draw your attention to a case in which the diagnosis is of the most vital importance. I have described a case of inflammation in the cranium, consisting of a series of symptoms all of a low character. There is slight degree of pain, abhorrence of light and noise, the inflammation is slight, delirium is slight, and every thing is slight. There is a disease which is exceedingly common after confinement, in which the symptoms are precisely similar. But what is strange is, that the symptoms are tenfold more violent. Those who have seen much of midwifery practice, will bear me out in stating that it often happens four or five days after delivery where there is more or less loss of blood, that the patient is taken with violent shivering. Now I said nothing about that with regard to inflammation of the brain. I do not say that it is not in connection with inflammation of the brain, but I say it is so decided that I know of no other disease where it is so. With violent shiverings, then you have headache of the most intolerable kind; and excruciating intolerance of light and sound. It is in such a case when you enter the sick chamber that you find the blinds down, the bell of the house prevented from ringing, the knocker tied, and the street strewed with straw. These things indicate a degree of intolerance of light and sound, and as I have said elsewhere, this is followed by violent shivering and violent headache. This disease is very common, and though it is so common, it was, I believe, until lately, called inflammation of the brain, and treated as such. I am persuaded that the want of a proper diagnosis has led to many errors of this kind.

It is by the very violence of the symptoms that you are to determine your diagnosis, and I always say, whenever the symptoms are slight and come on in the slow form, and in an insidious manner, you should suspect inflammation; and whenever the symptoms come on in a more violent manner, suspect that the case is different from inflammation. Now then, let us see how to determine the case when the symptoms are so dissimilar. When the case is slight, it is inflammation, when the symptoms are more violent, it is different. If you cannot discover any other diagnostic, the diagnostic is not altered by the use of a particular remedy. That remedy is blood-letting. In the case of arachnitis I need not tell you the remedy is blood-letting, and if you do not bleed freely the patient will die. In the other case, I believe blood-letting should not be used. But suppose you cannot determine the diagnostic. If you are quite satisfied from your diagnostic that it is not inflammation of the brain, then I have not another word to say. Now I will mention two cases that occurred the very same week, more than two years ago. I was called to a patient in Guildford-street. He was attended by Mr. R——; he had a very slight degree of pain across the brow, a slight degree of restlessness, and helplessness, and a slight degree of intolerance of light and sound. The symptoms were exceedingly slight. We came to the conclusion that it was inflammation of the brain. I said let him be raised perfectly upright and bleed him. This was done, and ten ounces of blood flowed. He did not turn pale, and Mr. R——dared not proceed farther. This was done on the first day. I went the next day and found the same state of things;—precisely that of coma. I said, "why not bleed him to syncope?" Mr. R—— said "we dare not." I left the room saying, "let the same thing be done." On that day twenty-four ounces of blood were taken, and the patient never fainted. On the third day the same thing was done, and twenty ounces of blood were taken; but that did not produce any fainting. On the fourth day eighteen ounces of blood were taken, and the patient fainted, and did not require to be bled again. I believe such a loss of blood could not have been borne had there not been decided inflammation; at any rate, I tell the fact to you, that the patient was well from that moment, and required no further blood-letting; and what I think important is, he did not suffer from the remote effects of the loss of blood. By that I mean that in many cases in which blood is lost by the system in the course of a certain number of days, there are throbbings of the heart, and the arteries, in the head, and so on. Such effects did not occur in this case. In the same week I was called to another patient, the wife of an eminent practitioner. I said to the husband, "what do you think of this case?" He said, "I think it is arachnitis or inflammation of the brain." I said, "that is

not my opinion. I do not believe there is any such malady here?" I should tell you there was a very deranged state of the alimentary canal; there was an excruciating pain in the head, and intolerance of light. I said, "I will tell you what you should do; you should go up, and bleed the lady until a state of syncope is produced." He replied, "yes, I wanted your sanction." I said, "I give it to you," and while he was gone up stairs, I wrote on a bit of paper, "the patient will faint before she has lost nine ounces of blood." She did so. Now that patient suffered from loss of blood; and that patient was a good many days in recovering from the remote effects of the loss of blood, though it was a very slight loss; whereas, the other patient, whose constitution was very strong, lost eighteen ounces, then twenty-four, then twenty, and then eighteen ounces of blood, on successive days, and never suffered in the slightest degree from the remote effects of the loss of blood. I am quite certain that I recommend a very safe measure when I recommend bloodletting; invariably putting the patient in an upright position. As I said before, you may mistake the symptoms; you may suppose there is inflammation when it is irritation, and you may mistake this for inflammation, and the more so because the symptoms of inflammation are insidious, but the symptoms of intestinal irritation are not slight nor are they insidious, but they come on with violent shivering, excessive headache, intolerance of light and sound, and very frequently delirium. In such a case as this you will take a larger quantity of blood in the severer symptoms, and a smaller quantity in the lighter, whereas, it should be just the opposite.

I must lead you, then, now to the second stage of the disease, and, as I said before, with regard to children, the second stage of the disease is the very opposite—the antipodes of the first: whereas in the first stage the symptoms are excessive, now in the second they are slight at first, but more and more severe ultimately. There is an obtusion of the senses, so to speak: a state of comatose insensibility becomes coma, and a state of half delirium becomes stupor. The patient now begins to experience intolerance of light. Now the patient, you observe, gradually becomes blind, and instead of more intolerance of light, there is very often blindness. Look at the pupil, it is contracted in the first stage, and dilated in the second stage. I consider the symptoms all of the same kind. I mentioned in the first instance, there was a disposition to spasmodic affection; instead of spasmodic affection you have, in this case, paralysis; there is some change that takes place which changes the state, that in the first instance produced spasm, into one that produces paralysis. I must explain the meaning of these two terms, and I will put to you an interesting physiological, and not an uninteresting practical question. I told you in the previous lecture, that lacerate the brain as you please, you cannot produce spasmodic action, nor in inflammation of the brain, will you have spasmodic action. There is not a more diagnostic mark of the softening of the brain, than the rigidity of the extremities. Now, then, comes the interesting question:—As it is impossible by any abrasion of the substance of the brain to produce any spasmodic affection, how is it that you have spasmodic action in the region of the brain? In that case of affection of the brain called ramollissement, this very rigidity takes place, from a mere affection of the brain itself. In every case of ramollisement, especially in the first stage, there is tumefaction. Now, therefore, the fact of pressure will produce spasmodic action. You remember the case I mentioned to you where pressure on the medulla oblongata produced spasmodic action, and in another case, a protuberance pressing on a nerve, produced spasm: and there was one case of protuberant disease, which, affecting the spinal marrow, produced spasmodic action. How do you account for this in the state preceding that of ramollisement? In inflammation, generally speaking, you have a state like that of tumefaction, and the organ is too large for the cavity; then, inasmuch as you have tumefaction producing pressure, that pressure will produce spasmodic action. Here, then, you have the phenomena accounted for. Then with regard to the paralytic state, paralysis arises from the irritation of the organ itself, and, as in the preceding state to ramollisement, you have spasmodic action and tumefaction, in the second stage of ramollisement, you have paralysis. In fact, every thing in this stage is paralysis. I have told you about the state of delirium passing into a state of coma, intolerance of light, and partial blindness, intolerance of sound, and partial deafness. So the state of undue sensibility passes into a state of entire insensibility. In the state of insensibility some very interesting phenomena occur, combining a very interesting practical point. In connexion with this point, I will detail to you a short case. I was called a short time ago, with several friends of mine, to see a poor man labouring under the symptoms of the second stage of inflammation in the brain; he was in a state of coma, and he was perfectly deaf to many questions I put to him. I cried out to him to put out his tongue, but he did not do so. He was perfectly unconscious, and agonizing pain was written on his brow. I said, "what can this possibly be?" Here is a point I want you to attend to. Now I come to it. In this state of half sensibility, the patient was not conscious of the natural wants, and therefore the bowels were insensible; the bladder was overflowing from being distended. Now the fact is this, the patient being unconscious, or in a state of things of half consciousness, or not conscious to such an extent as to allow of the acts of volition, and to void the bladder, the bladder being excessively distended, there is an extreme disentegration of the fæces from the sphincters, and therefore the urine flows from the violence of that disentegration. There is often pain under these circumstances, and it occurs in the case of typhus fever, and in common fevers. Invariably if you put your hand on the region of the bladder, you will find it to be full, and you will perceive a perceptible difference if it be empty. This man must have been suffering under the effects of a distended bladder; distended so far as to produce inflammation, and in this case recovery was quite impossible. The catheter was proposed, and the symptoms were relieved, and the agonizing pain written on the brow, was immediately removed. Here is undue sensibility, the very opposite state of things to what occurs in the first stage. Whereas in the first, all the functions were raised, now they are all in the lower state of insensibility. In this state of things, you are often called upon to see a patient, because, as I told you, the first state of things is insidious in its action, and its progress is slow. In the lower ranks of life especially, it passes on unnoticed, and then the second stage comes on before anything has been done to avert the symptoms of the first. You are called upon to witness such a case as that, in which you have comatose insensibility passing into a state of coma: there is no delirium, but a state of dozing: there is no abhorrence of hearing and seeing, but on the contrary, there is deafness and blindness. Every symptom in this state denotes a state of the brain such as that of unusual insensibility.

Here, then, you have the two first stages of the disease. I come now to the third stage, and all that I can say with regard to this is, that it is one which is severer still than the second stage. The coma is severer still. It is very often that in this case you observe paralysis, paralysis of that very arm, that was not previously contracted. Not only is there paralysis, but you observe a mucous substance infusing itself into the bronchial tubes, and causing an accumulation in the intestines. There is a slow sinking state of the system, and now not only does the urine pass involuntarily, but the bladder is more and more disturbed, and the intestines are more and more distended. Another symptom is that of a state of oblivion. That which was accelerated in the first stage becomes slow in this, and the symptoms are followed by death. There is little suffering in this case, which is a thermometer as it were of the progress of the disease. There is a curious circumstance connected with this sinking state mentioned by John Hunter, and he calls it a state of dissolution. Now it sometimes happens that there is excruciating pain in the case of hernia, and that the patient becomes altogether easy, all at once, all of a sudden, and if you are not immediately called in, you may give an erroneous prognosis. I attended such a case, and I saw the patient suffering from agonizing pain. Another practitioner who had been there before, had given a dose of calomel and this was followed by apparent ease, and every symptom seemed to be relieved and the pain gone; there was nothing to excite alarm. I left, and the next morning I heard with horror that the patient was dead. In fact, the state of cessation of pain was the sinking state, the patient lost all pain from the sinking state.

(To be Continued.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS: OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Summary.—Analogy between the monstrous productions of vertebrated animals and the permanent organic state of the invertebrata—Influence of the modifications induced by the metamorphosis of animals in the production of species among the invertebrata—Experiments of regeneration in the earth worm—Formation of the Polypodes, the vorticella, the rotellina, &c.—Formation of the shell of the aceres, of that of the limnæus ovalis, and of the bivalvular shell of the isaura cycladoides—Mutual relation of organogeny and of zoogeny as evidenced in the anatomy of the cirripides, considered as permanent embryos of the craw-fish.

The organization of the invertebrata is thus, when considered in its true light, but a reproduction upon a fixed plan of those organogenic data which we find it so difficult to determine in the changing embryogeny of vertebrated animals. With the former as with the latter, the organisms pursue an ascending course, and become subjected in this progress to the same laws of development. Like the vertebrata, the superior invertebrata traverse, during their periods of formation, the permanent organisms of the inferior invertebrata; so that these latter are, as it were, but the permanent embryos of the former. Observation or experiment will be still more decisive in the invertebrata than in the vertebrata; for that which in the latter takes place internally, and with a rapidity which renders observation exceedingly difficult, is in the former executed externally, and most frequently with a slowness which permits the observer to calculate its stages, and even to measure its variations. From this parallel progress of the organisms in the vertebrata and the invertebrata, springs a most singular and unexpected result. Whilst, in fact, in the vertebrata, the organic metamorphoses influence only the organisms, which are the seat of these changes, without altering or affecting the species or family, in the invertebrata, on the contrary, but especially in the lower ones, each metamorphosis, each transformation gives birth to a species, to a family, to a new genus. The genera, the families, the species, limited in the vertebrata, thus seem to be without limits among the invertebrata: a curious fact, the cause of which most probably depends on the parasitical life of the embryos of the vertebrata, as opposed to the free and independent life of the greater number of invertebrata. The comparison of these two species of life will moreover direct us towards the conditions of the uterine life of man and the mammifera, and may perhaps throw some light upon the cause of the abortions, so frequent in the human species.

We may remark that, in the invertebrata, life is freely performed with organic conditions, which we should denominate as monstrous in the vertebrata, for, in fact, the invertebrata are frequently but living monstrosities, if compared with the perfect vertebrata. Thus part of the polypi, and some infusorial animals, are *anenteric*, or devoid of intestinal canal, similar to the moles expelled from the female uterus. Others present only the anterior part of the alimentary canal: as for example, the *alcyona*, the *veretilla*, the *pennatula*, and

some *vorticella* among the *infusoria.* There are acephalous monsters, devoid of that which is denominated the head, among the invertebrata. A great number also, even among the higher classes, are destitute of a heart. These mutilations, these deprivations of organs are incompatible with the external life of vertebrated animals. An acephalous being devoid of a heart, or even of a part of the intestinal canal, dies on coming into the world; but before birth, it has a life of its own within the uterus: it has passed through a peculiar form of vitality; in a word, it has accomplished the life of an invertebrated animal. We all know that before birth, mammiferous monstrosities are endowed with life in the womb; but a fact less generally known, and hitherto scarcely regarded, is that there exists for these monstrosities a scale of uterine vitality,—a very important circumstance in a philosophical point of view, since it proves a species of independance in the being during embryonic life. Thus a fœtus devoid of a limb, will live longer in the uterus than one destitute of a heart and a head, as this latter in its turn will perish sooner than one in which the head only is wanting. These facts, in which science is already so rich, might, physiologically considered, tend greatly to clear the disputed question in anatomy as to the vascular communication between the mother and the infant. Suppose, that this communication does exist, do we not see that its cessation, or the natural detachment of the fœtus, should take place at the same period, whether this production be monstrous or not? What can the malformation of the fœtus have to do with this communication, if embryonic life be but a sort of grafting of the infant upon the mother? If, on the contrary, in embryonic life, the infant enjoy a species of independence, we may conceive that the malformations, or diseases, with which it may be affected, by abridging its life, must necessarily influence its expulsion, since a dead body cannot remain long within the womb of the mother.

We may, by the foregoing facts, judge of the influence necessarily exerted over the progress of organogeny, by the comparison drawn between the permanent organization of the invertebrata, and the transitory organization of the embryos of the vertebrata; but I will give still further examples of its importance. The successive gradation of the organisms in the embryo of man, and of the vertebrata, is one of the facts which has been especially contested in organogeny. Most are inclined to consider the embryo as an exact miniature of the perfect animal. Now, this question, so difficult to pursue in the young embryo, is repeated in the invertebrata under conditions the most favorable to its verification. Thus the earth-worm, arrived at the term of its development, differs greatly from the *polypus*, the *tænia*, the *helianthoida*, and the *arenicola*; but when we follow its various metamorphoses, we find that it is in the first stage a mere repetition of the *polypus*—in the second, of the *tænia*—in the third, of the *helianthoida*—and in the last, of the *arenicola*. What is also remarkable, is, that by experiments in regeneration, we find the counter-proof of this successive elevation of the organisms of the earth-worm; for in these experiments we make them descend in a manner similar to that in which they ascended in their natural development. Thus the first regenerations reproduce upon the new segments the structure of the *arenicola*—the second, that of the *helianthoida*, while the third and fourth give rise to zoonites of a structure similar to the *polypus*; for the force of reproduction becomes weakened and exhausted by its action, in the same way that the reproduction of the organic tissues of man is enfeebled and exhausted by too frequently repeated a regeneration.

By repeating these experiments upon the earth-worm, I have been enabled to bear evidence to the correctness of those zoologists who have distinguished several species of this insect, and by a comparative examination, I have become convinced that these various species are merely arrested stages of development of the more elevated species or type. Species may then, in vertebrated animals, be merely the result of modification produced by a greater or less metamorphosis. The most elevated metamorphosis will constitute the ideal type of the genus—the most inconsiderable will form the last species. Hence it follows, that the evolutions which, confined to the organs, give birth to the various organic species described by comparative anatomy, will, when regarding the organisms, produce in zoology the animal species. It is clear that we must adopt the same views in the study of zoology, as in that of comparative anatomy. Now, what would be the consequence if, in tracing each organ, we confined ourselves in an absolute manner to all the differences engendered by each evolution? We should evidently be led to consider these different states as different organic species. Thus, supposing an organ to possess four principal evolutions, like the prostate in man, or eight or ten, like the human kidney, we should have in the human species eight species of kidneys, and four species of prostates.

That which we have avoided doing in comparative anatomy, by reason of the progress of human anatomy being opposed to it, is precisely what has been done in zoology, in reference to the lower animals. We have taken and described as different species, the various metamorphoses which one species undergoes while traversing in the natural order from its original conformation to the term of its development. Hence, their exaggerated multiplication. I will illustrate this point by a few examples. When we trace, by the microscope, the development of the infusorial animals, we see these small beings successively clothe themselves with forms very different the one from the other: whilst some are arrested at the commencement of their development, others become transformed in their progress. At each step thus made, they leave their former associates behind; they traverse, as it were, to the bounds of their organization. The *kolpodes* are the principal genus upon which I have been best enabled to follow this transformation of forms. Their *ova*, when first laid, are obscure *monades*, buried in a colourless mucilage resembling the albumen of the egg; suddenly, this albumen becomes streaked with small lines, to which the *ova* are attached by *hila* so slender, that it requires a magnifying glass of great power to be enabled to distinguish them. The *hilum* is a sort of umbilical cord, by which the embryo of the *kolpod* receives its nourishment. Thus fixed, it develops itself, assuming the forms of the various species of *monades*, then of the *volvoces*, and the *gones*. At the moment of its becoming detached, this is the *kolpod cucullus*: a little later, we find it the *kolpod renarius*, which has successively clothed itself with the forms of the genera which are inferior to it. But all the embryos of the *kolpod* do not await this series of metamorphoses; many become detached earlier. Now, according to the period at which they acquire their liberty, these will be *monades*, *volvoces*, or *gones*, having their own individuality and life, independant of the group of associated embryos of which they made a part. The detached embryos become then species and genera constantly inferior to the *kolpod renarius*, which is the highest term of their transformation. The changeable *vorticella*, green or white, in like manner, presents in its development similar transformations.

The evolution of inferior species by the metamorphoses of species more elevated, has been already glanced at, in the *vorticella*, by M. Ehrenberg, who has also, by his able researches, reduced to their true meaning the numerous transformations traversed by the *vorticella convallaria* in the course of its developments. Observed at its different ages, the embryo of this *vorticella* differs so much within itself, that, according to the principles of differential zoology, it led Muller to consider each of its evolutions in the character of a distinct species, while Lamarck and other zoologists viewed them as the types of different genera. But M. Ehrenberg has again reduced these genera and species, by showing that the characters which serve as their basis are merely the transitory forms of the *vorticella convallaria.* "I am convinced," says M. Ehrenberg, "that the twelve species of Muller, of the genus *vorticella*, are merely the different states of a single species, and that with these twelve supposed species, Lamarck, Schrank, and others, have formed six new genera, that is to say, the *ecclissa*, the *ridella*, the *kerobalanea*, the *urceolaria*, the *craterina*, and the *ophrydia*, which are all but different ages of the *vorticella convallaria.*" In the new genus, which I have described under the name of *rotellina*, I shall be enabled to show, that the numerous species which this singular *infusorium* presents, are all merely simple modifications of the species with eight rays which serves as the type.

Among the *mollusca*, it is in the genus *aceres*, or *gasteropodes*, without apparent *tentacula*, that we best perceive the slight bonds existing between the *shell-mollusca*, and the naked species. It is in this genus that we can plainly trace the formation of the shell, or *testogeny*, for we here find all the stages of development of this species of protective armour, from its simple outline traced in the form of an entirely fleshy covering, up to a thick, solid, spiral shell, affording an ample asylum for the entire body of the animal. Considered in reference to the formation of the shell, the species composing this genus may be regarded as permanent embryos the one of the other, so that we can follow its development in them much better than we could do in the young embryos of any other molluscous animal. M. Dumortier has made similar and not less remarkable observations on this subject. Tracing the development of the molluscous *gasteropodes*, he has ascertained that the shell of the *limnæus ovalis* assumes successively, in the course of its formation, the characters proper to the species beneath it. "At the same moment," says this ingenious observer, "the shell commences to form itself at the extremity of the embryo. At first it presents the form of the shell of the *patella*; but, growing daily, it passes by turns through the forms of the *testacella*, the *crepidula*, the *ancyola*, and the *caborhon*, and when the animal opens, it presents that of the *succinea.*" Here then are five species of shells which are merely so many arrested points of the five transitory forms traversed by the shell of the *limnæus ovalis* during its development. M. Joly, while tracing the development of the bivalvular shell of a new genus which he has discovered among the *crustacea*, and which he has named the *isaura cycladoides*, in like manner confirms the observations of M. Dumortier.

The greater the progress we make in the study of organogeny, the stronger does the conviction become that the differential characters of organized beings are owing simply to the same organisms being sometimes more and sometimes less developed. Are not the insects which have undergone but a demi-metamorphosis, stages of permanent arrestation of those insects which have passed through a total metamorphosis? Are not the former advanced embryos, as it were, of the latter? By tracing, for example, the embryogeny of the bee, do we not see the division of its rings, at first in the state in which they are presented by the *hemiptera*, then in that offered by the *orthoptera*, and lastly as shewn by the *coleoptera*? Are not then the *hemiptera*, the *orthoptera*, and the *coleoptera*, in this respect, permanent embryos of the bee.

In applying this principle of zoogeny to the *crustacea*, let us choose as an example the *cirripedes*, the most difficult of classification among the invertebrata. Ranked by some with the *echinodermata*, by others with the *mollusca*; sometimes with the *annelida*, and at others with the *crustacea*, these little beings have been to classifiers, a constant source of perplexity. Now, what is remarkable, is that the imperfection of their organisms justifies all these conclusions; and, notwithstanding the able researches of which they have been the object since the time of Poli down to that of Cuvier, Thomson, Burmeister, &c., the *anatifa*, and the *balanea*, still wander from class to class; so that these animals have yet to be assigned the place which they ought definitively to occupy. Whence arises this fact? What can be the arrangement of their organisms, that it should allow their being classified, by some so high, by others so low? Will organogeny explain to us a contradiction so striking? It will explain it by its ordinary proceedings, if the *cirripides* are embryos arrested in their development. Suppose, in fact, that the *anatifa* and the *balanea* are *crustacea* in the progress of formation; suppose also

that this formation is arrested at a fixed period, is it not evident that their organisms will bear the stamp of this arrestation? Is it not also evident that you must class them, higher or lower, according as you take for the basis of your determination a more or less undeveloped organism? Now, this is exactly what occurs. Without stopping to justify these different classifications, I will shew that the *cirripedes* are merely permanent embryos of the *crustacea*, by drawing a comparison between their organisms and the embryogeny of the craw-fish. I shall, on this subject, lay the valuable researches of M. Rathke under contribution. The five pieces of which the shell is formed in the *anatifa*, the three pairs of jaw-bones, the divided state of their alimentary tube, the dorsal position of the anus, the enlarged vessel which represents the heart, the curved position of the body, not yet articulated, and furnished with paws, lastly the nervous system represented by a double chain of ganglia, these are the prominent characters of the *cirripedes*, and hence arises the unharmoniousness of their structure. If the arrangement of the shell induced Cuvier to approximate them to the muscle, that of the nervous system was a stronger justification for M. Martin St.-Ange in comparing them with the *annelida*. Now, by combining these conditions, we shall find in a permanent state in the *cirripedes*, those organic conditions which are merely fugitive and transient in the embryo of the craw-fish. Thus, at the second and third stage of its development, the bony covering of the craw-fish resembles the shell of the *anatifa*; the embryo is doubled up, and enclosed within it, as in the *cirripedes*. At the same time, its inarticulated body is furnished with paws—the heart is represented by a dorsal vessel—the branchiæ are in a similar position—the alimentary canal is divided—the anus is situated in the dorsal region—the mouth is composed only of three pairs of bones—lastly,as in the *anatifa* and *balanea*, the nervous system represents a double chain of ganglia, situated on the sternal bone, as described by MM. Audouin and Milne-Edwards. Suppose that the craw-fish becomes arrested at this period, will it not, in all respects, resemble the *anatifa*? Would not the organisms then present an almost perfect analogy? But whilst the *cirripedes* remain permanently at this period of embryonic formation of the *crustacea*, the craw-fish runs through its developments, leaving behind it the animals whose characters it had transiently assumed. The *cirripedes* then are embryonic craw-fish or *crustacea*.

This conclusion leads to another; for, if at a given period the embryo of the craw-fish reproduces the condition of the organisms of the *anatifa* and *balana*, we see that the zoological views entertained as to the *cirripedes*, are equally applicable to this embryo. Now, as the *cirripedes* have by some been ranked among the *echinodermata*, the *annelida*, and the *mollusca*, the embryogeny of the craw-fish must reproduce the echinodermata, the mollusca, and the annelida, to the same degree as the anatifa and the balana. I may further remark, that as the embryo of the craw-fish traverses, in its development the organic conditions of the *cirripedes*, which are its inferiors, so do the *anatifa* and *balanea* repeat, also in a transient manner, in their formation, the *oscabrione* and the *patella*, which, in the zoological scale, are placed far below them. There is, as we shall see, a continuous chain of resemblances and of repetitions of organisms, which, in the words of Geoffroy Saint-Hilaire, render almost indeterminable the *zoological species*.

Similar views may be drawn from the observations of MM. Carus, Dumortier, and Duges, upon the development of the *anodonta*, the *gasteropodes* and the *cephalopodes*. In comparing the transient states of the organisms of these embryos of the *mollusca*, with the permanent organisms of the *mollusca* which are their inferiors, we find in this class a repetition of the facts which have been just shown by a comparison of the *anatifa* and the *balana* with the different periods of embryogeny in the craw-fish.

Our conclusion is thus fully justified—zoogeny is but a fixed and permanent organogeny.

SOME CURIOUS PHENOMENA OF ELECTRICAL INDUCTION.

(Being a Lecture Delivered by Dr. Faraday, at the Royal Institution, on Friday, the 20th inst.)

Mr. Faraday commenced his lecture by stating that he hardly understood the feelings that came over him at these Friday evening meetings, for whenever he set about the preparation of anything which he thought might be interesting to his audience, he was always startled by the idea that he was about to deliver something which might be abtruse, and which, though it might seem interesting to himself, would turn out a very dull affair to them. He felt this on the present occasion, because although the subject of electrical induction ought to have a prominent place in the minds of those who were looking to electrical phenomena just now, when so many different hypotheses have gone out, and ought to be interesting to those he was now addressing—yet he felt it would be very dull indeed to them. It ought not to be so, because he was perfectly satisfied that any part of experimental science must be interesting to those to whom it is put in the form of clear ideas; and therefore he appeared before his hearers with the object, partly to instruct, partly to interest, and partly to amuse them by some illustrations of the induction of electricity, hoping that the bearing these phenomena had on the present state of knowledge with respect to this great globe, would be not merely their apology, but their justification.

It was always necessary at these evening meetings to assume that there were among the auditory some who did not know anything of the subject, and therefore there was always the necessity of bringing them up, as it were, to the point from which those well acquainted with the subject treated of, started. Now although he was about to treat of the subject of electricity—that extraordinary power in nature, yet withal so common, as to be to some extent exceedingly familiar, through the general diffusion of even a small portion of knowledge of every kind over society, yet unless the utmost attention was fixed on the phenomena induced by this extending power, that which was of the utmost consequence to philosophers and to mankind generally, would be treated as common place matters. By the aid of the glass rod in his hand, he was able to evolve a most extraordinary power *from* matter, *on* matter, or *in* matter, for a careful man knew not how to express himself under such circumstances,—yet, he had the ability by the simple instrument in his hand, to evolve, or put into action a most extraordinary power not apparent before. He had before him some gold leaves enclosed in a glass jar, perfectly separated from any external mechanical action—nothing could go near them—they were so suspended at one end, that the other extremities could separate and diverge, and by applying the rod of glass in his hand to the electrical machine in which the extraordinary power on which he was treating resided to a high degree, he could take from it a specimen or portion of that power, and by bringing it into proximity with the gold leaves, but not touching them, could make them diverge. This was but one illustration of the extraordinary power of electricity; that power on which, every day, life depends, which is ever moving in and about us, and without which we could not exist; a power of nature, which therefore ought never to be uninteresting to us. Another experiment of an interesting nature was that performed by means of the common Leyden jar, and this was all of his summary with regard to this power.

It was his intention so to treat what little he had to say of induction as to draw some conclusion, as far as he could go, or rather to educe some general expression with respect to certain phenomena of this kind, and which in nature we saw in the flash of lightning, the concussion of the air, and the electrical shock. It was strange, when we reflected upon the terrible effects sometimes produced by this power, that we could enclose part of it in a jar, so as to render it perfectly subservient to us, to be used by us when we pleased, and which we could bring into action when we liked; and produce precisely the same effect as the flash of lightning in the storm.

He would now advert to some particular properties of this extraordinary power, which, when put into action, manifested itself in various ways. There were certain phenomena of attraction and repulsion—though, perhaps, we were not quite sure about the matter of attraction, yet repulsion was certain, and in the minds of some the other was doubtful. He would, therefore, speak only of appearances, and those appearances were the very best for the observation of small portions of this power. It must be remembered, that in all experimental science, the smallest phenomena that could be manifest were sufficient, and were equal with regard to the inferences educed from them, to the phenomena of the most extraordinary magnitude. A lady, as she combed her hair, might frequently, on a dark evening, see sparks of light passing from the hair to the comb, thus affording to a certain extent, as correct a study of the nature of the flash of lightning in those small sparks as in the tempest or the storm itself, which in the open sea is so terrific. The velocity of the lightning, however, was the same in those small flashes which we could observe without endangering our life, as in the dreadful and terrific storm. Now by a rod of glass he could take from the electrical machine, a piece or specimen of electricity which he could communicate to another substance, and this he called induction, or the induced action of electricity. This induced action exhibited certain very curious conditions on certain occasions, and he used two kinds of instruments for the purpose of illustrating this. One instrument was a very beautiful one, called an Electroscope which consisted of a frame of wood, in which was suspended, by means of a fibre of glass, a rod of shellac bearing at each end a gold leaf. The glass was used because the electricity could not travel through it; and the shellac had the power of insulating or restraining the passage of the electricity from the gold leaf. The other little instrument was a very simple one, consisting of a rod of shellac with a gold leaf at the end, and by applying this gold leaf to the electrical machine, he could take a specimen of electricity, and then by bringing it into near proximity with the suspended leaves they were repelled. This was electric power in a very small quantity. This repulsion was owing to both bodies being in the same state, it being a law of electricity, that when bodies are in the same state, they repel each other.

Now induction caused the distribution of electricity on the surfaces of bodies. He would make this manifest by an experiment or two. He took a conductor of brass, mounted on a stem of shellac, and a metal jar mounted on its side upon a stem of glass: these he placed upon the table. Then, by means of a brass ball suspended from a string, he took a specimen of electricity and communicated it to the brass conductor, and he induced it again from the surface of this body, so as to cause the gold leaves in the glass to diverge just as they did when the electricity was taken from the large machine itself. The same experiment he produced with the other metal conductor on the glass stem. But to show that the electricity was only on the outside, he took a specimen of electricity from the machine and communicated it to the inside of the last-mentioned conductor, but from the inside of this vessel he could not again induce it so as to put the gold leaves in motion. He applied the metal ball to the outside, and there the electricity was, and he could now, by placing the ball on the outside of the conductor, and then bringing it near the gold leaves, cause them to diverge. The electricity had passed to the outer surface, though communicated to the interior. There was none at all on the inside, but on the outside it was abundant. This proved that electricity was entirely on the surface, and *that* by electrical induction. This was farther and better illustrated by taking a metal globe and hanging it up by itself, and also two hemispheres to go over it, and form what he termed an outside, so that he could place them on and take them off and examine them separately. This globe he electrified by the rod of glass, and the effect was

afterwards communicated to the electrometer, so that the gold leaves diverged. Then he covered the globe with the hemispheres, and the effect was transmitted to them. The electricity had entirely left the globe and gone to the hemispheres. No electricity could be taken now from the globe to which it was first communicated, although at that time electricity could be taken from its surface: but it being covered by the hemispheres, so that they formed an outside, it had all been communicated to them because they formed the outside. Another experiment made this more forcible. He took a metal vessel not charged, and by means of a carrier, or metal ball suspended from a silken cord, he charged it with the subtle fluid. He communicated this to the interior, but the indicator could not thereby be affected; on applying the conductor, however, to the outside of the vessel, he found that electricity was there, and its presence was made sensible to the indicator. This was a conclusive proof that electricity could be only induced from the outer surface of bodies. This experiment would lead to the understanding of what was meant by the electricity of a cloud being on the surface. A cloud consisted of myriads of little conducting particles, all held together by some strange condition or power governing them all. The electricity was not to be found on the exterior of the separate particles, but on the outside of the general mass. The metal radius, or an instrument consisting of a hemisphere with points radiating from its surface, illustrated this fact. This body could be charged with the electric fluid, but the central or the interior radius, did not manifest any signs of its presence; it was only to be found on those outside points which formed the circle or circumference of the whole. Again, he took a vessel formed of wire gauze perfectly open, so that in every part the light shone through it, and in every place the air could permiate through it. He charged it on the inside by means of the carrier, but on taking this out there was no electricity left on the inside; it had travelled to the outside, and there it was proved to exist. What was to prevent the electricity running through the wires to the outside? The inside and the outside were not the 100th part of an inch apart, and yet, though there was only this difference between the inside and the exterior, so that a mite would have to travel only half a second before it could get round, that which travelled at the rate of 400,000 miles in a second could not get round half the circumference which the smallest animalculæ in creation could go round.

It must be remembered that in every one of these illustrations, there was not a single phenomena in nature that was not touched upon in one way or another. Matters which might seem different, however different they were in their general character, the nature of all was summed up in one, and they were all subject to the same force and the same laws. Such were the general constitutions of the laws and forces of nature.

The experiments he had now to bring forward were to show the induction of electricity through air, and also its induction through other bodies. In the first place he inclosed some gold leaves in a jar, the top being open, and by means of a conductor he caused the gold leaves in the electrometer to diverge. On removing the conductor, the action did not continue, because it being only induced action, it could only remain as long as the induction lasted. This was induction through air. In the second place he placed on the top of the jar a piece of glass, and the same effect was produced; the induction took place through the glass as perfectly as through the air. He then removed the glass and placed on the jar a plate of sulphur (it mattered not, he said, how thick it was, on the contrary, the thicker the better), and on the approach of the conductor, the gold leaves diverged just as much as before. Connected with this experiment, it was a strange thing that the electricity penetrated the sulphur with double the force with what it was induced through the air. The same action was produced by substituting a piece of shellac for the sulphur or the glass. Now it was a strange circumstance that induction took place as perfectly through metal as through any other substance, provided the conducting power of the metal was not allowed to come into play. In induction through metal there was no distribution of the power, but the effect was the same as through the thick plate of sulphur.

The next experiment was to show that electricity acted through air, and that too to a great extent. He had repeatedly taken a specimen of this power from different parts of the theatre in which he was now lecturing. In order to show that electricity was induced through the air, he had suspended against the wall of the theatre a silk handkerchief with threads attached, so that it could be drawn together and removed without its coming in contact with any other substance. Attached to the electrical machine was a large metal bell mounted, near to the wall where the handkerchief was suspended. The machine was then put in motion, and this bell charged with electricity. In a minute or two he removed the handkerchief which was charged with electricity, as was made manifest by the electrometer. This experiment could be performed in the gallery or any part of the theatre; and, in fact, a specimen of electricity could be taken from the head of any one of the audience, and carried to the indicator in the same way as he had carried it in the handkerchief. Thus was this extraordinary power manageable, sometimes by the same condition and quality that it was unmanageable at others. It was a property of electricity to produce the opposite state in everything that was conducting near it. In performing the next experiment, he took a slate or metal vessel and placed it on a plate of shellac, with a metal plate on that, and he then placed in that shell another, and in that another, and then a fourth in the last. These vessels did not touch each other, and yet there was a perfect action induced through all the shells, and all the electricity was on the surface of the inner shell, so that when that vessel was removed, all the electricity was taken from the apparatus. It had passed through the air to the metal, and was all on the outer surface of the inner shell. The same result would be obtained with a thousand shells. It was important to observe that not the smallest amount of power was ever lost in any of these experiments. It was an important thing to notice a fact which the mathematician would understand, that the sum of the focus was precisely the same under all circumstances. Dalton had illustrated this beautifully, in some chemical phenomena, where there was a certain definite chemical effect; and so in electricity, there was a certain definite action in all the variations. There was no adding to, or taking away from, the amount of power.

Great consideration was now being given to the condition to this earth, which was a globe electrified in space. In illustration of this, some striking phenomena were produced, which led to the question, "What is the state of this globe?" We were in the habit of thinking that on the surface of this globe on which we live, there was a certain action going on, that of repulsion. The vicissitudes and changes that were going on on its surface, did not tend to changes in its electrical condition. It must not be supposed that the most important electrical and atmospherical phenomena were exhibited in the thunder storm, for though electricity existed in the atmosphere, all things in existence partook of it, and it was manifested in the growth of plants which were continually and silently discharging electricity to the air. It was pretty sure that plants had this power, and that they were great lightning conductors. On electricity depended the health and the growth of plants; it was this influence that made them grow and become serviceable to mankind. On the other hand Beltier had, with respect to this globe of ours, given out a notion that was very startling, and which was quite in opposition to the views of philosophers up to the present time. This philosopher thought that this globe of ours on which we live, was in a highly negative state, and that space around us was in a highly positive state. It was worth a great deal to know in what state this globe was. It might be that space was in the opposite state, or what was more likely, that the objects in space—the planets, the sun, and the stars, were in a negative state. There were some objections to the theory of Beltier, but there was no doubt the sun, the moon, the planets, and the stars were in one state or the other. Leaving this matter, he illustrated the effect of the lightning on the surface of the globe, by placing on an insulating machine a board, the surface of which represented the surface of the earth. He then placed on this board a small mouse, and then putting the machine in motion, directed some electric sparks to the board near the mouse; the little animal seemed to be no more affected by it than by being a little alarmed at the suddenness of the light. The fact was, that although the animal was in a highly excited state, it was not at all conscious of it, and this probably accounted for our not being aware of, or not being physically made sensible of the presence of the electric fluid constantly surrounding us. We must not however conclude that the notions advanced by philosophers about the state of this globe on which we live, were all imaginative because we could not feel personally the effects of it. The condition in which we exist must be a very curious one, because the external state may depend on the arrangement of the electricity in the atmosphere, which we could not feel unless a spark descended upon us, as in the experiment with the mouse; the little animal was sensible of nothing but the vivid flash of light and the startling noise, because the flash was not directed immediately upon it. It was remarkable that there was no variation in the experiments on this subject. He had sought by a mirror placed at the top of the house to detect whether there was any difference in the direction of the electric flash, and he had invariably arrived at the conclusion that the induction was not in straight lines but in curved lines.

There was one very curious matter he must bring forward with reference to thunder storms and clouds. First of all there was clear light air, which was perfectly a non-conductor; electrify it as we might we could see no effect. Now the definition of water in a state of vapour, was to form a cloud above us; then this globe was a conductor, and the moment the cloud was formed and approached the earth, a kind of induction took place. These particles of vapour combined, formed as it were a surface, and the cloud took up the electricity. The electricity of a cloud he illustrated by a tassel of tissue paper on a rod about 12 feet in height, and on electrifying this rod, a most beautiful divergence of the tassel was produced. Now all the electricity in the tassel was found to exist on the extremities of the slips of paper, on the outside of the radius. It was a curious circumstance, that a cloud consisting of watery particles charged with electricity did not break up, that these particles did not separate and fly off by the action of repulsion and become distributed into space. The same power, however, might cause them to hold together; they might be kept in their united form by the induction of the air. How otherwise he could not conceive, from the nature of a cloud, it could hold together, and that the whole of the clouds did not distribute and make winds by their action. The electricity was then on the exterior of the cloud, as it was on the exterior of this tassel, in a state of divergence, but by taking electricity from the earth by means of a conductor, and applying it to the points of the tassel, the divergence was destroyed, and they collapsed. This was precisely the effect produced upon the cloud by the induction of the earth.

In conclusion, he hoped these few excursive observations had afforded to his audience sufficient interest to induce them to take up the subject with that attention its importance demanded, and at a future time, he hoped to be able to bring forward something more definite on the subject.

Value of Mercury in Syphilis.—Mr. Bacot concluded, after carefully noting the reports from the British and other European military hospitals, that when mercury was not used in the primary treatment of syphilis, the average number of secondary cases occurring was 1 in 10; but only 1 in 75 when mercury had been employed.

CURABILITY OF CONSUMPTION.

(Continued from page 26[illegible].)

To the Editor of the 'Medical Times.'

Sir,—I have endeavoured to trace, however faintly, the outline of nature's plan for the cure or mitigation of consumptive disease. The more satisfactory task now remains to point out the manner in which she may be successfully imitated by art. I desire, however, to make a few general observations by way of preliminary to this department of the subject. From age to age, she has been indicating to medical observation the true and simple process of treatment in this destructive malady, unheeded and in vain. A singular fatality has persecuted the question from the dark days of Chiron, the Centaur, down to the present times; which, in these northern latitudes, boast of being enlightened by two great luminous bodies,—our Royal College of Physicians, and no less "Royal" College of Surgeons, in whose collateral light move many wandering stars of various magnitude—from the charlatan of the sixth, to the physician ordinary or extraordinary of the first degree. And yet this spot upon our disk still remains in visible darkness—palpable obscure—so far as any light reflected from these sources can enable us to discover. Our shelves are encumbered with tomes, ponderous or light, and our poor brains puzzled with interminable disquisitions on its causes, varieties, and treatment; nearly all these differing on every point but one, its incurability by art. The grave is the place of rendezvous where all those travellers meet. On the Continent, pathological research has thrown a dim religious light upon the subject, and taught Laennec and his disciples to expect a cure, by remedial art in certain stages and circumstances, and, by nature, frequently. The experience of that eminent innovator on established prejudices led him, in the latter part of his life, to consider cases of cure as extremely common. He felt assured that when the lungs were not completely disorganized, a cure ought not to be looked upon as impossible, either in reference to the nature of the disease, or the organ affected, an opinion appropriately prefixed to Dr. Ramadge's very original and practical work on Consumption. He mentions that on the shores of the Bay of Douarnenez, his native place, whither he retired in a state of latent phthisis, one-half of the consumptive cases were cured. Unhappily for science, this great man was cut off prematurely by the very disease he had so deeply studied. Had his opportunities of observation been on an equally extended scale as this great metropolis supplied to Dr. Ramadge, or had he survived some years to mature his views, I entertain little doubt but that he would have arrived at the conclusions I have been endeavouring to describe, and adopted sounder and less empirical principles of treatment.

Fournet, who obtained the prize at the Concours of the Hospitals of Paris, for his clinical researches on auscultation of the respiratory organs, in the preface to his work, expresses the confident hope that his investigations may impress the influential classes of society with the salutary conviction that consumption *is* curable, and that an opposite opinion is not only barren but mischievous. Among our English writers on the subject, Dr. Carswell forms a pleasing exception to the desponding school of incurables. Permit me to quote the following appropriate confirmatory testimony from his pen:—

"The important fact of the curability of the disease has, in our opinion, been satisfactorily established by Laennec. *All the physical signs of tubercular phthisis have been present, even those which indicate the existence of an excavation, yet the disease has terminated favourably, and its perfect cure has been demonstrated by the presence of a cicatrix in that portion of the lungs in which the excavation had formerly existed.* . . . . There must be few practical pathologists who will not consider these anatomical facts as evidence that tuberculous phthisis is a curable disease. No objection has been brought forward, calculated, in the slightest degree, to invalidate the conclusion to which we have been led by the repeated observations of the changes we have described, viz.:—that these changes are positive indices of the removal of the material element of the disease, and also of the cure of the lesions of structure to which it gives rise, even at an advanced period of its progress. . . . *We cannot avoid repeating the fact that pathological anatomy has, perhaps, never afforded more conclusive evidence in proof of the curability of a disease than it has in that of tuberculous phthisis.*"

In these sentiments he is happily at variance with our other modern English writers on the subject. What a discreditable exhibition of the state of our medical science does Dr. Young's work on consumption furnish! He says, "It is probable that, without assistance, not one case in a thousand of the disease would recover, and with the utmost power of art, not more than one in a hundred will be found curable." The facts are more nearly the reverse. His preceptors and coadjutors at St. George's Hospital must have made a negligent use of their opportunities of autopsy, not to conduct him to sounder conclusions, and the time he consumed in deciphering Egyptian hieroglyphics, had better have been devoted to pathological research. Sir James Clarke characterizes his work as a monument of industry! Why did he not add, ill-directed? I question whether he ever took the trouble of opening a dead body. Had the scalpel been more frequently in use among the members of the College of Physicians, their character, hitherto, would have been more highly estimated. Pathology has been sadly neglected by them. Dr. Baillie's work on morbid anatomy has been appropriately designated by Mr. Lawrence as a mere catalogue of appearances, in which several important parts of the human body have been omitted. Having occupied a wing of the old College, he had ample opportunities of becoming familiar with the museum, of which he has been heard to say that the seats of a hackney coach would contain all the preparations in it of any value. One of the Curators once observed that any person of moderate industry might accumulate as good a collection in a couple of years. The sums expended by the College on its festivities, before Dr. Baillie made them a present, of his preparations, as it were, out of charity, would have been more judiciously employed in purchasing morbid structures of the human body illustrative of obscure diseases.

As to Dr. Baillie's work on morbid anatomy, a very cursory perusal will shew to any one at all familiar with the subject, that he did not pay due attention to the most ordinary *post-mortem* phenomena of diseased lungs; for instance, he takes no notice of the semi-cartilaginous cicatrizations which are so very common, etc. For a long series of years, there were no dissections of the human body either at Oxford or Cambridge. The anatomical Museum at Oxford was of such slight consideration at a recent period, that its locality, as well as I can recollect, was in an attic. Facts such as these in some degree account for the erroneous views relative to phthisis, too long prevalent in this country.

The late Dr. T. Davies—whose position as junior colleague to Dr. Ramadge, for some years, at the Infirmary for diseases of the chest, apparently entitled his *dicta* to respect,—was a zealous apostle of the doctrine that consumption is incurable. It may not be amiss to state that the charge I have already made against our physicians generally, was but too applicable to him, as during his connexion with the Institution, he did not attend more than one-half the time, and for the last ten years the term of his visits seldom extended to half an hour. The hurried manner in which, as a necessary consequence, he must have examined his patients, was not only commented upon by them and the matrons, but rendered it impossible that he could derive any sound practical information from his infirmary practice. The following anecdote may not be uninteresting. He was requested on one occasion to re-examine the body of a person who had died in the New North Road. It had been previously opened by Mr. Baker, of Brudenell Place, and another practitioner, and they had taken away the stomach for the purpose of examining it minutely, and analysing its contents, as it was suspected the deceased had taken poison. Notwithstanding this, Dr. Davies discovered, it appears, another stomach, which he pronounced to have been in an ulcerated state!!! in fact, he mistook a dilated portion of the large intestines for that viscus. Mr. Kiernan, F.R.S. was present at this remarkable discovery, and joined heartily in the laugh it raised afterwards at the doctor's expense, and, as a purturbed countenance indicated, by no means to his satisfaction. To stamp his authority with double weight, he was in the habit of stating that he had been long a pupil of Laennec, whereas, I have been indirectly informed, through that skilful and intelligent physician at Camberwell, Dr. Caldwell, that such could not have been the case, otherwise he (Dr. C.) must have been cognizant of it, having resided in Paris and attended Laennec for many years, including the time specified by Dr. Davies. I was not a little puzzled in perusing an article which he communicated to Dr. Townsend, to reconcile with credibility or consistency the Tabular statement therein given of several cases of empyema successfully operated upon by his directions, the proportion of cures to deaths being as four to one, a proportion not before or since boasted, I believe, by any practitioner. In the majority of instances, empyema is a consequent on phthisis. If the latter be incurable, even when uncomplicated, how can it be cured in this highly complicated form? or is it to be taken for granted that all these successful cases were unconnected with phthisis. This would be *reductio ad absurdum* in good earnest. Laennec very justly remarks that this operation, paracentesis, in cases of empyema, is rarely followed by success, owing to various causes not generally well understood. One is the bad condition of the lung itself, being frequently tuberculous; another, the admission of air into the chest, producing irritation on the surface of the pleura, and carrying off the patient by a great and offensive discharge; and a third is the compression of the lung against the spine and mediastinum, and the nature of the investing false membrane, which, from its tendency to become converted into fibrous tissue, is a great obstacle to the dilatation of the lung. In the face of these obstacles, however, this lucky physician claims the merit of having succeeded in the proportion above named! So far as the infirmary practice was concerned, I can give the following facts:—Two cases were seen there under treatment by him. One was a boy 10 or 12 years old, an out-patient, who sunk under a fetid and exhausting discharge in the way described by Laennec. The other, and only one operated upon in the infirmary by his directions, was an interesting young man, named Thomas Beamond, who was admitted on the 12th November, 1833. He had previously been under the care of Mr. Septimus Reid, of Jewin Street, who could testify to the very favourable and satisfactory state of his general health at the time of admission. The operation was performed by the individual mentioned by Dr. Davies, as having under his orders achieved great success. The result subsequently was, as Mrs. Hine, the matron, can corroborate, that reduced to the lowest conceivable state of exhaustion by a constant, irrepressible, and intolerably fetid discharge, he was removed to his own home, where he shortly after expired.

A little boy, named Moses Dacosta, aged nine years, residing with his parents at 14, Sheppard Street, Spitalfields, a supposed case of empyema, was admitted as Dr. Davies's patient on the 30th May, 1839. Having first been put under a course of mercury for more than a month, with the view, I presume, of removing the effused fluid by absorption, he was about to suffer paracentesis from the successful (?) operator just alluded to. The boy's mother, however, at the instance of Mr. Garcia, her usual medical attendant, whose advice she asked, referred the case to Dr. Ramadge. This physician, upon examination, ascertained that it was not a case of empyema, but one of well-marked phthisis with a very large cavity in the inferior lobe of the right lung. The operation of course was not

performed. Mrs. Gordilier, the present matron of the infirmary, had frequent opportunities of seeing the boy previously, and remarked his progressively declining state. He was then placed under Dr. Ramadge's care; his constitutional symptoms gradually yielded to remedial treatment; the cavity, after some period, was obliterated by the expansion of the lung through artificial means, and he is now in the enjoyment of excellent health. He has been seen and examined by Dr. Hull of Peckham, Dr. Parkin of Torquay, and Drs. Fitch, Newton, and Hull, of Philadelphia; all of whom were attending the Infirmary; and also by myself and many others.

In his lectures, subsequently published, Dr. Davies has given the name of another practitioner, who he states, was successful in several cases of paracentesis for empyema, under his auspices. Perhaps the following was one of these auspicious cures. —A boy, named Cailly, residing near Finsbury market, was pronounced by Dr. Davies to have empyema, and to require the operation. No time was allowed for the chance of a cure by absorption, which is not uncommon, or by one of those rare accidents where the matter makes its escape by pointing exteriorly. Arrangements were forthwith made for the paracentesis. A vessel was placed *in situ aduneo* to receive the expected matter, and the practitioner referred to, being in a favourable position to admit of its exit, made an attempt to introduce the trochar. Encountering, however, some unexpected impediment to its entrance, his courage failed him, and maugre all the encouragement he got from the Doctor, he declined persevering, and it was abandoned. Yet the boy got well, and no doubt had a fortunate escape. Was this one of the successful operations? Perhaps the gentleman in question may still have some slight recollection of it; if not, I could refresh his memory by reference to a medical confrere who was present on the occasion.

Inquiries were diligently made respecting the cases under the two practitioners alluded to, in which this success was so unprecedented, and two handsome donations offered to the Infirmary, on condition that the statements should be substantiated. This condition was never complied with, and the donations of course were not made to the institution. The foregoing observations supply their own comment; they shew that the authority of some of the most decided opponents of the curability of consumption is of little or no value, and I would conclude by saying, *ex his, disce plures.*

When medical men make up their minds to despair of success in the treatment of consumption, they do much towards rendering it really desperate. I grieve to think how many are left to perish who might be saved were proper efforts made by professional advisers. The associations that surround this subject as it has been left for ages, are truly melancholy. Hitherto it may be said of consumption, with its wide embracing arms, as of the greedy sea, "Thou hast treasures in thy bosom—the beautiful—the brave!" Few indeed are the families that do not at one time or another mourn over bereavements from this formidable disease. Beauty's fairest flower cannot charm its eye, nor the proudest strength of manhood arrest its progress. The tongue of eloquence is mute in its presence, and the fire of genius turns pale and expires. The sighs of weakness and the frowns of power are alike disregarded here;

> ——*Æquo pulsat pede pauperum tabernas*
> *Regumque turres.*

It lurks in the abodes of the poor, boldly lays siege to the thrones of monarchs, and claims as its own at least one-fourth of the domain of human life, even in this land of science. We have too long silently acquiesced in the usurpation. But the advance has sounded in the ranks of physic as well as surgery. Let us take for our motto, "*nil desperandum*" and do our duty. The cheering conviction will soon arise from the result of successful efforts that we have yielded too much to imaginary fears, and that this great economy of life is neither invulnerable nor invincible.

DISCIPULUS.

(To be continued.)

VARIETIES FROM THE GERMAN.

(For the Medical Times.)

THE FIRST VENESECTION IN RUSSIA.—The father of Peter the Great, the Emperor Alexis, in a fit of ungovernable passion, fell down senseless. The court physician was immediately called in; he could scarcely feel any pulsation; the countenance was blue; the lips pale; in vain were all the most forcible stimulants applied. The situation of the patient became every moment more critical, and the physician declared that nothing but immediate venesection could save the Emperor. The chief officers of the court were called in; the doctor bound the Czar's arm, and was just about to plunge in the lancet, when the Emperor came to himself. On seeing these unusual preparations around him, he raise himself, and angrily asked the doctor "what were his intentions." The doctor replied that as a too sudden accumulation of the blood had thrown his Majesty into peril of his life, he had considered venesection the only remedy. The Czar enquiring the meaning of the term, the doctor explained the nature of the operation in the most attractive phrases in his power, when the Czar responded, "What, dare to wound, me, on purpose to shed my blood?" The doctor replied, that though in Russia venesection was not yet known, that in France, Germany, and Poland, this operation had been long resorted to with success. He assured him that it would enable him to breathe more freely, and prevent the chance of increased inflammation. The Emperor now nearly relapsing into a state of insensibility, said, is there no other remedy left? Is venesection deleterious to a sound person? If not deleterious, is it at least unnecessary? Is it possible to open the vein of a sound person without death ensuing? Being answered satisfactorily, the Emperor insisted on having the operation performed first on the doctor's own arm. The physician objected, that he would not be able to perform the operation on his Majesty, the arm, if bled, requiring repose, but proffered to submit to the operation as soon as he had tied up the Emperor's arm. The Czar sharply scrutinized the doctor's countenance, and hearing again that it was absolutely necessary, called several of the first and most distinguished dignitaries of the state, ranged them in a row, and then ordered the doctor to perform venesection on them in succession. The courtiers did not know the Emperor's object, but submitted blindly to the order, and showed no small dismay while observing their blood issuing in streams from their veins. Encouraged by the absence of any dangerous symptom, the Emperor bared his arm, turned aside his head not to see his blood flow, and the first royal Russian venesection was performed.

EATABLE BIRD'S NESTS AND THEIR COLLECTION NEAR KARAMBALANG, ON THE SOUTH COAST OF JAVA.—In the neighbourhood of Karambalang, is the river Kalie Lara, (viz., the river of Lara). Thousands of small birds, which, with the exception of their diminutive tails, resemble much our swallows, here build their nests on perpendicular cliffs, bathed by the waves of the Pacific. Their nests resemble much a mustard spoon with a long handle, hang together by pairs, and are so placed by their long ends in the cavities of the rocks, that they are protected from the influence of the wind, &c. The collecting of these eatable nests, is accompanied with much danger, many people are killed in this endeavour, on which account only the native labourers are employed in this work. They built scaffoldings of Bamboo on the precipice and the caverns of the rocks, in which the Purong Salanzen (this is the native name of these birds) are to be met with. They then break them off with iron hooks, no matter, whether there be young birds or eggs in them. The nests collected near Karambaling belong to the inferior in grey quality, whilst the better white sort is collected near Bajermassing in Borneo. In the latter place, the collecting of nests is not so dangerous as in Java, on which account there are some volunteers who collect them. In the Dutch possessions in Borneo, they are the property of the governor. Many of them are also stolen by persons who have no leave to collect them. In Java no Chinese is permitted to come nearer than 3,000 yards to the rocks of Karambalang. The substance of which the Puren Salanzen make their nests, and the reason why they do not putrify soon, is not yet decided by naturalists; yet it has not been taken notice of, that the rocks on which they are to be found, contain a good deal of saltpetre, which drops down from the cavern. It is, therefore, probable, that the air also is impregnated with particles of saltpetre, which penetrate the substance of the nests, whilst they are building. If these nests are not properly cleaned, they retain an obvious taste of saltpetre. Travellers have observed, that rocks where saltpetre has been found in former times, and where its formation does not take place any more, these birds will cease to build their nests, and the few which might be still found, are broken and crumbling to pieces. This may be the reason that so many birds resort to Karambalang, although their nests are destroyed almost every season.

ON THE ORIGIN OF THE USE OF COFFEE.—(From an Oriental MS.)—It is generally reported, that a shepherd boy had observed in Arabia, that whenever his goats eat of the leaves or flowers of the coffee tree, they always were more lively. He had thought on the subject, and found that the use of the plant produced the same effect upon himself. This is the general belief of the introduction of coffee into general use. Our manuscript gives however, the following. In the first period of the Mahomedan creed, there lived in Mecca a widow and her daughter. Their occupation was to receive and to entertain travellers, and on that account they did not escape the scandal of the neighbours; the Shiek, in consequence, ordered them to leave the town, and the mother soon after died in misery. The daughter made the grave of her mother near a coffee tree, and selected a neighbouring spot for her own grave, where she was laid when dead by a holy hermit, who had taken care of them during life. Shortly after, a severe plague devastating Mecca, the Shiek who had expatriated the poor people, died, and with him several others who had behaved ill to the family. This opened the eyes of the successor of the Shiek, who convinced that they had wronged mother and daughter, ordered the expiations usual in the Orient, especially the usual ablutions. For the sake of making this as efficient as possible, they used a decoction of the leaves of the tree, under which the two martyrs were laid. A sense of superstition led to the drinking of the decoction, and successively the berries coming into repute, were used first raw, then roasted, and finally ground to powder.

ON THE CULTURE OF ROSES AND THE MAKING OF ROSE WATER, AND THE CELEBRATED ATTAR AT GHAZEEPOOR.—About Ghazeepoor, nearly 150 acres of land are planted in small allotments with roses, of which each contains 2,000 plants, which yield

two lacs of roses, and produce 8140 Rs. The roses flower from March to April, are gathered in the morning and delivered in long bags to the place of distillation. The apparatus used for it is a kettle, of 3248 quarts, made of copper or iron well tinned, having a narrow neck. Of 1,000 roses, mostly one and a-half lacs of rose water are distilled, but of the best only one lac, and the remainder of the water used for distillation is exposed to the Sun, and its price is very low. For the purpose of making attar, the rose water is put in a basin covered with white muslin, and placed during one night two feet in the ground. The pellicule formed during the night is taken off with a spoon, and placed carefully in a little phial, and this is continued for several days, and every access of the Sun carefully avoided. After a sufficient quantity of attar is collected, it is strained off clear, and filled in small bottles. Pure attar is first light grey, afterwards it becomes light yellow, and melts at a temperature of 84 deg. Roses, the flower of which are well developed, and such as have been exposed to night frosts, yield most attar. That sold in most Oriental bazaars is mostly adulterated with sandal or almond oil, and the pure is not sold under 8000 rupees for the Talah. Generally, the inhabitants of Ghazeepoor, do not remove the calyx of the roses, but it is considered, that such oil will not keep long, and will have a sour smell. A great quantity of roses is sold at Penean, the amount thus realised may amount to 70,000 rupees, but has been on the decrease lately

TO CORRESPONDENTS.

An Antiquarian *may, we understand, procure copies of Sharp's celebrated engraving of John Hunter, after Sir Joshua Reynolds, from Mr Stone, the sub-librarian, or Mr. Clift, the conservator of the College of Surgeons.*

Dr. Coghlan *of Wexford, sends us a case of great professional hardship. After attending a midwifery case occurring at midnight, on a rainy night, at a considerable distance, under a promise of immediate payment of his fee, the doctor was obliged, after repeated demands of payment, to summon the husband for the amount before the presiding barrister at the Quarter Sessions, when the claim was negatived, and its expences thrown on Dr. Coghlan's shoulders, on the ground that being a physician he could not sue for fees. Now as Dr. Coghlan is a member of the College of Surgeons, and an Accoucheur by education and profession, we should take leave to doubt the legality of denying him payment for services performed in those capacities, because in addition he happened to be a physician. But, whatever the law is, the practice has run in the direction of the presiding barrister, and well justifies in its exceeding absurdity our respected correspondent's question "Will putting my medical diploma in the fire protect me from its disqualifying influence?" This is one anomaly among a thousand calling for redress.*

A Subscriber (J. R.) *will find the mode to mesmerise fully explained in No. 152, vol. 6. This answer must suffice for a number of similar enquirers. From what we have noticed, those who simply place the fingers' tips directly before the eyes of the patient, appear to produce the comatose state with most ease.*

A. M. and other Correspondents. *If there be no candidate doubly qualified, a licentiate of the Hall can certainly be elected by the Guardians' Medical Officer to the Union. The exception is specially made by the Poor Law Commissioners.*

Dr. M. Hall.—*We must decline the many communications we have received on this physician.*

Mr. Cook, Enniscorthy.—*The numbers from 33 to 38, forming a part of vol. 2, are out of print. We have sent the more recent numbers.*

L. N. (A Medical Student.)—*Mr. Nottingham lives in Roscommon Street, Liverpool. For second question consult a good bootmaker (our next door neighbour for example) who will probably answer in the affirmative; for the third look at our advertisement page.*

Mr. Baker.—*The classical subjects for examination at the London University are not made known to us, but a letter to Mr. Rothman, the Registrar, would doubtless be courteously responded to.*

Alethes *must furnish us with his name, the respectable party he responds to being known to us.*

P. S.—Mr. I. H. P., Glasgow—Philo—Potus—Deum Optimo—Justitia—A Medical Reformer, *declined.*

A Physician *with a German degree may practise as a physician—as indeed any quack may—if he practise seven miles out of London. The preparation of his own medicines, and the donation of them prepared, is no infringement of the Apothecaries' privileges.*

H. W. *has a higher opinion of his writings than our judgment of them justifies. They are preserved by an accident and if he still think them worth sending for, will be found lying at our office for him.*

A Correspondent sends us a coat of arms for Dr. M. Hall. We cannot insert it. Does our Correspondent know that the pills which make so conspicuous a figure in his sketch, are emblazoned on the coat of the celebrated Medici family? The disparagement is certainly not there.

We are obliged to postpone Dr. Williams' Lecture till next week, when we shall also publish the conclusion of Dr. Clay's papers on Factory Diseases.

In answer to many new subscribers we beg to give the following information on our first numbers.—Vol. 1 contains Lectures by Lawrance on Surgery, vol. 2 is in part out of print, vol. 3 Lectures by Lawrance on Surgery, vol. 4 contains Lectures by Lawrance on Surgery, and by Professor Owen on the Reproductive Organs, vol. 5 contains Lectures by Velpeau on Diseases of Women, Scoffern on Chemistry, Chomel on Pneumonia, vol. 6 contains Lectures by Velpeau on Diseases of Women, Roupell on Materia Medica, Professor Chomel on Pneumonia, Professor Owen on the Nervous System, Orfila on Arsenic. Those are all the Courses of Lectures published up to the present volume.

Mr. Close is probably right, but it is difficult to refuse every importunate applicant.

A. B.—*Gentlemen in A. B.'s position may be retained in office in the event of their obtaining the Commissioner's leave, or in the event of no doubly qualified candidate presenting himself.*

THE MEDICAL TIMES.

SATURDAY, JANUARY 28, 1843.

Si judicas, cognosce.

HAVING in preceding numbers considered the medical arrangements of Austria and Prussia, we are now led, by a natural transition, to the MEDICAL ORGANIZATION OF BAVARIA, a kingdom in which, from the high intellectuality and daring zeal for all kinds of improvements characterizing its monarch, we may expect, and not vainly, to find our profession a little better regulated, and marked by somewhat more of symmetry than in some older monarchies, under Governments of far higher pretensions.

The first distinguishing circumstance worthy of remark is, the absence of our division of Surgeons and Physicians. Each member of the higher body of practitioners is at once Doctor of Medicine, Surgery, and Midwifery. He is all or nothing. The earliest age for commencing his professional studies is fixed at twenty-two. Before entering himself as student, he must shew certificates of having completed with satisfaction his preliminary studies, which must include a comprehensive course of Philosophy: and he must be approved, by the Dean and Secretary of the University, as in possession of the moral and physical qualities deemed to be necessary in an accomplished practitioner. The studies occupy three years, or six sessions, take place necessarily either at Munich, Erlangen, or Wurzburgh, and are terminated by two rigorous private examinations, and the composition of a theme, in Latin or Greek, on a self-chosen subject. The diploma is now given, but no right to practice, which is only purchased by two further years' attendance on hospitals, or respectable private practice at home or abroad—and by sustaining with success an examination on practical points, before a Special Commission, formed by certain University professors, certain city physicians, and a selection of public medical functionaries.

The charges are moderate. Less than £1 paying the two annual sessions for the Professors, and £20 covering all the expencesof the examinations.

There is but one limitation of practice throughout the whole kingdom, and that is one well worthy of remark. By a recent law, the number of medical men is restricted to a certain proportion of the population: and thus our Bavarian brethren rise or fall with the rise or fall of their patients—a true sliding scale of physic. We are told, as illustrative of this singularity, that at Munich, with its 80,000 inhabitants, 87 Doctors are held to be, according to the scale, 17 too many. Till this anomaly be removed, therefore, only one new Doctor (whose title is always seniority) is allowed to enter the field of practice for every three vacancies.

Besides, however, the "Doctors," there is an inferior class of practitioners, about the policy of whose preservation there exist at present warm differences of opinion. They are called *Landarzte*, or *Beider*, bathers, or barbers. These must have finished their humanities—that is, must have acquired at least a competent knowledge of Latin, and the general principles of composition. There are special schools for them at Bamberg, Landshut, and Ratisbon—and they are not permitted to attend as regular pupils at the higher University courses. Their studies last only three years: they are then twice examined by their own Professors (the cost of all amounting to about £15), and are allowed forthwith to enter practice, which is, however, limited to the division of the kingdom in which they were educated, unless they submit to a second examination. Their duties are restricted to the more simple medical and surgical cases, and to midwifery. If they venture on cases not sanctioned by the law, they are liable to penalties of from 30s. to £10, to imprisonment, and to loss of their diploma. Their numbers are regulated, also, on the principle of the sliding scale. In cases of

a too healthy neighbourhood, these subordinate practitioners have permission to eke out an income by acting as bathers, barbers, or hair-dressers.

The Army Doctors in Bavaria offer little requiring notice. Their education, examinations, and titles, are identical with those we have already described: they are at full liberty to practice in or out of service, which they can leave at pleasure.

The Medical Organization of Hesse Darmstadt is similar, in reference to the two grades of the profession, but different with respect to many of the details of education.

Preliminary education is proved by candidates for the Doctorship, either by certificates of a completed college course, or by a practical examination—a wise and very liberal arrangement. The only school of medicine is at the University of Giessen, where the students must pass at least two years. A third year is passed in hospital attendance, which may, however, be spent in any German or foreign medical institution. The course of study followed, is according to the preference of the student; but, on examination, he is required to prove by certificates that he has attended courses of mathematics, natural history, logic, psychology, chemistry, botany, therapeutics, medicine, surgery, general pathology, anatomy in all its branches, physiology, midwifery, jurisprudence, diagnosis of diseases, and operative surgery. The examination lasts several weeks (*five* being the minimum). The answers are both oral and written; which, if found satisfactory, are followed by a printed thesis, the propositions in which the candidate is obliged to sustain in public, before the University Professors and the City Doctors. In cases of extreme timidity, a dispensation is occasionally accorded, when the candidate does not aspire to a Professor's chair. The diploma when given, gives the universal right of practice, except in *public* employments, where an additional examination is required.

Here, as in Bavaria, the *Wundartze* exist but in a smaller proportion, being but as six to ten. Their examination lasts only about two hours—about an hour and a half longer than that of our candidates at the College of Surgeons.

PENCILLINGS OF LIVING MEDICAL MEN.

Mr. Frederick Tyrrell.

Next in order after Mr. Green comes Fredk. Tyrrell, Senior Surgeon to the Royal London Opthalmic Institution, Surgeon to St. Thomas's Hospital, Professor of Anatomy and Surgery to the Royal College of Surgeons, &c. &c.

If the remark of Marcus Aurelius be correct, that a man full of talent spreads around him a performance of a characteristic nature—that his soul and his disposition can be seen in his acts, if physiognomy may be placed, as Bacon laid it, in the fixed sciences, Tyrrell's face ought to be what it is not—"the tablet of his thoughts." But, although the *mens divinor* has taken up its abiding place under an humble roof, he can cite the similar examples of Zeno, of Æsop, and Socrates, and other great worthies, ancient and modern, and console himself with the fact that the poets who wrote the best comedies and epic poems were, like him, bilious, melancholique, and triste in appearance. A heavy, dull, sallow, saturnine caste of countenance, shaggy iron-grey brows, small grey retrocedent eyes, prominent bulbous shaped nose, long thick *un*aristocratic upper lip, cheek bones, too forward to be handsome—yet aiding to give an appearance of firmness and squareness to a face otherwise too long, too monotonous, and too unrelieved to be accurately or expressively intellectual.—so composed is the face of Tyrrell: the details would seem to contradict the general configuration; for, when the eye is lit up, and he is animated, it presents a pleasing prepossessing, agreeable, *tout ensemble.* He is about fifty-six years of age—of a square robust figure, and about the middle height; his thoracic developments, round and spacious, gave promise of many years of unimpaired health, which, we regret to say, have not been realized. His manner as a lecturer was always heavy—the tones of his voice and the action with which he tries to give effect to his language destitute of variety: his articulation is thick, yet distinct, but marred by the sameness of his voice; his gestienlation consists of a slight movement of the head; his matter, not being original, or enlivened by anecdote or illustration, does not improve his manner. You might as well expect the moss rose, or the lily of the valley, to bloom in Puddle-dock or St. Giles's, as to look for a scintillation of genius or electricity, or a brilliant and eloquent idea in any portion of the oral or scriptural discourses of Mr. T. His style is feeble and without polish, ancient or modern; it is certainly unlaboured and in keeping with his sentiments. They say the character of the man is moulded from the accidental impressions of childhood. Tyrrell, then, must have been born near a churchyard. In his deportment to the pupils he is firm, precise, and formal,—mistaking taciturnity, for tranquil dignity, and pomp for pride. Some regard this with a more favourable eye, and look upon it only as a proper degree of distance, which every professor should assume to repel freedom or familiarity. We think he feels the elation of his station; he looks down upon the inferiority of others; he is, therefore, a haughty man. The proud man is he who dwells with complacency upon his own perfections. His cold and distant behaviour towards his brother practitioners—his imperious bearing towards the officials at the college and hospitals—prove him to be, if not a proud, certainly a conceited man.

His indisposition prevents his attendance regularly at the hospitals. The labour of lecturing is out of the question. Formerly he was very industrious, and his clinique was practically instructive on the principle that there are sermons in stones and books in running brooks.

He is the son of the chief remembrancer of the City of London. By his municipal influence and apprenticeship, he was favourably introduced into St. Thomas's Hospital. He arrived at the object of his ambition through the royal road of matrimony; he wooed and won the niece of Sir Astley Cooper, when the power of that worthy baronet was paramount; he is thereby brother-in-law to Bransby Cooper, and of Aston Key, who was also fortunate enough to secure professional promotion on such easy and agreeable terms. Sir Astley Cooper was not *only* an able surgeon, a successful lecturer, and a consummate diplomatist; under his directions, love was made the handmaid of fortune and of interest. By the assistance of his friend, the Treasurer, he afforded us a very pleasing refutation of a very vulgar notion, that marriage was "a lottery and made in heaven;" for all those fabricated in Guy's and Thomas turned very fortunate for all parties, and he succeeded in thus comfortably disposing of all his relations and connections. Whilst many in the buoyancy of their youthful ardour, in the golden hours of their young hopes, were wasting the spring-tide of their strength, the noon of their manhood, in scientific pursuits, cultivating an honourable name, and flattering themselves that by their contributions to knowledge, they were acquiring a fame that would give them claim to fill situations of responsibility, utility, and distinction: whilst genius pre eminent, is thus toiling up the rugged steep ascent, with its untiring energy and enthusiastic isolation forcing its way through mountains of difficulty towards the bright goal that acts as its incentive, and calls forth all its latent resources—another secures the prize that should reward "the toils which to this summit led," and not by talent, not by study, not by merit, or acts of high emprize,—the legitimate avenues to such public appointments—he takes the roseate path of amorous dalliance—the well counterfeited sigh—the stolen glance, that so rapturously and eloquently heralds the heart's wishes, or the passions' promptings—the hand delicately, yet expressively, impressed in the mazes of the dance, introduce the favoured one into the porch of science, into the very sanctuary of the sterner maid. He wins fame and fortune; he carries off the prize; Venus proves more powerful than Minerva. Genius, disappointed, mortified, disgusted, retires from a contest frequently from a profession that holds out no inducements, that offers no rewards, that presents attractions only to *deceive.* First-rate men are thus lost to society. The exciting, the active spirit, the enthusiasm of discovery which is the master element of commanding genius is destroyed. The effects of the blighting system of patronage are retardation of scientific improvement; the discontent and degradation of the moral character of the profession. The sycophancy of a great man, the sympathies of sectarianism, the predilections of faction, the favours of the fair sex, are the most efficient means to promote our prospects in life. All are placed in the unworthy foundations of extraneous patronage.

In 1825, Mr. Tyrrell commenced an action against the *Lancet,* in which, we may say, he was defeated. He was described as the prince of medical dunciads. His notes and illustrations of Sir Astley's lectures would seem to justify the correctness of the epithet.

Common place remarks, wretched composition, inappositeness of the cases adduced, puerility of the inferences, satisfied Sir Astley that a man had no greater enemy than an injudicious friend; and he published his lectures freed from the dead weight of Tyrrell's lucubrations. Between this and the publication of his work on the eye, he confined himself to clinical lectures. His observations on diseases of the hip are practically useful; here, as in the work to which we shall advert, he never gratifies his hearers with a discussion of other plans, or by adverting to the opinions of others. Counter-irritation and generous constitutional treatment are his curative principles.

In 1840 he published a practical work on the diseases of the eye, in 2 vols. He says, "my knowledge has been collected as the industrious bee collects its store from cultured and uncultivated sources, and as the provision

of the busy insect is said to be most precious when obtained from uncultivated flowers; so I consider that I have gained my most valuable knowledge from observing nature simply, but closely, and, I trust, without prejudice." In his introduction we are treated very gratuitously to elaborate encomiums upon Dr. Farre, and a few sentences upon that truly deserving man, Mr. Saunders. "My own labour has been simple, for I have had but to pursue the path marked out by Mr. Saunders. My endeavour has been to render the path more distinct and easy for others, and in doing so, I consider that I have opened some new prospects which would *probably* have been done by Mr. Saunders, had he lived to carry on the plan which he commenced in so *masterly* a style."

He commences with a very ordinary essay on diagnosis. He then gives a few simple but serviceable suggestions as to the mode of examining the affected eye. He is averse to large abstraction of blood in general, "just so much as to *relieve* the tension of the arteries. He is favourable to fomentations and opposed to cold lotions applied for hours together as is frequently the case. Counter-irritants he applied in the neighbourhood of the eye—Blisters and issues behind the ears. The introduction occupies one half the 1st. volume He begins the work itself with a very defective description of the anatomy of the conjunctiva, and its morbid conditions of which he makes the following varieties:—

Simple Opthalmia.	Chronic Opthalmia.
Pustular.	Strumous ditto
Catarrhal Opthalmia	Exanthematous.

In simple opthalmia or conjunctivitis when it depends on functional derangement, a plain nutritions diet, a moderate proportion of animal food—a glass of wine and water—1 grain of calomel, and 3 of blue pill every night, and some compound decoction of aloes with tincture of senna and manna every morning, tepid water to the eyes, and blisters are his customary remedies. Such objectionable expressions as the following frequently occur. "The effect of the local treatment is beautiful! To a peculiar condition of debility he gravely assigns symptoms, the most prominent of which is a feeble *pulse!*" Dr Farre, he says, recommended a beneficial change of constitutional vigour! In obstinate and irritable cases, change of climate is beneficial. He comprehends the Egyptian, the gonorrhœal, and that of neo-natorum under purulent. This is a valuable chapter. Bleeding, nauseating doses of tartar-emetic; mercury to check adhesive effusion, local bleeding. The disease when specific should be treated more actively at first. Strong solutions of nitrate of silver at the commencement. When chemosis of the cornea takes place it adds fuel to *fire*.

"The constant failure of all ordinary modes of treatment in the second stage of purulent inflammation, when complete, led me frequently to close and attentive consideration of the subject—and eventually induced me to adopt a plan for its relief. I became satisfied from careful observation, that the cornea did not derive *its life* from the inflammatory action affecting its structure, and I also ascertained by other morbid conditions of the conjunctiva and cornea, that the former was the principal channel by which the vessels of the latter passed for its supply and nutriment. It was easy then to conclude, that the chemosis, by mechanical influence, produced arrest of circulation, or strangulation of the vessels in the conjunctiva over the margin of the cornea and sclerotica, and that thus the cornea and its conjunctival covering being deprived of nutritious fluid lost their vitality or (as he says in other places) lost their lives." The remedy that suggested itself was the free division of the chemosed part, so as to relieve the tension of the conjunctiva, and to allow of the escape of fluid from the subjacent cellular tissue, as in cases of severe phlegmenous inflammation.

In the plan proposed, the incisions are to be made through the sclerotic portion of the conjunctiva, and the subjacent cellular tissue, beginning at the margin of the cornea, and extending towards the orbit in a direction as *rays radiating* from a centre, but avoid immediately the transverse and perpendicular diameters of the globe, that the large vessels passing to the cornea might not be injured. In several cases I found it successful beyond my expectations. Locally, after the division of the chemosed part what must be free, simple fomentations for twenty-four hours. In case of pain returning, leeches to the palpatræ freely after the pain has subsided to be made astringent by alum. If the anti-phlogistic plan be pushed too far there is an obstinate chronic stage of the disease which is avoided by moderately, generous diet. In Lawrence's work of 1834, there is no allusion to this mode. Purulent opthalmia in the infant commences most frequently on the third day after birth. First and most common cause, a morbid, vaginal secretion from the mother, leucorrhea; second, gonorrhœa; third, exposure to damp and moisture. He applies a leech or two to the lids, and, if necessary, he would divide the chemosed part. Has he ever done so? No; but a weak solution of alum in poppy decoction to be used frequently, 2 grains to the ounce. The cornea becomes nebulous and vascular from the long continued inflammation of the palpebral portion of the conjunctiva acting as a mechanical irritant. To this granular state, he applies a solution of diacetate of lead. Then comes the anatomy and description of the cornea and its pathological conditions after ulceration. In prolapsus iridis, he recommends the use of belladonna and weak solution of nitrate of silver to excite adhesion around the edge of the ulcer. His observations on the diseases of the choroid tunic will well repay perusal. Acute retinites occurs most frequently in females between 40 and 60. Mercury, local bleeding, and narcotics, opium, ointment to temples. Functional and organic amaurosis is well described.

He acknowledges the present arrangement as far from perfect. He offers very fulsome adulation to old Dr. Farre for his able guidance during their investigation of the disease. What have their conjoint labours effected? Nothing. In strabismus, not one of the modern improvements or operations is even alluded to.

Every step of the operation for cataract is described in detail He performs keratonixis in the following simple manner: the needle should be held in the hand not occupied in fixing the superior lid, in the same manner as in the operation for depression, and the point should be introduced through the cornea, near its junction with the sclerotic at the temporal side, one flat surface being opposed to the iris. It should be carried on n the anterior chamber through the pupil, and directed to the capsula of the lens near to the upper part of the pupillary margin of the iris, where it should be made to penetrate the capsule. It should then be directed downwards, so as to lacerate the capsule perpendicularly The needle should be withdrawn as soon as the laceration is affected. He applies belladonna to the temples.

Mr. Tyrrell prefers extraction to depression, and states, that *several high authorities* prefer depression because extraction is *too difficult for them!* He contends that the radiated opacity often seen in capsular cataract is not in the capsular, but in the posterior hemisphere of the lens. He does not operate for extraction of cataract in winter.

In cases of capsular, or capsulo-lenticular cataract, Mr. Tyrrell frequently employs with advantage a modification of the anterior operation by solution, which he calls drilling A fine straight needle is carried through the cornea, near its temporal edge; it penetrates the capsule, and enters the lens to the depth of one-sixteenth of an inch. The handle is then rotated between the finger and thumb—so as to make the point act as a drill. This is repeated every three or four weeks in a fresh point of the capsule; it causes no inflammation, but excites absorbtion.

Throughout the work there is not the least allusion to the labours of Lawrence, or others. Now this absolute absence of reference to others is a singular feature in this department of surgery. He was determined to avoid the fault of Lawrence: too much description of the plans of others, and too little of his own. The judgment evinced by Lawrence in the selection of his matter is admirable,—there is two much labour in it, there is too much learned compilation, and too little of the result of his own experience; but it is a mine of information—an immense mass of knowledge, collated from all writers on the subject. This and McKenzie's learned and comprehensive work are most read—Middlemore and Guthrie next; the last work, most certainly, for artificial pupil, above all the others. His heroic treatment of opthalmia by the ung. opthalmicum magnum is worth reading.

The value of Mr. Tyrrell's book is the detail of his medical treatment; in other respects, it is inferior to the German and English works that preceded it. His anatomical descriptions are faulty and inaccurate,—for this there is no extenuation: yet he is the most successful operative oculist we have It would appear that anatomy and practical medicine do not move in parallel lines. His views are unscientifically urged. In almost hopeless cases, his generous diet and tonics performed miracles. Bark and carb. sodæ, with mild mercurials, in particular cases His deliberate protest and predictions against operative proceeding in squinting are very foolish and unfortunate.

It is a well known fact, that with extensive chemosis there are conditions of the cornea that indicate increased vascular supply of that part,—viz., ulcers, suppuration, and interstitial deposition. If, again, the supply to the cornea is thus cut off, why does it not slough in its entire structure. Chemosis is a frequent consequence of gonorrhœa, opthalmia, and of the operation for strabismus often to a great extent; so as to conceal the whole of the cornea —yet sloughing does not occur. Romer and Pampperheim injected the cornea, and demonstrated the posterior vessels from the sclerotic trunks; Valentin and Lawrence are of the same opinion. He very truly remarks, that, if those favourable results should be confirmed, the treatment will constitute a valuable addition to our means of contending with a violent, rapidly destructive, and most alarming disorder. By enquiries we have ascertained that this improvement upon Scarpa's plan is rarely had recourse to at the Opthalmic—that it is fast falling into desuetude. The style of the work is diffuse; it was written for Mr. Tyrrell by Mr. Leach, a literary man, who has brought out some works for students preparing for the hall. We believe that numerous avocations

See page 133

and a delicate state of health, prevented Mr. Tyrrell writing it himself.

In 1839 he read a paper upon nœvus at the Chirurgical Society. Some years ago he had a controversy with Dr. Blicke, in which the brothers-in-law figured in a very strange light, Dr. Blicke, in his analysis of the evidence which he published at the time, was very severe upon them. Key and Tyrell became bewildered in the cross-examination, and contradicted each other, In the case of Beale, v. Self, these two gentlemen appeared in the same capacity to support Beale, who had been Mr. Tyrrell's dessecting porter. We have seen the certificate of Mr. Story and others who attended lectures at the time, stating that no such person was known to them. Now these gentlemen had better not hunt in couples any more; it may be very convenient to have a relation to prove one's view of a case, and bringing in the weight of situation, they may hunt down the general practitioner; but re action will follow. Let it not occur again; the timidity they displayed was witnessed by hundreds of practitioners, many of whom are not afraid to grapple with them, if an opportunity should occur. Verbum sap. sat.!

Tyrrell and Liston have both declined giving the Hunterian oration; one on account of illness—the other feels that "he is no orator, as Brutus is." Arnott is preparing for the task.

Mr. Tyrrell is now a finished, a safe, an elegant opthalmic surgeon. His manipulations of eye and instruments are perfect. His treatment we have praised before. He is at the head of the scientific oculists of this country.

PROBE.

EXTRAVASATION OF URINE.

PHYMOSIS.—INFILTRATION OF URINE.—URINARY FISTULÆ—SLOUGHING OF THE SCROTUM.

By W. Smith, Esq., Brompton, Kent.

JOHN PHILLIPS, aged 29, contracted gonorrhœa on the 30th Oct. 1842, and on the 1st of November Orchitis succeeded. The prepuce was much swollen, and it was found necessary, by another medical man, to divide it partially in order to relieve the tension. Aperients were administered with tartar emetic and poultices were applied; but not finding himself any better, he applied to me for further medical advice; when he presented the following appearance.

The scrotum was very tumid, of a dusky red colour, tense, and three or four times its natural size; the perineum was equally red and tense, and presented all the appearances of infiltration of urine. He had a severe gonorrhœa with intense scalding, phymosis, and two large ulcers on the dorsum of the penis, extending into the urethra, and allowing the urine to escape. Pulse 120, and full. Bowels open; tongue white, and loaded; skin hot and dry; mouth parched.

Several longitudinal incisions were made through the tegument of the scrotum, and it was found necessary to divide the remaining portion of the prepuce, from which about three ounces of very fœtid pus escaped. Through the incisions made in the scrotum, a quantity of urine-like fluid escaped guttatim: warm fomentations were kept applied upon the parts, and the following medicines administered:—

℞ Infus. Sennæ Co. ℥ij. statim.
℞ Ant. Tart. gr. ¼
Pulveris Opii. gr. ¼
Hydrarg. Chlorid grs. iij. ft. pulv. 1, 4tis. horis, sumenda.
Cataplasma.

3rd. November.—Feels much relieved to-day from the fomentations. Scrotum not so much inflamed; Pulse 98, and soft; skin moist; bowels open; tongue clean; urine (drawn off by a catheter) natural.

℞ Sol. Calcis Chlorid ℥ss.
Aquæ lb. 1. ft. lotio.
Rep. Pulv. et Cataplasma.
℞ Tinct. Opii. m. xx.
Liq. Ammon. Acet. ℥j.
Aquæ. ℥ss. ft. haustus hora somni sumendus.

4th November.—Much better. Pulse natural; skin moist; bowels open; tongue clean; scrotum much reduced, and feels quite easy.

Rep. Pulver 6tis horis.
Cataplasma.
Rep. Pil. Calcis Chlorid.
Rep. Haust. Anodyn.

5th November.—Scrotum natural size; pulse natural; skin moist; tongue clean; bowels open. A sinus was discovered extending above the pubis on the right side, and communicating with the urethra; an incision was made on a directer, and a quantity of pus flowed out.

Rep. Cataplasma et Haust.

6th November.—Slept very badly last night; complains of pain in the scrotum, but in other respects, easy. Tongue clean; pulse natural; bowels open; skin moist. On examining the scrotum, I found it soft and fluctuating about the lower third, and very painful; thinking that pus might be burrowing there, I introduced a directer at the ulcer on the dorsum of the penis, and found it pointed at the soft part in the scrotum. I therefore laid it open for about two inches, and about six ounces of pus escaped, which gave him great relief. Charpie râpee was introduced, and a poultice placed over it.

Rep. Haust et Lotio Calcis Chlori.

7th November.—Slept well; feels much easier; pulse natural; tongue clean; bowels open.

Rep. Haust et Lotio.
Cataplasmata.

8th.—Continues to improve.

Rep. Haust et Lotio.
Cataplasmata.

11th.—Continues to improve; bowels constipated.

℞ Infus. Sennæ Co ℥ij. statim.
Rep. Haust et Lotio.
Cataplasmata.

15th.—All inflammation in the scrotum and penis has subsided, and it was now found necessary to bring the edges of the wound in the pubis together. Pulse natural; skin moist; bowels open; tongue clean.

Rep. Lotio et Haust.
Cataplasma.
Charpie Râpée.

20th Nov.—Much better; wound in pubis nearly united; pulse natural; tongue clean; bowels open; skin moist.

Rep. Lotio.
Charpie Râpée.
Cataplasma.

25th Nov.—A sinus formed (through which the urine escapes), extending from the dorsum of the penis to the lower third of scrotum. I therefore introduced a gum-elastic catheter, which he is to wear constantly; applied some cupri sulph. and charpie, and brought the edges together. Bowels open; tongue clean; pulse natural; skin moist.

Rep. Lotio et Charpie Râpée.

30th Nov.—Wounds in the pubis; prepuce; and dorsum penis quite healed; urine passes through the catheter easily, and since wearing it he has not had any pass through the sinus in the scrotum, which is healing up quickly; all but one part near the raphé which looks sloughy; pulse, bowels, and tongue natural.

Charpie Râpee.

4th Dec.—Slough in scrotum has come away, and is now healed up; a few fungous granulations remaining in the centre of the cicatrix. I applied some nit. argent, which soon destroyed them; bowels constipated.

℞ Infus. Sennæ Co ℥ij. statim.

7th.—The wounds have all healed up; he discontinues the catheter, and as he is now quite well, it is unnecessary for me to attend him any longer.

ROUGH REPORTS FROM GUY'S.

PHYMOSIS AND BUBO. Bartholomew Scandal, æt. 19, was admitted into Guy's Hospital Nov. 16th, 1842, under Mr. Aston Key. He was of a spare, pallid, and strumous habit. Phagedenic sore at the end of the urethra; partial phymosis from thickened prepuce, (five weeks); suppurating bubo. 17th. Epithema plumbi applied to sore, poultice to bubo, and potass iodid grs. v., ter. die. ex dec. sarsæ comp. 19th. Bubo opened, poultice applied. 21st. Phymosis disappearing, sore looking healthy. 25th. Sore covered with a layer of yellowish white fibrine; still strongly touched with argent nitrat. Dec. 2d. Phymosis healed, bubo healed,—to apply emplas. ammon. chyd. Dec. 6. Presented cured.

CHRONIC ENLARGEMENT OF TESTES, WITH HYDROCELE. John Palmer, æt. 23, was admitted into Guy's Hospital Nov. 16th, 1842, under Mr. Aston Key. He has chronic enlargement of testes, and hydrocele on the right side, with superficial ulcers on the legs, (two months.) 17th. Pil. hydd. ℈i., potass iodii. ʒii. ft. pil. 60, 1 ter. die., ung. resinæ to sores. 21st. Hydrocele lessening, ulcers on legs much improved by poultice alone. 24th. Mouth touched, pil. i. bis. die.; sores improving; hydrocele lessening. Dec. 2d. Sores on legs healing fast. Dec. 8th. Sores healed, and hydrocele quite disappeared. Presented cured.

PERISCOPE OF THE WEEK.

ORGANIC CHEMISTRY.—The following is an analysis of the milk of a woman, a cow, and an ass, made by Dr. Playfair:—

	Woman.	Cow.	Ass.
Casein......	1·5	4·0	1·9
Butter......	4·4	4·6	1·3
Sugar	5·7	3·8	6·3
Ashes	0·5	0·6	—
Water......	88·0	89·0	90·5

The casein is the nitrogenised principle which affords nutriment to the muscular and other tissues. This is in greatest quantity in the cow. The butter and sugar are the combustible materials which by their combustion supply heat to the body. The ashes consist of phosphate of lime and common salt, both of which materials are necessary for the healthy function of the body. Thus, we have in milk all that is necessary for the growth of the body, and it is the type and representative of all food; for unless food contain the principles of milk, it is not fitted for the purposes of the body. Casein is the principle of cheese. In its ordinary state, as made for the food of man, cheese contains both casein and butter. The stomachs of young animals are not adapted for separating the nitrogenous principles from food, and the casein of milk is supplied to them ready separated. All food for weaning children should be prepared on the model of milk, changing the relations of the nitrogenised to the carbonaceous materials only as circumstances require. In the milk of the cow the carbonised materials are as two to one, but in the food of adult animals they are as six to one. The large quantity of casein in milk is required for the rapid development of the body; the butter, a highly carbonized material, is required for supporting a large amount of animal heat.

GENERAL EXUDATION OF MILK—Dr. Rasi cites a remarkable case illustrative of the phenomena af metastasis. An usually healthy and robust peasant woman, twenty-seven years of age, was obliged, by broken breast, to wean her infant. Subsequent to this, owing to vaoious imprudencies which are not particularised, the secretion of milk suddealy

stopped, simultaneously with which the joints of the lower extremities became affected with sharp pains. The patient was at first treated for arthritis, by ordinary antiphlogistic methods. The joints, however, were neither painful on pressure, nor exhibited the blush of inflammation, and much doubt was entertained as to the real nature of the disease; when, on the 17th day, after an abundant perspiration, the whole surface of the body became covered with specks of a whitish colour, strictly similar in appearance to those seen in military disease, but which, in about twenty hours, became converted into vesicles, containing a white fluid, to all appearance resembling milk. This fluid was somewhat heavier than water, slightly reddened turnsol paper, was not coagulated by acids, and when submitted to the action of ether, gave origin to a deposit of white filaments, which, treated with dilute hydrochloric or acetic acid, dissolved completely, thus manifesting their identity with the caseum of milk.

Phymosis and Paraphymosis—their Treatment.—For those conditions of the prepuce, belladonna has been recommended by some French physicians: an ointment of 30 parts of cerate to half-an-ounce extract of belladonna, to be rubbed hourly over the prepuce or dens penis, witth the further addition of an opiate in the event of much inflammation and pain. In phymosis, a solution of four grains of extract of belladonna, and half of aqueous extract opii in an ounce of water is advised; to be applied by sponge, or as an injection between the prepuce and glans, with warm baths of infusion of belladonna to the parts affected. Mr. Lane enjoins low diet, the horizontal position, saline aperients, and antimonials for phymosis, with lotio plumbi, fomentation of poppy-heads, and bread poultice as local applications. Leeches are not generally desirable. In severe cases take blood from the arm, however, and nauseate with antimony.

Statistical Record Respecting Cancers.—Of 134 operations for this disease performed at the Hotel Dieu in Paris, during the five years, from 1836 to 1840, inclusive, 95 were for the excision of cancers from the breast, and 29 for the ablation of the testicle. Of the 95 subjects of breast-operation, (91 females) 75 recovered: the remaining 20 died—4 between the 5th and 10th days after the operation; 7 between the 10th and 20th; 4 between the 20th and 30th, and 5 from 1 to 2 months afterwards. Of the 39 subjects of castration, 5 died—3 before the 6th day, 1 on the 9th, and 1 two months after the operation. Of the 91 female cases, 75 occurred in married or widowed females, and mostly between the age of 40 and 50; while the diseases of the testicle were found to prevail mostly before the age of 40 years.

Seminal Emissions.—For these and like debilitating occurrences, in the genito-urinary organs, after all exciting causes have been removed, Mr. Phillips advises the application of nitrate of silver within the urethra. For exploring the canal, Mr. Phillips prefers an elastic catheter, in passing which into the bladder, denotes accurately the point where the pain produced is the most acute. He then arranges the caustic apparatus, so that it shall not reach so far by an inch; the prostatic portion of the urethra being seldom implicated in the irritation. The place where the caustic has commonly to be applied, is as nearly as practicable about the orifices of the ejaculatory ducts. The caustic, having been exposed at this spot, may be slightly revolved along the floor of the urethra for half a minute, for it seldom excites much pain. Some smarting on the passage of urine, and discharge may be produced; but these symptoms abate in a few days, and the condition of the patient is often changed greatly for the better in a few weeks, and without further use of the remedy.

Coming Events cast their Shadows before.—The observation "Nascitur, non fit" will certainly apply, not only to the poet, but to the painter, the physiologist, the surgeon, &c. That this is fully true respecting the latter, is instanced in the following anecdote of a late eminent member of our profession. Astley Cooper was nursed by a foster-mother. A son of this person, somewhat older than himself, had been ordered to convey some coals to the house of the vicar. While on the road, by some accident, the poor lad fell down in front of the cart, one wheel of which passed over his thigh, causing, amongst other injuries, the laceration of its main artery. Sinking from loss of blood, he was carried home; where Astley Cooper, having heard of the accident that had befallen his foster-brother, directly arrived. All was alarm and confusion—when the young Astley, in the midst of the distressing scene, alone capable of deliberating, and perceiving the necessity of instantly preventing the farther loss of blood, had the presence of mind to tie his pocket-handkerchief around the injured limb, so tightly that it acted as a ligature upon the wounded vessel. The bleeding was thus stopped, and the life of the patient preserved, till further assistance was obtained; and this was the successful debut of Sir Astley in the art in which he afterwards became so distinguished.

Painter's Colic—Means of its Prevention.—A formula is given in a contemporary journal for the manufacture of *sulphuric beer* which has been found an effectual preventive of colic in some extensive lead works at Birmingham, when taken as a beverage by the workmen. Take—of treacle, 15lbs., bruised ginger 8 oz., water 12 gallons, yeast a quart, bicarb. soda 1½ oz., sulphuric acid, 1½ oz., (by weight). Boil the ginger in 2 gallons of water; add the treacle and the remainder of the water, hot. When nearly cold, transfer it to a cask, and add the yeast. When fermentation is nearly over, add the sulphuric acid, previously diluted with eight times its quantity of water; and then the bicarb. soda dissolved in a quart of water. Close up the cask, and in three or four days the beer will be fit for drinking. The sulphuric acid remains in considerable excess in this preparative; which probably acts as a preservation in the system, by transforming the poisonous carbonate penetrating it, into innocuous sulphate of lead.

Treatment of Burns.—On taking a general review of the constitutional treatment of burns, the first object should be to relieve the system of an abnormal quantity of fluid that must have accumulated in it in consequence of the arrest, to a greater or less extent, of so important a secretion as the perspiration. This may be accomplished either by the administration of diuretics, by guarded blood-letting, or by encouraging the process of suppuration. Secondly—any appearance, however slight, of supervention of inflammation in the organs contained within the head, chest, or abdomen, should be watched with the utmost anxiety, and treated, if it does occur, as actively as the circumstances of the case will admit. Thirdly—the process of suppuration should be maintained or arrested with a due regard to the state of the internal organs and the condition of the powers of the system.

Medical Statistics in Portugal.—An army hospital report states that, in all, 4,485 cases requiring medical treatment had occurred in the Portuguese army in the first half of 1838. The number of syphilistic cases, primary and secondary, had been 700; of gastro-entirits, 283; and of bronchitis, 340. The great relative proportion of the last to many other complaints, specified, is both striking and startling. Portugal being a country to which persons with chest disease have been so often expatriated from this country, nominally for their benefit. But, in reality, Lisbon, &c. have been cried up greatly beyond their merit, as places of resort for invalids; for whom many sheltered places along our southern and western coasts would be found much more beneficial.

Opium.—This remedy would seem in some maladies to exert an effect which can hardly be traced to its sedative properties, but appears almost of a specific nature. A case is reported of a lady, 80 years of age, a pimple on whose finger brought on much pain, with swellings in the glands of the arm and axilla of that side, and was supposed to be of a cancerous nature. Nitrates of silver, and mercury, iodine, *pills of mercurial ointment*, purgation, and a host of other remedies were taken without effect. The pain and sleeplessness of the patient increased, and the wart had increased to a bleeding and ichorous tumour. Local baths of poppy and belladonna were ordered, with half-a-grain of watery extract of opium every night. All the previous symptoms now gradually disappeared; and in two months a mere trace was visible of the original formidable swelling.

Cochineal in Hooping Cough.—Dr. Waehtb of Vienna has elicited the best results from the employment of cochineal in the above disease, the use of which was suggested to him by an English periodical. He uses a mixture composed of cochineal, 10 grains; bitartrate of potass, 20 grains; sugar, an ounce, and water, 6 ounces; of which a tea-spoonful is a dose. In nine cases which he cites, it had produced a cure or convalescence, in periods varying from 3 to 11 days. From the disposition to putridity of the cochineal, no more should be dissolved than is required to last from 36 to 48 hours:—warm water is required for its dissolution. This remedy is observed to be very efficacious, also, in the cough which accompanies measles.

Chemical Decomposition.—Persoz distilled gluten with sulphuric acid and chromate of potassa, and obtained as products, first, carbonic acid, and afterwards prussic acid. The residue contained chromate, alum, and sulphate of ammonia; it seems, therefore, that gluten yields, by oxidation, nothing but carbonic and cyanic acids and ammonia.

New Remedy.—Rheumatism, glandular enlargements, neuralgia facialis, &c. are said to have been cured in from 8 to 15 days, by the bi-sulphuret of carbon, externally or internally applied. A celebrated Danish professor orders 4 drop doses of a mixture of one part of the bi-sulphuret, and two of rectified spirit to be taken every two hours, or on external application, an embrocation of one part of the bi-sulphuret to two of olive oil.

Successful Treatment of a Fractured Thigh.—The vis medicatrix of nature has exhibited itself in a remarkable manner in the following case, occurring in the practice of a medical man near the metropolis. Mrs. F. æt. 89, of a spare frame, and temperate and regular habits, sustained an oblique fracture of the thigh bone, near its centre. She was immediately placed in bed, and the limb was encased in pillows. Next morning the fractured portions were placed in exact apposition, and kept so by judicious means till the forty-fourth day. At

this period the apparatus employed for the latter purpose was removed, and the fractured part was found to be firmly united, allowing of motion in any direction. In a few days the patient was enabled to put her foot to the ground, and even to step on it. Little time elapsed before she could move about without the aid of a stick, and in less than four months from the time of the accident she was quite enabled to take exercise out of doors, the weather permitting. No deformity exists in the limb. This case is well adapted to encourage surgical practitioners, particularly the junior portion, not to be too despondent of osseous union after fracture, even in patients so advanced in life as the subject of the present instance.

Secretions in Diabetes.—In this disease a practitioner of Bonn has found not only the urine, but the perspiration of the patient also to contain sugar. The same substance wa found in the saliva, which, on being treated with yeast, underwent vinous fermentation. The presence of sugar in the perspiration, &c. of diabetic persons is, however, not constant, as proved by our countryman, M'Gregor. Lehmann, also, was unable to detect it in the saliva of more than one in three persons affected with the disease.

Grafting Extraordinary.—The singular experiment of transplanting a cornea belonging to one animal to the eye of another deprived of that part, has been tried in Germany, and found successful; that is to say, the newly implanted cornea forms an union with the structure in contact with which it is placed. The same event happens even if the cornea in the eye on which it is grafted belong to animals of a different species! And it is further said that the experimenters have been able to procure a partial transparency in the cornea so treated, without which indeed the value of the experiment must have gone for little or nothing.

Formation of the Red Globules in the Blood.—Dr. Remak, whose observations on the minute anatomy of the nerves have become well known to the medical world, has turned his attention also to a microscopic observation of the blood globules He has seen the red globules in the blood of an embryo chick as early as the third week of artificial incubation, as well as in the embryo pig, an inch in length, in which last he finds they are from four to six times as large as in the full-grown animal. To ascertain the mode in which the red globules are reproduced, Dr. Remak took from a horse 30lbs. of blood on one occasion, and removed a less quantity for several successive days afterwards. On the first day the red globules were very abundant, while only a few colourless globules were present. Next day the latter were numerous and mostly enlarged, having in their interior one or more globules of a pale red colour, surrounded by small granules. On the fourth day it was obvious that red globules, similar to those existing in the blood in an independant state, had been formed within the larger colourless globules, and set free by the bursting and disappearance of the latter. According to Dr. Remak the clot formed in blood after it has been drawn, is in a great part formed of the films of the colourless globules, correlative to the number of which is its degree of softness.

Malformation of the Heart.—An instance of this kind occurred in a child, which when four months old was sent to the Foundling Hospital in Paris, and which died in the infirmary there of dyspnœa, after general cyanosis, in less than a fortnight afterwards. On opening the thorax nearly all its anterior half was occupied by the pericardium, and on laying open this, it was seen that the heart consisted of only one ventricle and one auricle, the deep sulcus between which was filled with a process of the liver, and a part of the diaphragm. The auricle was much larger than the ventricle, with parietes very much thickened, and at its posterior part the two venæ cavæ opened into it by a sort of sinus, apparently a rudiment of a right auricle. The pulmonary veins terminated in the ordinary manner. The ductus arteriosus was wanting. No other viscus was malformed.

Aneurism.—Two remarkable cases of this disease have been recently made public—one affecting the ascending aorta, and the other of the abdominal portion of that vessel. The first case occurred in a short and muscular man, 35 years of age, admitted as a patient at the Birmingham General Dispensary. He complained of a short dry cough, with shortness of breathing, and a sensation of oppression at the upper part of the chest. He dates his illness from an accident he had met with about four months since, when the shaft of a cart was forced violently against his chest, in which he felt great pain for some days after. On percussion of the chest, the right side was found generally to be rather duller than the left, but not so dull as to have attracted much attention, but on auscultation, the respiration of the left side was found louder than usual, accompanied with a loud rasping sound which extended all over the left side of the chest, at its greatest intensity under the first and second costal cartilages and sterno-clavicular articulation. Underneath clavicle a peculiarity was perceived, which Dr. Fletcher thinks is not uncommon in aneurisms of the arch of the aorta—namely, the respiration was bronchial, and was interrupted, synchronously with the arterial pulsations. No normal pulsation was to be felt in any part of the chest; the man was subject to giddiness and singing in the ears, but his bowels acted well. Bleeding to twelve ounces; aperients and saline medicines were prescribed; perfect rest, with very mild and sparing diet, and avoidance of all stimulating drinks. For about a month, little permanent alteration took place in the condition of the patient, except that he continued to get thinner. At this period pain and dulness of sound in the region of the heart augmented; pericarditis supervened, and the respiration had a sub-crepitant rattle; leeches to the seat of pain and aperients were ordered, but the oppression, pain, and dulness continued to increase. Intense dyspnœa came on, and the patient died.—On examination, about six ounces of clear fluid were found in the pericardium, about twelve of the same kind of fluid in the right pleura, and about half the quantity in the left. No adhesion in the pleuræ; left lung perfectly healthy; right lung œdematous in its whole extent. The pericardium was inflamed, and affected with hypertrophy and dilatation, like all the cavities of the heart except the left auricle, which was so pressed upon by the aneurism of the ascending aorta as to be lessened in its cavity, and to have its appendix almost completely obliterated Upon the sigmoid valves, on the posterior part of the ascending aorta was an aperture $1\frac{3}{4}$ inch in length, and in width about one-third of the circumference of the artery, communicating with an aneurismal sac, the parietes of which seemed formed of the external coat of the artery only, and which measured about three inches and a half in its perpendicular measure, and about ten inches and a half in circumference. It projected posteriorly, to the right about a third, and about two-thirds to the left, pushing down the pulmonary artery out of its normal situation and completely occupying its place, and projecting in its inferior third into the cavity of the pericardium. In this situation, its wall was so thin, that had the patient survived long, most probably it would have been the seat of rupture. On the distant side of the aneurism, the aorta seemed perfectly healthy,

In this case were several circumstances of interest. Dr. Fletcher, under whose care the patient had been, stated that it confirmed "his opinion respecting the incorrectness of that part of the late Dr. Hope's diagnosis of these diseases, where he says (in the third edition of his work on diseases of the heart) "an aneurism of the ascending aorta or arch would occasion a pulsation, murmur, or tremor, above the right clavicle or on the right side of the sternum, or above both clavicles." There was in this case no pulsation, murmur, or tremor in that situation, and Dr. F. had seen other cases in which there were not." The second case to which we have alluded, was that of a gentleman, about 38 years of age, of active habit, who complained of a pain in the back, which had been gradually increasing for a long time, and had suddenly become much more severe on his hearing some distressing intelligence six weeks previously. On examination with the stethoscope, a loud and distinct bellows-sound was heard on both sides of the spine, which, with the other symtoms, left little doubt as to the nature of the disease. The general health declined, the appetite failed, the patient gradually became weak, emaciated, and exceedingly nervous; there was strong pulsation in the epigastrium, but no tumor, nor was the action of the heart much increased; the pain in the back was of two different forms—one was a continual sense of weight and uneasiness, which never intermitted; the other was an acute, sharp, darting pain, felt on each side of the spine, recurring generally at midnight, and which, for a considerable time, always yielded to anti-spasmodic remedies. As the case proceeded towards its termination the emaciation increased, the pains became more severe, and extended into the lower extremities, particularly on the left side. In this manner six months passed away, when a rupture of the aneurismal sac, attended by symptoms, which our limits will not allow us to describe, carried off the patient. The abdominal aorta was found to give origin opposite to the cæliac axis to a tumour, about three inches in diameter, extending to the right side, projecting in front but little beyond the level of the spine. The bodies of the two first lumbar and last dorsal vertebræ had been absorbed from the pressure of the tumour, which presented a cavity filled with lamellated, dark, fibrous matter. Behind the peritoneum, on the left side of the spine, an immense clot of blood extended from the diaphragm down to Poupart's ligament, which had evidently been caused by a recent hæmorrhage referred to a period about two days previous to death. The practitioner who reports this case, remarks, that no symptom of aneurism is more pathognomonic than the pain, when viewed in connection with the other symptoms, and it was the peculiar character of this symptom which led him to diagnose aortic aneurism in the present case. Epigastric pulsation and *bruit de souffle* might occur in cases where there was no organic disease. He had met with a case of aneurism of the thoracic aorta, in which, as well as in this, the opening occurred in the posterior wall of the artery, and the pain endured by the patient was, also, of two kinds; one an aching, boring pain, which was constant; the other an occasional nipping pain, darting along the ribs or in other directions.

Imperforate Pharynx and Anus.—A curious instance of this kind lately occurred in the practice of a gentleman at Liverpool. A child of the full period, apparently well formed, lived only thirty-six hours; and death having been apparently produced by suffocation from the administration of a little cream and water, the body was opened. The pharynx, one and a quarter inch only in length, was found to terminate abruptly in a cul de sac, though the lower part of the œsophagus was perfectly formed and communicated by a rounded aperture with the trachea, just above its bifurcation. The rectum also terminated in a pouch, and communicated by an aperture with the prostatic portion of the urethra. There was only one kidney, which stretched across the vertebral column, being, however, supplied with two ureters and suprarenel capsules. No other details of importance respecting the case have been given.

Mortality from Burns.—The period at which death may be expected to occur in cases of extensive burns varies considerably, of course. But, on an aggregate of 50 cases, 33, or 66 per cent., have proved fatal in the first week—27 subjects dying within the first 4 days—and the other 6 on the 3 following days. Of the remaining 17—8 died during the second week, 2 in the third, 2 in the fourth, 4 in the fifth, and 1 in the sixth. Thus, it happens that the greatest number of deaths occur during the first few days, in the stage of congestion, or while that is passing into an inflammatory condition. After this period the mortality diminishes progressively till the fifth week, a period fatal mostly from suppuration, purulent infiltration of the lungs, &c.

Liquor Amnii.—Vauquelin and Buniva found 100 parts of this fluid to consist of 98·8 parts water, and 1·2 albumen and salt of lime and soda. Geoffroy St. Hilaire says it contains atmospheric air, but Lassaigne and Chenrevil believe the gaseous fluid in it to be a mixture of carbonic acid, gas, and azote. Tromhirz and Gangert found in it benzoic acid and urea. Dr. Davy has also detected urea in the liquor amnii, but this principle is not constantly found in it. There can be no doubt that this, and the other constituents of the urine, are secreted by the kidneys of the fœtus long anterior to birth, and that in a perfect state of the organs the urine is constantly escaping through the bladder, and mixing with the amniotic fluid. Dr. Rees had lately analyzed the liquor amnii, and found it to contain in 1.000 parts—water 983.4, albumen 5.9, albuminate of soda and chloride of sodium 1.6, and traces of alkaline sulphate.

Statistical Observation.—The twisting of the cord round the neck of the fœtus is a very common occurrence. In 1,920 cases, Dr. Churchill says it has been observed 201 times. There is no doubt that it is a very common case in protracted labour.

Causes of the Progress of Hydropathy.—Dr. Symonds, in his lecture before the British School of Medicine at the opening of the present session, attributed the popularity of Preissnitz and his system to the following circumstances. First, the system is very simple: diseases may be manifold, but the remedy is single, though variously applied; second, the universal application of the remedy seems to harmonize with its universal distribution over the globe; third, the system dispenses with the use of drugs, most of which are disageeable and many injurious; fourth, it gives ample proof of the super-abundant energies of many of the invalids who seek its aid; fifth, it generally induces diaphoresis, which is a process much in favor with most invalids. But Dr. Symonds goes on to say—"After the present popular excitement has passed away, cold water will, like all other remedies, find its proper level." (Preissnitz is singularly unfortunate in the fact of water inevitably finding its level in the end.) "The supposed universality of its powers is one of its chief attractions at present; and when that has been disproved, as it surely will be, there is ground for *fearing* that the remedy will sink in popular opinion to a degree which will be the exact counterbalance to its present undue elevation; the dyspeptic, the hypochrondriacal, the nervous, and the victims of *ennui* and satiety, as they at one time invoked the mummeries of mesmerism—at another swallowed, at the bidding of an empiric, hundreds of vegetable pills—or at another, flew for aid to Wildbad, and Baden-Baden, and Schlangenbad, and were disappointed—will not now unnaturally appeal to hydropathy, and perhaps with some better success. But the subjects of fevers, exanthemata, and acute visceral inflammations, the unhappy sufferers from organic diseases, and those who require the skilful knife of the surgeon—all, in fact, who are in the direct need of the remedial art, will, we venture to say, remain adherents of the practice which has been built upon the confirmed observation of disease for successive centuries, and upon the accumulated improvement which every year has added to the knowledge of the human body in health."

Function of the Spleen.—The attempt to determine this long contested question at present agitates the brains of many inquirers, not only in this country, but, as it should seem, by sympathy in distant British colonies also. Dr. Haygarth, a practitioner of Launceston, Van Diemen's Land, appears to accord with Mr. Eagle in considering the spleen the secretor of the colouring matter of the blood. He argues as follows:—"All the fluid productions of the system necessarily have their producing structures. For producing the bile there is the liver; for the urine, the kidney; for the chyle, mesenteric absorbents. But, is there any fluid existing in the body which has no organ assigned for the production of it? There is. What organ of the body forms the blood? The heart propels it; the vessels distribute it; the lungs aerate it; the chylous vessels supply replenish it; the kidneys and liver purify it. But what organ forms—what organ produces it? When I find a certain fluid going into an organ, and a certain fluid coming out of an organ, and none other fluid than this either coming out or going in, I naturally come to the conclusion, that such organ is for the purpose of exerting an agency over the fluid in question. The fundamental constituent of the blood,—that element which peculiarly constitutes it blood—is the red principle of this fluid. The souce rof all the other constituents of the blood can be accounted for; but in what region of the system is the red principle of the blood elaborated? I shall not here enter into a detail of those instances of impaired states of the system in which the red principle of the blood is defective, and in which, at the same time, the spleen is palpably and principally known to be at fault—such as in the pallor attending the sequelæ of intermittents, and in the systemic condition characteristic of chlorosis; but I will simply remark, that in these instances we have a visible defect in the system, and an especial organ visibly deranged; and the concomitants point out plainly enough that the one condition is dependant on the other. The spleen is the laboratory for the red principle of the blood."—A letter from Mr. Jackson, published in our last week's number, ably exposes some of that gentleman's opinions on the same subject, and contains some strictures on the abstract previously set forth of the views and discoveries of Mr. Stevens, respecting the structure and function of the spleen. We shall here give an abridged statement of Mr. Stevens' labours and conclusions, which have just been made public in a contemporary periodical: "The spleen comprises a mere congeries of capillary vessels; for, on examining the circulation in that organ by the microscope, during life, it becomes quite plain that it contains little or no intervening nervous parenchyma, or extra-vascular tissue. The ultimate capillaries are remarkably uniform in size, carrying a single file of blood corpuscles. Now capillary courses may sometimes be seen to run side by side, though in opposite directions, without sufficient distance existing between them to include anything more considerable than what may be supposed to be the coats of the vessels. I have concluded that a capillary artery and vein sometimes run together, meeting another capillary artery and vein—the artery of the first merging into the vein of the later, and *vice versa*. But such appearances are only to be detected in particular places, and upon very attentive watching, as the whole field of vision is in motion. The arteries communicate directly with the veins, and not at all with the lymphatics, as most injections of the dead organ would lead one to suppose. If the question be asked, 'What does all this blood here?" we must be content to say that we simply see it passing. The splenic artery is the chief branch of the cœliac axis; the spleen thus receives a very large portion of arterial blood, which, after traversing the capillaries of the organ, palpably without any deduction, is delivered into the portal circulation." Mr. Stevens admits that "the secretion of bile is palpably diminished when the splenic blood is cut off from the portal circulation." But the result which he gives, as that to which his microscopic observations have led him is, "that the spleen is merely the necessary interposition of capillaries between the splenic arteries and the venous portal circulation;" to avoid the "unprecedent d infringement of the laws of general anatomy—an arterio-venous anatomosis." Thus Mr. Stevens may be considered as uniting with Mr. Jackson, in regarding the spleen simply as an assistant circulatory organ; in opposition to Messrs. Eagle and Haygarth, who believe it to secrete or elaborate the colouring matter of the blood.—In this undetermined state the question still remains.

Cauliflower Excrescence of the Uterus.—A case of this kind occurred in the Dublin Lying-in Hospital: the tumour was removed by ligature. On making a section of a portion of the tumor its structure was seen to be much more complex than it had seemed when examined externally; it was finely laminated, appearing in section as if formed of somewhat parallel plates of a whitish matter, separated by reddish lines, which proved to be the layers of a beautifully vascular, and very thin membrane. In a morsel of the membrane highly magnified, Dr. Anderson detected a fine fibrous structure of great delicacy, absolutely swarming with blood corpuscles and cells, to the presence of which great part of its apparent thickness seemed due. The course and distribution of the capillary vessels could not be distinguished with sufficient exactness. Besides the corpuscles which retained their form, there were others apparently undergoing various changes,

exhibiting every variety of shape, and mixed with nucleated cells of different aspects. Of the latter, some were clear, with a single nucleus; others exactly like Dr. Barry's figures of the ovum in certain stages, being full of young cells; there were caudate corpuscles, like those Müller saw in cancer, and other bodies of various shapes. In the white laminæ, examined in the same way, no fibrous basis existed; the whole consisted of an uniform mass of cells, precisely alike, of an irregular form, from mutual compression, and full of a granular matter. On washing away the white matter, the membrane remained entire. It did not consist of parallel laminæ, but was beautifully flocculent, branching out very complexly from a thicker central portion or stalk. The cauliflower excrescence, then, has for its basis a membrane of extreme tenacity, ramifying in a most complex manner, amply supplied with blood, and possessing the power of forming from that blood a whitish cell substance, which is deposited in a layer about it. Hence each portion of the membrane forms, after maceration, a kind of lobule or flat villus, but in the recent state these adhere closely together, so as to give the whole tumour a nodulated aspect.

No. 176. VOL. VII. LONDON, SATURDAY, FEBRUARY 4, 1843. PRICE FOURPENCE. STAMPED EDITION, 5D.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

By C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN,—At the close of our lecture, yesterday, we were considering some of the varieties of morbid respiration. There are two more that may be mentioned; the regularity of the succession of respiratory motions varies not only in the two sides, but altogether; and there may be irregularity, likewise, as to the number which take place in a given time. *Frequency* is the usual standard: in an adult this is about twenty in a minute; so that there are about three pulsations, or rather more, to every respiration. But, by disease, respirations are very often much increased in number, and rise as high as sixty a minute, so as to become in peculiar diseases equal to the pulsations. They bear, however, a general relation to the pulsations, for where the pulsations of the heart are increased, the respirations are increased likewise. In many instances, the proportion of respiration to pulsation is as one to three, so that when the pulse is 120, the respiration instead of being twenty is about forty, and so forth. This is the more usual, and the more normal condition of the respiration. Respirations sometimes, on the other hand, are extremely few, sometimes only as many as ten in a minute.

Now, this variety of respiration is not, as you may readily suppose, connected with any disease of the respiratory organs; it almost always arises from disease of another kind, more particularly from disease of the nervous system, diminishing, somewhat, the sensibility of the relation, on which the motions of respiration depend. And these extremely rare states of respiration are found in disease of the brain, as in apoplexy. Very frequent breathings may take place without relation to the respiratory organs. Where the motions of breathing do not take place in regular succession—when one motion takes place after another, at a considerably longer period than usual, it does not necessarily indicate a derangement of the respiratory apparatus itself, but it rather depends upon some disorder of the nervous system. This irregularity of respiration takes place in great congestion of the lungs.

Besides the frequency of respiration we must notice its *extent*. Where the respiration is frequent, it is often very shallow, each movement of the respiratory machine being quite superficial or shallow, and the breath not deeply taken. Now, this may proceed from one or two causes, it may be from disease of the lung, the lung not being penetrable as in cases of *phthisis*, where the lungs are extremely diseased, and air cannot enter fully and deeply into the chest. This is one set of cases important to be observed in connexion with disease of the respiratory organs.

Another phase of diseased respiration may arise from debility, as in cases of fever, or other serious illness, when from great weakness patients have not the power to make an increased effort; what takes place then is a series of short breathings, as weak as they are frequent, owing to the want of perfection in the development of the motions. But the mode of distinguishing one from another is obvious. In the latter case, although the breathings are short, they are produced only by an effort. The patient can, by expanding his chest, take a deep inspiration, so that although the respirations may commonly rise to forty or fifty in a minute, yet if you desire the patient to take a long breath, it will be taken deeply and fully by a supplementary effort. This kind of disorder of inspiration is very common.

Frequency of breathing is generally met with in diseases of the respiratory organs themselves. I have seen it as much as sixty in a minute. But where there is this want of relation between the frequency of the breathing and respiration, and where a short and free breath can be taken on an effort, you may be quite sure of disease in the nervous system, and weakness of the organs, instead of disease in the respiratory organs themselves.

Respiration is sometimes prolonged to a peculiar degree. This may apply to either inspiration or expiration: sometimes both are prolonged. Where both are prolonged, it usually arises from some obstruction in the larger tubes of the bronchii, as in the case of croup or spasmodic affection of the tubes. Here the breathing is prolonged; inspiration is prolonged, often accompanied by a peculiar sound, and expiration also. You may trace this to its source in a great measure, by observing the condition of the inter-costal spaces; the respiratory apparatus acting with freedom, and there being no fault in the lung itself, if there is a fault in the tubes by which the air is supplied, when inspiration is applied with force and vigour, atmospherical pressure will act on the chest and inter-costal spaces, and cause them to be more depressed than usual. Sometimes the intercostal spaces swell by the effort of inspiration, owing to the difficulty of the passage of the air out of the proper tubes. The proportion between inspiration and expiration, is important to be observed in many particulars, it is very often affected by diseases in the lungs and the tubes. The details we shall consider under the head of particular diseases.

So much, then, for sight and touch, as means of investigating disease within the chest. They certainly do much to prepare for the more accurate and definite, but more difficult examination by the sense of hearing. Hearing may better serve to indicate the condition of the motions of the chest, and in consequence of this not being commonly applied for investigating disease generally, it has assumed the character of a separate science connected with the study of disease. *Auscultation*, as it is called, ought never to be separated from the study of pathology on the one hand, or the proper study of physical signs on the other. It is merely one mode of obtaining physical signs. There is this difference between the sense of hearing, and sight and touch, that in listening to the physical signs produced by disease, we can distinguish them when they are not obvious to sight and touch, though sight and touch are more commonly used. We are more familiar with the indications that take place in the case of hearing, in matters with which we are familiar, for instance, the sounds of language, or different voices in the streets, and the footsteps of persons approaching, and so forth, or we learn by experience to distinguish these different sounds; but we are not in the habit of practising our hearing to distinguish between the minute sounds, that take place in the changes of motions within the body; therefore it becomes a separate study; and, again, these signs are studied as signs and representations of the physical condition of the organs both in a state of rest, and in a state of motion.

Then, with regard to the mode of studying this phenomenon of sound, or *acoustic signs* as it is called, there are two modes which I shall not enter into particularly. One is by mere individual experience, the result of attention to the sounds, and observing what motions of matter produce those sounds, observing the consonance, accordingly, in matters of memory and observation. This is what the child does in practising its senses; it studies the thing until it becomes familiarized with it by observation. The other mode is by generalization of these observations, and the experience thus obtained; that is, by referring all these different phenomena to the general laws which regulate the production, transmission, reflection, and so forth, of sound.

Now then there are laws of sound as well as laws affecting matter and mind, laws which apply to the generality of cases, and therefore when you get hold of a law, and understand that law, you are master of the general facts which are the exemplifications of that law. And this mode of studying sound is so far useful that it gives us it were a handle to the phenomena and their development by observation; and after observation has made us acquainted with a great number of phenomena, by collecting them, they become intelligible signs of health or disease. We cannot study auscultation without a certain combination of them all; even those who reduce the study to the most empirical mode, by observing and recording what they observe, cannot get more than a generalization of the phenomena. Auscultation is useful to make us acquainted with the laws of sound, because it makes us more familiar with the changes of disease than we can be by observation. The proper way of empirically observing acoustic sounds would be independent of pathology. The student or medical man observes that in certain cases the chest sounds dull on percussion, and in these cases certain remedies are useful. He might go on in this way independently of any pathological knowledge to make auscultation useful to him, and no doubt it would be so in a certain sense. I understand that veterinary surgeons, even blacksmiths, without anything like a scientific knowledge of the heart, have been in the habit of making use of auscultation for many years past. This may be very useful now and then as a guide of the beating of the pulse without understanding the relations of the pulse; but this is a very reserved use of it, and it is in no way so useful as it becomes when the mode in which the signs are produced is understood. For a proper study, therefore, of the nature of the phenomena of sound in the chest, and a proper study of those general acoustic laws which regulate these different phenomena, you will do well to study some works on acoustics. Several elementary works may be necessary for this purpose. I have a little work on pathology and diseases of the chest, in which there are a few general remarks on this subject, with regard to sound, most applicable to the study of the sound of disease. You may enlarge on the subject. My reason for noticing it was the egregious errors into which both writers and teachers have fallen upon the subject of auscultation, errors not only with regard to experienced phenomena, but errors of anatomical fact. I could give a great variety of illustrations from various sources.

Now, the first mode of judging of the acoustic properties of bodies or forms that I shall mention, is by percussion. This is applicable to the chest and other organs in a state of rest. This mode of examination was first applied extensively by Ehrenberg, and it has been extended greatly by Laennec and others. Now, this may be illustrated by phenomena on the chest itself, or by any other way. When the chest is struck with a certain degree of

force, it gives a certain degree of hollow sound, which sound is very different from the sound given by striking the thigh. It is easy to distinguish between the two sounds. Now, I take the principle on which this depends as a guide to assist us to understand the phenomena, and to mark it altogether. This was formerly said to be produced by the hollowness of the chest. A person striking the chest and obtaining thereby a hollow sound, this was supposed to be an indication of a hollow; and some who attempted to apply acoustic laws to this, went on to explain that it was the revibration of hollow resonance produced by the interior of the chest on percussion. I believe few things more injurious in a practical art than erroneous interpretations, or improper applications of a science, and I conceive this attempt at explanation is not accurate, it is not consistent either with fact, as by examination, or the laws of sound as generally developed. As an example of this kind, an illustration given is to suppose the chest upon percussion gives a hollow sound in the same manner as a bottle gives a hollow sound in the interior. Now, we may bring this to an experimental test. If it depended upon the explanation given, it is very well known that, in conformity with the laws of acoustics, the hollow sound produced by striking a hollow body is in exact relation to the size of the interior, and to the freedom with which the interior communicates with the exterior, and that the sound would be greatly modified by closing the orifice. The sound becomes changed to quite a different character. Now, if the sound produced in the chest is of a similar kind, it ought to be modified by the freedom with which the air communicates from the exterior to the interior. When I strike my chest with my mouth open and speaking, having a free communication with the external air, the sound is precisely the same, as when I close my mouth and close the glottis, so that there is no communication at all. The sound is the same under both circumstances. Again, another mode by which this can be proved to be not the case, is that by varying the size of the cavity, the sound will be a different one: the internal resonance of the cavity will be deep toned in proportion to the size of the cavity, and by making the cavity smaller it can be easily proved. Now, we can alter the size of the cavity of the chest by expansion, yet the difference is scarcely apparent. I take a full breath, and breathe out, and the sound is still the same. It appears, therefore, clear, that whatever it depends upon, it does not rest on that general law by which hollow sound is produced. I take it, then, at once, that the cause is, that the sound which is thus produced —the sound on percussion,—depends on the vibration of the walls of the chest: it does not depend on the hollow within the chest, any further than that hollow enables the walls themselves to vibrate and give a sound, and these walls vibrating are the causes of the sound. These walls, then, constitute the body struck, and so vibrating cause the sound; but they derive a character, in their vibrations, from the body or bodies underneath them. If, for instance, these bodies are the lungs filled with air, then the sound will be clear, because the lungs filled with air do not interfere with the vibrations, therefore, the sound is prolonged; if, on the other hand, there is, in the place of air, [illegible] in the chest, an impediment exists to the rapidity of the vibrations, and a short and abrupt sound is produced. A solid body within the chest has a similar effect; that solid body coming in contact with the chest, interferes with the freedom of the vibrations, and the sound, instead of becoming prolonged and free, becomes short and dead. I generally illustrate this by the experiment of the hat, and I do not know whether we can get a better illustration of it. The sound or the vibrations of the hat will represent the mode in which the vibrations vibrate, not unlike the sound that some very good chests will produce. Suppose I introduce some spongy or porous matter into the hat, the vibrations will then be much shortened. If I introduce a handkerchief or anything of that kind into the interior of a bottle, it will deaden the sound, and a tubular sound will be produced; but not so in the hat. Take another illustration: suppose we introduce a solid body into contact with the walls, it will at once deaden the sound. This will illustrate the way in which the lungs become compressed, and then the sound becomes deadened. The lungs becoming consolidated by disease act in the same way. Suppose we pour some water in the hat, the sound becomes dead; remove it, and the sound is restored. By this very simple illustration, we have a very good proof that the walls themselves of a body constituted like a hat—the chest is in some degree like the crown of a hat—are sufficient to cause the sound independently of what is contained in the interior, but the interior being dense modifies the sound. The chest is constituted by an elastic frame of bone and cartilage, covered with membranous expansions and integuments, and so forth, thus constituting walls free to vibrate, and they receive the character of their vibrations from the organs which are underneath. Accordingly, when the lungs rise, the sound of the chest is clear, because the walls are free to move and to vibrate, the upper structure of the lung not interfering with the vibrations. On the other hand then, over the liver, which is a dense solid organ, the sound, instead of being so clear, is dead, compared with the sound produced in the chest. The sound that takes place over the region of the heart—particularly on full expansion which presses the heart in contact with the walls of the chest—is here modified, owing to the contact of the heart with the walls of the chest. So also with regard to bodies of a different density to those which lie next to them in their natural position. If at the upper part of the chest the lungs become consolidated by disease, the sound will be rendered deader, and the vibrations will take place with greater rapidity; and that taking place, the character of the vibrations will be raised. This is a law of acoustics, that sound varies according to the rapidity of the vibrations. If there are many vibrations the sound will be like a high note, if few the sound seems dead. Different circumstances will deaden the sound, and tend in some degree to raise the note. This is another important fact. In some cases it is difficult to say whether the sound is deadened in tone or not. We can distinguish whether it is different in tone: and though diseases do not tend to deaden the sound, they may raise the tone, by rendering the vibrations more rapid. Water in the cavity of the chest may deaden the sound more than the consolidation of the lung will do. This may be illustrated by the experiment of the hat. On the other hand, if any circumstances increase the aerial contents of the chest, and move or diminish the solid matter, the chest has a tendency to produce increased vibration; there is more resonance than usual. This arises in cases of *emphysema*, or dilated condition of the air cells, the lungs containing a greater quantity of air. In *flaccid emphysema* there is a diminution of proper consolidated matter in the chest, and here the sound on percussion is deeper than usual, and more resonant and longer. There is another example,—as when air is infused between the lungs and the walls of the chest, and this is called *pneumothorax*. Now, as you may be ready to suppose, this renders the vibration more easy, and when there is nothing but air, the vibration is still clearer, and there is an increased resonant sound.

As the walls give the sound, it is clear that they are the source of the sound, and it is necessary that they should be dense enough to be sonorous. If they are so flaccid as to be dull, you will get no sound out of them, nor can you get it out of a solid body by percussion of the external parts, as in some cases where it is illustrated by the walls being flaccid, or covered with fatty matter, or in others muffled with œdema. And in some parts of many chests a similar difficulty is met with: in the mammæ for instance, the breast and muscles in very muscular subjects, and those parts of the chest where there are deep layers of muscles, it is difficult to elicit the proper sound owing to the thickness of the walls.

Now, under these circumstances, what you want is something to supply the defects of the exterior, and this you have in the pleximeter invented by M. Piorry. He recommended percussion to be made on some solid body, rather than directly on the chest, in which case you can elicit sound from parts otherwise too flaccid to give a sound. The *pleximeter* is simply pressed on the parts from which the sound is desired to be obtained, and percussion is made by means of the tip of the finger. The chief objection to it is the clacking sound which is produced. There are other inventions made to counteract this clacking sound. There can be no doubt that through the medium of the pleximeter more delicate results are obtained than where percussion is applied immediately to the chest. Dr. Golding Bird invented a pleximeter, which consisted of a sort of hammer, and a plate to strike upon. With this you would go to the patient's chest, and with a large formidable hammer, enough to frighten some nervous patients out of their wits, who would fancy you were going to inflict some formidable operation upon them. The German physicians invented an application of this kind, and Dr. Bennet made some improvement upon it. When the thing was about I set my wits to work to try to find out something that would answer the purpose; and this is, a little bit of whalebone covered with velvet, and a little hammer. This little instrument is very portable, and with it you may perform percussion in all cases where it is very difficult to use the finger, and get the most delicate results that may be obtained by the more formidable instruments. I do not see that the apparatus is absolutely necessary, and a little practice will enable you to obtain immediate percussion by using the finger and the left hand, placing the hand on the part, and striking it with the finger of the right. You may thus obtain percussion over the whole surface, or you may place a finger on a particular part to practice percussion on that part. The best recommendation of the hand is that you are not likely to leave the apparatus behind you.

There are varied modes of percussion; sometimes it is short, sometimes gentle and flat, and sometimes it is fillipping, by which sound is developed with very little force.

Now, as to the test of the condition of the chest by percussion. You will remember that percussion is an indication of the density of the parts within the chest, and you must remember what those parts are—what is the natural position of the organs within the chest, in order to make the sounds on percussion available as signs of their condition. I have endeavoured to make this intelligible by representing the chest as a sort of transparency, so that you may see the apparatus within the walls. Now, then, with regard to the examples of sound. Just as the different organs lie in their natural conditions, the sounds on percussion can be modified by a combination of these organs. About the upper parts of the chest you will have a pure pulmonary sound. When you come to the contents of the abdomen, about the nipple, or between the fourth and fifth rib, you will have a more forcible sound on percussion, not quite so clear. The sound is clearer than when you get the mixed sound of the liver and the lungs together, which is, in fact, a mixed sound, the two bodies modifying the vibrations of the chest. The same thing is observed with regard to the region of the heart. In the upper region of the heart, or the left side, or the axilla, you have a clear pulmonary sound: and when you come to the third rib, close to the sternum, or between the fourth and fifth rib, nearer to the breast, the sound is more modified, more particularly by forcible percussion, which elicits the sound of the interior as well as the exterior. Coming over the region of the heart you have not so good a sound as you have higher up. And that will be modified still more by expiration, which increases the contact of the heart to the chest. About the region of the heart the sound becomes modified by the intestinal or stomachic organs. There is a bottle like sound, arising from the contents, and likewise from the walls of the stomach being free to vibrate. There is the tympanitic or drum like resonance; a mixed sound, which is obtained at the back part of the chest. In the chest, the sound is more purely pulmonary; the walls of the back are thicker, covered with a greater thickness of muscle, and by the scapula; and in short subjects, the sound is not so clear as in the lateral parts of the chest, but what you do get is pulmonary. The sound is opposed by the entire scapula, and sometimes by the long ridge of the scapula. Remember the structure of the lungs;

they do not slope out so much, they are not so lengthened anteriorly as they are posteriorly, consequently there is not the transmission of the liver sound behind as before. The same thing may be said with regard to the intestines opposite the hollow of the diaphragm, in the lower part of the back; here you get an intestinal sound, mixed up with a pulmonary sound.

This is the natural condition of the chest, and I have already adverted to some of the modes of developing sounds from the superficial and from the deep seated parts. The sounds from the superficial parts are to be gained by superficial percussion; by percussion by a stroke so gentle, that it shall not extend to the deeper parts, as when you strike an image, you hear nothing but the sound of the image. But suppose you strike harder, then you have not only the sound of the image, but a sound composed of that of the image, and the table on which it rests. This is a compound sound; the other is a superficial sound. The same thing applies to the walls of the chest when you strike them gently, you get a superficial sound, and accordingly if you want to know the condition of the lung which is lapping over the liver, and, independently of the sound of the liver, you use the gentle fillideing percussion; but if you wish to know the condition of the deeper seated parts, you use more forcible percussion. The same thing may be said with regard to the other parts, and may be rendered available in disease. Percussion is the test of the condition of the chest, not only when it is in a state of rest, but when the lungs are expanded, when the motion of respiration takes place. Also, with regard to the heart. The sound is considerably more dull on expiration than on inspiration; on the other hand, if there is adhesion to the pericardium or the chest, or a great enlargement of the heart, or the lung is diseased, and expiration does not take place, then you have a difference between full expiration and full inspiration which does not exist generally. On the other hand, if the lungs are permanently in a state of full inspiration, or in the case of emphysema, this will make no change in the sound on percussion, (whatever efforts are made to perform percussion on the chest,) nor a resonant sound over the region of the heart. But the great rule in the application of percussion is comparing the opposite sides. There is a correspondence between the sound given out by the opposite sides. Accordingly when we wish to know a healthy condition of sound, we judge not only whether the sound is clear or dull, but whether it is as clear as the corresponding point on the opposite side. In some cases the sound is dull and not equal upon comparison, but, in clear cases, you have to ascertain the depth of the motions. Sometimes disease affects one side, and not the other, or else it affects one more than the other, and hence comparison is the great test or means of indicating percussion.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

The next element we have to speak of is chlorine, which, whether considered as a medical agent, or in relation to certain theoretical views, which are intimately associated with its history, we shall find to be an exceedingly interesting body. Chlorine was discovered by Scheele in 1774, who called it *dephlogisticated marine acid.* He prepared it by distilling muriatic or *marine* acid, with the black oxide of manganese, which latter was supposed to deprive the acid of an imaginary substance termed by him phlogiston. I have before now had occasion to remark that this term, phlogiston, was not very exactly defined or understood, even by those who were in the habit of using it most, being like the word *sympathy*, so much employed in medical practice, one without any definite meaning, but serving admirably the purpose of simplifying an explanation if not an idea. The word phlogiston may, however, in many cases be translated hydrogen, which, if done in the present instance, Scheele must be owned to have had a cleverer comprehension of the nature of chlorine than any subsequent chemist until the time of Davy. The French chemist, Lavoisier, and his colleagues, in their spirit of generalisation, laid it down as an axiom, that oxygen was the sole acidifying principle, therefore they maintained that the dephlogisticated marine acid of Scheele, or chlorine, must necessarily contain oxygen. This view was adopted until the year 1810, and when Davy first made known his doubts as to its correctness, he was regarded as a kind of scientific infidel. The French theory of the composition of chlorine, broached as it was at a period when the nomenclature of chemistry was undergoing a complete revolution, influenced, as may be well imagined, the visible structure of this science, to a very great extent, and as a consequence, the opinions and prejudices of men. Indeed, on casting our glances where we may over the wide field of chemistry, we cannot help being struck with the peculiarity of its nomenclature, as it regards the pertinacity with which chemists have insisted that oxygen must necessarily form part of every acid. This fallacy is too deeply mingled with the science and its nomenclature for any one to expect its complete removal. Chlorine does not possess any acid properties, although we find it to have been called dephlogisticated marine and oxy-muriatic acid. Davy, in 1810, proved that, according to the strictest logic of chemistry, chlorine must be regarded as a simple body, inasmuch as oxygen, far from being loosely combined with muriatic acid in its formation, as was imagined, could not be proved to exist in it at all. This view of the nature of chlorine is now universally received, and here its history terminates. Chlorine is found in both kingdoms of nature; although its properties are such that it would be fatal to both animal and vegetable life, if existing in an uncombined state. In the inorganised kingdom, it chiefly exists in combination with sodium, forming, in various parts of the world, rock salt, and also in the ocean. It is also found in combination with magnesium, calcium, lead, silver, and other metals. In combination with hydrogen, forming hydrochloric or muriatic acid, it escapes occasionally from the craters of volcanoes.

In the organised kingdom it is found in combination in both animals and vegetables. Sprengel affirms that maritime plants exhale this gas chiefly during the night. Hydrochloric acid is said to be a constituent of the gastric juice of animals, and chlorides, or combinations of chlorine with simple bodies, are found in many other animal secretions.

There are several ways of preparing chlorine, but only two of any practical importance.

1.—By heating hydrochloric acid with binoxide of manganese.

2.—By heating together a mixture of sulphuric acid, common salt, and binoxide of manganese.

In process 1st, two equivalents or 74 parts of hydrochloric acid, react on one equivalent or 44 parts of the binoxide, and yield one equivalent or 36 parts of chlorine, one equivalent or 9 parts of water, and one equivalent or 64 parts of protochloride of manganese. Symbolically, the decomposition is thus expressed—$Mn\ O^2$ and $2\ Cl.\ H$ give $Mn\ Cl$, Cl and $2\ HO$.

The second process, however, is cheapest, and most convenient; the theory is as follows:—Two equivalents or 80 parts of sulphuric acid, react on one equivalent or 44 parts of the binoxide, and on 60 parts or one equivalent of chloride of sodium, and yield one equivalent or 36 parts of chlorine, one equivalent or 76 parts of sulphate of the protoxide of manganese, and one equivalent or 72 parts of the sulphate of soda. In symbolical language, thus $Mn\ O^2$ and $Na\ Cl$ treated with $2\ S\ O^3$ produce $SO^3\ Na\ O + SO^3\ Mn\ O$ and Cl is evolved.

In practice, when following the last process, it is usual to mix three parts of dried common salt with one part of the binoxide of manganese, and to add to this, placed in a retort, so much of sulphuric acid diluted with an equal bulk of water, as may be sufficient for producing a thin paste. The heat of a spirit or oil-argand lamp, is amply sufficient for developing the gas, which may be collected over water in a common pneumatic trough, or by displacement. The first portions should be collected and thrown away as they are impure, but chlorine being an exceedingly irritating substance when breathed, it should never be allowed to escape within a building. Books recommend the collection of chlorine over *warm* water, because cold water absorbs it to a certain extent; however in practice, I invariably use the latter, thinking it better for many reasons. If warm water be used, the gas is made to expand, and if bottles be filled with it in this expanded state, and the stoppers inserted, the force of atmospheric pressure on them is such that they are frequently incapable of being withdrawn; moreover a warm water bath diffuses through the atmosphere a sufficient quantity of the gas to seriously interfere with breathing. On the other hand, by collecting chlorine over cold water, a portion of the gas is lost it is true, yet the absorption soon attains its maximum, and the vessels become speedily filled with the substance considerably diminished in volume by the agency of cold.

Chlorine when thus prepared is a greenish yellow substance, whence its name, of an exceedingly suffocating odour, very irritating to the air passages when inspired. The specific gravity of this gas is 2470. It does not burn, but supports the combustion of some bodies. The flame of a taper when immersed in a vessel containing this gas is not immediately extinguished, but burns for a second or two with a dull red light, giving off black carbonaceous fumes. Many bodies, however, take fire spontaneously when immersed in chlorine; of this powdered antimony, and phosphorus are examples. If a paper saturated with oil of turpentine be immersed in this gas, it immediately takes fire, and dense clouds of charcoal are deposited. This phenomenon is dependent on the great affinity which chlorine possesses for hydrogen. Oil of turpentine consists of carbon and hydrogen united together, of these chlorine abstracts the latter, and leaves the former in an isolated state. The affinity of chlorine for hydrogen is very great; when mixed, these gases gradually unite even at common temperatures, and suddenly with explosion, if set on fire by a taper or the electric spark. It is in consequence of this great affinity for hydrogen, that chlorine is enabled to decompose most organic substances.

Chlorine is occasionally employed in medical practice as a fumigating agent, disinfectant, and antiseptic. Also as an antidote in poisoning by hydrocyanic acid, sulphuretted hydrogen, and hydro-sulphate of ammonia, but in all these cases, chloride of lime is a far more agreeable agent. It has been employed moreover in certain pulmonary diseases, such as chronic bronchitis, with apparent benefit; nay, it has been even said to cure phthisis, but the assertion is not well supported. By far the most important uses of chlorine are to be sought for in the arts, where it is chiefly employed as a bleaching agent. The old plan of bleaching linen consisted in exposing it to the combined agency of light, air, and moisture, for a considerable period, when the oxygen, under these circumstances, united with the colouring matter, and formed colourless compounds. It had been remarked that the peroxide of hydrogen, a compound hereafter to be spoken of, was a very powerful bleaching agent, and moreover that dew water bleached more effectually than water from any other source; then it was forthwith imagined that such water contained peroxide of hydrogen, to which its bleaching properties were attributable. In short, the process of ordinary bleaching was said to depend upon the formation of colourless oxides of colouring matter. The bleaching properties of chlorine were referred to the same cause; it was said that this gas could not bleach except water were present, under which circumstances the latter becoming decomposed, its hydrogen uniting with the chlorine to form hydro-chloric acid, and its oxygen yet in a nascent state, allying itself to the colouring matter, and producing a colourless oxide. This theory is exceedingly simple, and seems no less plausible, but according to the experiments of Dr. Kane, it is not correct. This chemist says, that chlorine enters into the constitution of the new substance formed, sometimes replacing hydrogen, at other times simply combining with the colouring body, and in some, its reaction being so complex, that its immediate stages cannot be immediately traced

Chlorine, when brought into contact with water at a temperature of 32 deg. F. forms a crystalline compound, which is decomposed by a temperature of about 45 deg. If a quantity of these crystals be sealed up in a strong glass tube, and heat be applied to one end whilst the other is cooled, the chlorine during its liberation, exerts so much pressure on itself, that it becomes condensed into a fluid. 100 volumes of water at 60 deg. F. and 30 inches bar. absorb 200 volumes of chlorine, but it is necessary that the water should have been freed from all other gases by boiling, and that it should be agitated with the chlorine; otherwise the amount of absorption does not take place, and hence may chlorine be collected over cold water without any practical inconvenience. Water holding chlorine in solution, possesses the taste, odour, colour, and bleaching properties of the gas. The combination of these two, however, is not very stable, for when exposed to the light chloride of hydrogen, (hydrochloric acid) is formed, and oxygen gas eliminated. This change may be known to have occurred by the solution having lost its colour, and acquired the property of reddening litmus. The oxygen thus liberated during the formation of hydrochloric acid under the circumstances just mentioned, is in a condition particularly prone to unite with other bodies; and hence chlorine acquires the property of a very powerfully oxidising substance. In the greater number of instances, however, according to some philosophers, the oxidising influence of chlorine depends upon other causes. Thus it converts protoxide into peroxide of iron, by combining with one portion of the metal, and leaving all the oxygen to unite with the remainder, but I cannot help attributing the chief oxidising property of this body to its power of decomposing water, as just indicated.

Chlorine unites with oxygen in four proportions forming a very perfect series of compounds. Its affinities are very extensive indeed, being capable of uniting with nearly all the simple bodies, and forming compounds termed *chlorides* or *chlorurets*. With metals it yields compounds, analogous in many respects to the same bodies with oxygen; but with non-metallic simple bodies, the analogy is by no means so clear. For the most part, the compounds of chlorine with simple bodies are very soluble, in this respect differing widely from oxides; chloride of silver, and chloride of mercury, however, are well known exceptions. In some cases chlorine unites with metallic oxides, but the results of such combinations are not very stable. Sometimes it unites with protoxides without decomposition; at other times it displaces a portion of the oxygen of a peroxide, which becomes replaced by itself. Thus with lime it forms Ca O. Cl; with protoxide of lead, PbO. Cl; with Baryta, Ba O. Cl which probably correspond to Pb O_2 and Ba O_2. In addition to the properties of chlorine, which I have mentioned casually, the following must be impressed upon your memories.

100 cubic inches weigh nearly 77 grains. Its specific gravity is 2.5 nearly. Its equivalent weight is 36, omitting fractions, and its equivalent size is equal to that of hydrogen. By a pressure of 4 atmospheres, i.e. 60 lbs. on the square inch, at a temperature of 60 deg. F. it is condensed into a yellow liquid, having a sp. gr. of 1.33. The colour, odour, and bleaching qualities of chlorine are distinctive characteristics of the gas, when uncombined or merely united with water. Moreover, either in these or any other conditions, so long as it does not form part of an insoluble compound, it yields with nitrate of silver a white curdy insoluble chloride of the metal, which blackens on exposure to the solar rays, or even diffused daylight, which is totally insoluble in boiling nitric acid, and soluble in liquor ammoniæ. These characteristics are peculiar to chlorine alone, and hence are the distinctive tests for that substance.

FOREIGN PHYSICIANS IN PARIS.—The number of foreign physicians now authorised to practice in Paris amounts to thirty-one. Within the last ten years only two or three permissions have been granted, in spite of the numerous demands addressed to the Minister of Public Instruction.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c. &c.

LECTURE V., Delivered December 12, 1842.

(Concluded from p. 276.)

I have not purposed to read anything in these lectures, but there is an essay by Sir Henry Halford, which gives an interesting description of a case that relates to the present subject, and you must allow me to read half a page. It is what I have observed repeatedly myself. This patient had all the symptoms previously mentioned, and I must remark that this was the case of the late Dr. Warren. Sir Henry Halford says, "A young gentleman of family, about 25 years ago, took cold whilst under the influence of mercury; the fever increased daily, until it was accompanied at last by so much fever and delirium, as made it necessary to use not only the most powerful remedies, but also personal restraint. At length, after three days of incessant exertion, during which he never slept for an instant, he ceased to rave, and was calm and collected. His perception of external objects was correct, and they no longer distressed him, and he asked pressingly if it were possible that he could live?

On being answered tenderly, but not in a way calculated to deceive, that it was probable he might not, he dictated most affectionate communications to his friend abroad, recollected some claims upon his purse; 'set his house in order,' and died the following night." I should not have quoted this case had I not seen similar cases, and in fact many cases are calculated to deceive, whereas the fact is that the patient, instead of being better, is worse. He goes on to say, "The reason why so unfavourable an opinion was entertained of his state was, that the apparent amendment was not preceded by sleep, and was not accompanied by a slower pulse." Now the fact of a patient in this state being worse is an important thing; for, when a patient seems better and is no better, you must come to the conclusion that the state of things, called the sinking state, what John Hunter called a state of "dissolution," is not a state of amendment.

Before I conclude the subject of the symptoms, I want to detail to you an interesting fact, which I believe to be a new one, corroborated by an interesting case lately published by a gentleman whom I have the pleasure and honour of knowing, namely the convulsions that arise from inflammation of the membranes of the brain. My friend, Mr. Henry Smith, performed this experiment a short time ago; he took a dog and removed the upper part of the cranium, and lacerated the brain in every direction. There was no convulsive affection. At length he removed the entire substance of the brain, leaving nothing visible but the upper part of the medulla oblongata, and the membranes at the bottom of the brain. Now this is the important fact—he pinched the different membranes at the base of the brain, and to my astonishment there was every system of spasmodic action in the face, the neck, and the upper parts of the animal. The fact is that lesion of the membranes at the base of the brain produces spasmodic action. In fact, by inflammation of the arachnoid membrane you may have spasmodic action, and any lesion of the dura mater, like this membrane, will produce spasmodic action, and in this manner you account for those spasmodic affections not previously accounted for until this was known. This fact is important in a physiological point of view.

A near relative of mine had a favourite horse; he was fond of riding. On opening a gate, and leaning forward to do so, the animal did what many horses are apt to do; it tossed up its head violently, and this action gave my friend a blow upon the anterior part of the skull. He was never free from head-ache from that hour. He became affected with delusive ideas; he was frequently buying every plot of ground that he saw, and at length he became incapable of taking care of his own concerns, and died in a lunatic asylum. That case is one of atrophy. Atrophy of the brain is the result of disease. There is a depression upon the brain. The *modus operandi* of this is unlike inflammation. It is produced by effusion into the membranes; this effusion, where there was before a cavity, produces a depression upon the brain, which is indicated by the symptoms I have before detailed to you, in noticing the case of atrophy. The symptoms are pain and delusive ideas, and it becomes of the utmost importance to be aware of these. There was paralysis of speech, the patient lost the power of articulation. He lost the mobile power of the opposite side of the body, so that when he walked, he used one arm and one leg before the other. Now, emphatically, I say, the point which it is important to bring before your attention in regard to such cases is this, to distinguish between insanity and diseases of the brain producing delusive ideas. I need not tell you that this case was not a case of insanity, but was a case of partial arachnitis, an injury of the membranes of the brain. It was a disease of the brain producing delusive ideas. It is very important to distinguish between these cases, for in this case, however it might bear the appearance of insanity, it was but a disease of the substance of the brain, producing incoherent or delusive ideas. Another very important thing is, that you have in many persons delusions which are similar, and in one you may have a slight degree of inarticulateness in the speech, and a slight degree of paralysis. That is the case I have alluded to—the patient was not insane; there was disease of the brain producing insane ideas but not insanity. The prognosis in these cases is most important from the reasons I have mentioned to you. I have a case under my care just now of a very interesting character. The gentleman I am alluding to I have attended for three years. He is affected with paraplegia. The paraplegia has been very much removed, and he recovered from it sooner than is usual in such cases. From losses which he sustained he was violently affected in his mind, and became deranged; I must call it insanity. He was taken to an asylum; I was called in to that asylum, and I gave it as my opinion that that patient had paralysis with his insanity, and could never recover. He is now capable of conducting his own affairs. That very patient dined with me the other day. I had invited him with a friend of mine in order to see whether there was any malady remaining, but his conversation was as intelligent and as full of information as that of any person at the table. Was it deception? The deception was as to there being real insanity with the paraplegia, and that kind of paralysis that comes on is not a case of insanity. The prognosis here is invariably fatal as to the recovery of the disease and to the duration of life.

I cannot conclude this lecture without saying a few words more about arachnitis. I am not going over again what I said about the importance of blood-letting as a diagnostic, as I suppose the subject is sufficiently impressed upon your minds. Now with regard to the second stage of the disease. I must revert in the first place to what I said before—place the patient upright in the first place, so as to enable you to judge of the nature of the disease, and the strength of the patient. The next thing to be done as soon as possible is to put the patient under the influence of mercury, because this will probably have a tendency to the subjugation of the disease. Now I have only one statement to make in order to guide you. If the symptoms do not subside, you must repeat blood-letting. If the quantity taken is very slight, repeat the dose, but then it must be very small, for you may depend on it the case will not bear a repetition of the blood-letting. If the symptoms are not entirely removed, you may hope day after day to see a mitigation of them, but if the symptoms continue, and you have taken as much blood from the arm as you can, cupping may be adopted as being more valuable than leeches, and this may be applied daily, and you may watch its effect, and as soon as possible put the patient under the influence of mercury, the sooner you do so the better. Dr. Abernethy recommends in cases of this kind, croton oil as the best purgative. These,

then, are the remedies. Then there are some other points. In the first instance place the patient with his head and shoulders raised. The best mode is to place an inclined plane under the bed or mattrass, so as to raise the whole of the body. In such cases there is a little disposition to the patient slipping off the bed, and this is obviated by raising the pillow. The next important thing is very cold applications to the head. Another important thing is to keep the feet exceedingly warm, reversing the order of things, keeping the head as cool as possible, and the feet as warmas possible.

PRACTICAL OBSERVATIONS ON THE NATURE, PECULIARITIES, AND TREATMENT, OF SOME OF THE MOST PREVALENT DISEASES, &c. CONNECTED WITH THE POPULATION OF NORTH CHESHIRE, AND SOUTH LANCASHIRE, EMPLOYED IN COTTON FACTORIES.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Manchester.

(Concluded from page 261.)

It is impossible to view the adult operatives of factory districts, without being convinced of the fact of constitutional depreciation. Those who escape the fatality of the many diseases to which they are exposed in early life, live onward, only to prove more decidedly the inroad made into their constitutions; when, if differently employed, they might have been of the most healthy character. Many years ago, some of the best recruits in the service, were raised in Lancashire, and Cheshire; but now, a young man brought up in a factory, passing a physical examination as a recruit, is very rare indeed. It has been said, "they have too much good sense to enlist;" but the truth is, it is useless to enlist, and be rejected. I have myself rejected many, and in fact, I seldom saw a good recruit come out of the factories; miners on the contrary, and some other classes of workmen were stout athletic young men, who could bear fatigue, and were well calculated for the service. No one would wonder at this difference, when he examines the physical developments of the different artisans.—One, who has passed nearly all his time in a factory, looks at least ten years older than he is; and it is difficult to find one who may be said to enjoy robust health.—Much depends on the departments in which individuals are employed, for the development of various forms of disease.—For instance, asthma, in various forms, and obstinate constipation attack those employed in the card-room, the consequence of breathing an atmosphere constantly loaded with fine particles of the cotton dust, &c.; whilst spinners, from their extraordinary muscular exertions, are subject to hæmatemesis, hæmoptysis, phthisis, &c., as well as the more active inflammatory diseases,—pneumonia, peripneumonia, hepatitis, and enteritis. Their long continued standing position brings on varicose venous affections of the legs; ulcers of a very obstinate character, and hæmorrhoids; inguinal and scrotal hernias are also very common. From violent exertions long continued, excessive perspiration is exuded, which, if carried too far ends in debility, constipation, anorexia, atrophy, and phthisis. Sometimes, the perspiration is suddenly checked by frequent exposure to atmospheric changes, (very different to the high temperature in which they generally work); hence arise frequent attacks of fever, often degenerating into typhus, almost certain to become typhoid if bled, and very often fatal if depletion is resorted to. Where they escape attacks of general fever, rheumatism, acute and chronic, tic doloureux, and obstinate diarrhœas are very common, and constipation equally so, which is greatly increased by the daily use of inferior cheese, which adds no little to the list of dyspeptic patients, which is certainly very numerous. The operatives, generally speaking, are not cleanly, and their coarse inferior diet is made much worse, by bad management on the one hand, and improvidence on the other, which will in some manner account for the prevalence of eruptive diseases, chiefly the itch, and scorbutic affections. One seldom sees gout, apoplexy or insanity in this class.

Chapter VI.

The Declining Period of Life in Both Sexes.

If we pursue this subject to the declining period of life in both sexes, we shall only be the more confirmed in our views already stated. In females, the period of menstrual cessation is an extremely critical one, and not unfrequently accompanied with fatal results, and very many are rendered truly miserable by prolapsus uteri, ani, &c. I am not aware that cessation of menstruation occurs at an earlier period than ordinary amongst this class, but it is common for the females to marry very young, and they generally have children quickly, so that at forty or fifty they appear old women. When individuals are past their prime, and incapable of a certain amount of work, they seldom get employed; indeed, it is rare to see a person at fifty employed in a mill at all.

What must be considered the declining period of life in this class is little more than the prime of an agriculturist's life, the men appear bowed down with age, when not old, and their physical faculties almost annihilated, real old age is seldom attained; and should it be, it is attended with so many diseases, that life must be a burden to the individuals, if not to those on whom they depend for their scanty comforts—few have the courage and industry to save a little money in their youth, to enable them to purchase necessaries for the decline of life. This sad catalogue of miseries is not overrated. The whole lists of maladies are an every day occurrence in those districts, and convince a reflective and observing person, that *this is* the locality "where wealth accumulates, and men decay."

CURABILITY OF CONSUMPTION.

(Continued from page 281.)

(To the Editor of the 'Medical Times.')

Sir,—Before commencing the superstructure of treatment, permit me to remove a little more of the rubbish that lies in my way, in the shape of misconceptions or misrepresentations on certain leading points of this question, which have gained currency among many members of the profession, who are either too busy or too negligent to do more than give it a mere cursory attention. Having met with some of these errors, in an article lately manufactured in the intellectual laboratory of Sir George Lefevre, I shall notice, *in transitu*, a few of the remarks made by that physician, who has so long been a sojourner in a foreign land.

He states, *inter alia*, "The public have of late acquired some new and very consolatory ideas as to the nature of consumption. When attacked by the disease they no longer despair as formerly; they have hopes of permanent cure. If this fail they know that their lives may be prolonged to an indefinite period, for they are now aware that the flame may be kept alive by half a lung, or two lobes out of three, or three out of five, and then they may catch a severe cold which will cure them radically. (See Dr. Ramadge on consumption.") I confess my surprize that this gentleman should have so far mistaken Dr. Ramadge's statements as to misrepresent them in this egregious manner. He no where asserts that the vital flame may be supported by half a lung, &c., nor that after the almost entire loss of the lungs, from obliteration of the air-cells or otherwise, a severe cold will cure the patient radically. This loose, vague, and erroneous mode of commenting on the statements of an author, is, to say the least of it, unfavourable to the interests of science. Further on it is observed in the same paper, that "an inflammation supervening in the form of catarrh may, by its adhesive processes, form a barrier between the sound and the diseased parts of the lungs, preventing thus the contamination of the former, and we have to thank Laennec for the discovery." I shall feel obliged if he will indicate in what part of Laennec's work the doctrine is inculcated that catarrh is either partially or perfectly capable of arresting the progress of consumption, which I suspect is the intended meaning of the above obscure and unpathological sentence. On the contrary he carefully avoids enunciating so bold a theory, and distinctly deprecates in his chapter on catarrh the inference that he supposes it a preservative against tuberculous development. The discovery is due to Dr. Ramadge, and if there be any merit in it—

Palmam qui meruit, ferat.

However, whether it proceeds from Laennec or any other, is to him a matter of profound indifference. He regards with shrewd suspicion all attempts at cure when the disease is established, and would attract notice more exclusively to the preventive part of the treatment.

When the town was besieged, the sapient currier declared that his fellow-townsmen might do as they pleased, but in his opinion there was nothing like leather. This physician does not venture to dispute either Laennec's or Dr. Ramadge's theory. They may be right or wrong, but in his opinion there is nothing like *thermal comfort* as they enjoy it in Russia. His glowing description of the arrangements made in that frigid climate for the production of this most desirable effect will, I sincerely hope, have the good effect of melting down the objections many consumptive patients entertain against cold climates. Were they hybernated in Russia, if I might so speak, all the year round, instead of migrating to warm climates, the chances of recovery would be multiplied: not by the elevated temperature of the Russian apartments, but by the catarrh which either in a mild, dry, and latent, or in a manifest form, could scarcely fail to supervene on the daily transition from this warm atmosphere to that out of doors, and it is to the frequency of this catarrhal state I should, in a great measure, be inclined to refer the comparative infrequency of consumption in Russia and other countries in the far north. The history of his own health, given by this writer, renders the supposition highly probable that anteriorly to the catarrhal affection under which he has laboured for so many years, tuberculous deposit had taken place in his lungs, and phthisical symptoms more or less manifested themselves. It is also not unlikely that his bronchial disorder first attacked him in the winter season, and that but for this coincidence the Russian embassy would have never had the benefit of his services, nor the public his advice to imitate the Russians in their thermal defence against hyperborean blasts. He concludes by confessing that there are a few drawbacks on the advantages of heated apartments, such as languor, lassitude, uneasy sensations of the head, impaired appetite, and other disagreeables, all which are in his estimation merely secondary, and, with a *naiveté* for which I was quite unprepared in a courtier, candidly acknowledges that he has a great deal of prejudice to encounter in propagating his views among the English, who are "a cleanly people," pertinaciously adherent to the old-fashioned practice of admitting fresh air into their rooms, and so sensitive in their olfactory organs as to abhor the effluvia of rancid bear's grease, and all other offensive, sickly, musty, varieties of atmospheric contact.

Jeffrey's respirator, and similar contrivances or expedients, should not be resorted to by consumptive persons. The infirmary for diseases of the lungs was originally instituted chiefly for the purpose of providing wards artificially heated for phthisical patients. Dr. Ramadge informed me that he has never found them of any utility in such cases, but often the contrary. The excitement in the first instance may give a fillip to the constitution and lead to some indications of amendment, but these are always fugacious, and the symptoms soon resume the previous or a worse character. When he admits such patients, which is very rarely, the object is either unconnected with the temperature of the wards, or to prove to some of the medical gentlemen attending the infirmary that his views on this point are borne out by facts. If this be true, what shall we say of nascent institutions putting forth prospectuses, and collecting large subscriptions for extending similar accommodation to patients at their own homes, or in apartments hired for the purpose at different parts of the metropolis. The intention is benevolent, but the money so expended will defeat its own object. The ignorance of the profession, and not that of

the public, is to be charged with the misappropriation of these funds.

Another instance of the loose unsatisfactory way in which the views of Dr. Ramadge have been handled, is furnished by a foreign physician, Dr. Ulric Palmedo, of Berlin, in his treatise on the cure of consumption. He seems, however, to have read and considered those views more carefully than the first-named physician. His words are, "The examinations and observations of cases of cures in this terrible disease, which an English author, (Dr. Ramadge,) had related as having fallen under his inspection, in living persons as well as in bodies after death, were striking, and his explanation of the process resorted to by nature to heal pulmonary tubercles, was so evidently in harmony with her laws, that it left a powerful impression on my mind." He then proceeds to state, that he had made trial of the mode of cure recommended by Dr. Ramadge, which he says failed in his hands; at the same time candidly expressing his fears that the cases may have been of such a nature that either the disease had already caused too powerful a destruction of the lungs, or from some other reasons they were improper for the treatment, or the method recommended had not been applied and followed up with the necessary perseverance and punctuality. I shall take an opportunity of referring to these remarks in a future number, and explaining the causes of Dr. Palmedo's want of success.

To remove every erroneous impression as to my views on catarrhal antagonism, I beg to repeat that when very severe, catarrh hastens the maturation and liquefaction of tubercles previously formed, and sometimes when these are numerous and the softenings simultaneous, the fatal *denouement* is precipitated. It is not recommended that patients should expose themselves to currents of air, or sleep in damp rooms, or beds, &c. I would protect them against bronchial affections with all due care, but at the same time avail myself of their presence when moderate, and give them credit for what good they really do effect. But I would say both of this and the other morbid agencies employed by nature,

> "*Non tali auxilio, nec defensoribus istis,*
> *Tempus eget.*"

We have other means at command, more simple, safe, and efficacious. I shall discuss the TREATMENT under two heads:—

1st.—The Mechanical or Surgical and Primary.

2nd.—The Medicinal or Constitutional and Subsidiary.

One great and leading fact obtruded on our attention by the symptomatology and pathology of phthisis is, that nature very frequently attempts and succeeds in effecting a partial and temporary, or perfect and permanent cure by *some* means. The analysis given in the former articles brings us to the discovery of the agencies employed, and a little further consideration conducts us inevitably to the conclusion, that they all act in one way, viz., *by expansion of the lungs.* But we find that in producing this, nature sometimes oversteps the boundaries of prudence, and that she does evil in her efforts at doing good. She frequently makes the expirations too prolonged; fails in restoring the nice natural balance between inspiration and expiration. The evil is either equivalent to the good done, or it is less; greater it would be hard to suppose. The business of art, therefore, is to diminish or prevent the evil effects of her operations by judicious control or assistance, and, if possible, accomplish her aims by an agency similar to her own, and not liable to its objections.

The expansion of the lungs may be effected to a certain extent by exercise, and there are certain species of exercise which expand them more than others. This prophylactic operates both generally and locally; it invigorates the body and mind, thus obviating debility, which is the great cause of tuberculous deposition, and by stimulating the lungs to deeper and more frequent inspirations, increases their volume and gives enlargement to the chest.

Sea-voyages, land journeys, riding, running, swinging, &c., and whatever sports or employments exercise the pulmonary tissue prove beneficial. In trotting, which is the best species of horse exercise, the ascent and descent of the trunk on the saddle is followed by a greater diaphragmatic descent, which gives the lungs more space for expansion, particularly the lower lobes, on whose integrity so much depends.

The increased exercise of the lungs themselves is advantageous on the same principle as in other tissues. The muscles of voluntary motion from their frequent action are very rarely indeed the seats of tubercles. The lungs, as by a general rule, may be stated to be first affected in the parts where least motion is allowed, viz., the upper lobes. The lower, from their proximity to the yielding and descending diaphragm, and the greater arches of the ribs, are less interfered with in their motions, and therefore the less liable to become diseased, unless where there exists some adhesion to restrict their expansibility. In sea voyages or new localities, the action of the lungs is deeper and fuller from the stimulus of the unaccustomed atmosphere. The increased pulmonary action, and consequent improved sanguification, may be regarded as the causes of the amelioration we observe effected by changes of locality in convalescence. The consideration however of this by no means unimportant section of the subject, belongs more properly to the second head of treatment—the subsidiary. As the employment of general exercise is sometimes forbidden by circumstances, or is not practicable to any great extent, nor are its effects sufficiently constant or dynamic when the disease has declared itself; we must then come to more decided and certain measures. We must be provided with the means of exercising the pulmonary tissue, and expanding the air-cells surely, steadily, and directly. Now in order to accomplish this, let us endeavour, after the manner of nature, *to prolong the expiration.* This can be done by a very simple contrivance. Let a tube be constructed, so that when breathed through, backwards and forwards, the air will be inspired more easily than it can be expired. The impediment offered to the expiration need not be considerable, and can be graduated. A common quill, larger at one end than the other, will answer the purpose tolerably well. But it is better to employ a tube, nicely constructed on the principle laid down. For a particular description of the different sorts of tubes now or hitherto used for this purpose, I must refer to a subsequent article, to which I shall add an engraving descriptive of each, and directions for use.

The effects of prolonged expiration are the same, whether produced by natural or mechanical impediments. I shall briefly recapitulate them, viz., imprisonment of the air in the lungs; distension of all the permeable air-cells; increase of the pulmonary volume; enlargement of the cavity of the thorax, from the pushing out of its walls in every direction by the expanded lungs; approximation of the surfaces of cavities, from pressure on all sides by the pulmonary tissue external to them; union of these surfaces, if early, by a soft membrane, if late by a semi-cartilaginous intervention, &c.; arrest of the tendency to fresh tuberculous deposition from exercise and full expansion of the pulmonary tissue, and a state of dormancy or quiescence more or less complete of the tubercles already formed and uneliminated, they being surrounded by black secretion, isolating and often rendering them innocuous. Such are the effects of prolonged expiration in favourable cases. The great comparative advantage of the tube over nature lies in the following circumstances. It is capable of being so made that we have neither more nor less prolongation of expiration than is exactly necessary; it can be taken up and laid aside at pleasure, so that the lungs when fatigued with this abnormal exercise may have repose; it can be persevered in for any desired length of time, and abandoned when no longer necessary; or, when contra-indicated by the supervention of some accidental malady or symptoms; and finally, from its proper use no evil consequences will be found to result. It is in short, an instrument completely at our command, simple in its mode of operation, certain and safe in its effects. It may be properly called a surgical or mechanical means of treating phthisis. No medicated vapours are required. The simple atmospheric air is the great medicinal agency, and elasticity its essential ingredient. We have no occasion for the fumes of tar or iodine, of chlorine, hemlock, or turpentine. With the value of these medicated vapours I have nothing to do. The principle of the treatment I advocate is essentially different, as has already been seen.

Simple as this instrument is, its power is greater than can be appreciated by those who have not used it. Let it not be despised on account of its apparent simplicity being so incommensurate with its pretensions.

When Naaman, the favourite minister of the Syrian monarch, applied to the wonder-working prophet of Israel for the cure of his leprosy, he was ordered to bathe in the waters of Jordan, but indignantly exclaimed, "Are not Abana and Pharpar, rivers of Damascus, better than Jordan's contemptible stream?" His servants judiciously reminded him that it was but a little thing the prophet had commanded. He bathed in the prescribed waters, and his leprosy was removed.

Thus would I counsel those who at first may treat this simple instrumentality with the haughty disdain that sits so lordly on the brow of more complicated science, and imposing agencies. Is it not a little thing? The difficulty in making the experiment is little; try it, and though I have no pretensions to the gift of prophecy, or the working of miracles, I promise you success, exceeding, if such may be, the sanguine expectations I have endeavoured to create.

There are, however, certain rules which should regulate its use, and stages, symptoms and complications of consumption in which it is either inefficient, inadmissible, or for intervals longer or shorter to be suspended. These are essentially necessary to be well understood, and shall be explained in a future communication.

DISCIPULUS.

(To be Continued.)

HOMŒOPATHY.

THIS elaborately learned species of empiricism has been recently much the subject of general attention, in consequence of the death of the Countess of Denbigh shortly after her confinement, and while under the attendance of a homœopathic physician. From a correspondent (M.D.) who does not give his name, a contemporary furnishes the following statement of circumstances :—

"Though in her confinement, eighteen months ago, she nearly lost her life by homœopathic treatment, her belief in it, strange to say, continued unshaken ; and on again becoming pregnant, recourse was had, as before, to the disciples of the infinitesimal system. This lady was of a very plethoric habit, and, according to the accepted practice in similar cases, should have been carefully watched by her medical attendant during the whole period of gestation, and such means adopted as were likely to prevent any undue determination to the head during or preceding labour. Thus might have been prevented the probability of apoplexy or convulsions. But such treatment is against the principles of Hahnemann and his disciples; and therefore could not have been followed by the homœopathic attendants of this unhappy lady. As the period of her expected confinement drew near, she was seized with convulsions ; and, as a matter of course, their fractional grains and their globules had no sort of power to check them. Some time was lost in these fruitless attempts—and we all know the great value of even an hour in such cases. By accident, a medical man of some eminence was in the house, and was requested to see the case ; he pronounced the lady to be suffering under puerperal convulsions, requiring from those in attendance the most active and energetic measures, and the assistance also of a skilful accoucheur, to forward the delivery of the patient,

which seemed to him urgent and necessary. No, the homœopathic doctors spoke confidently, and the poor husband was not shaken in his faith of their skill and power. The infinitesimal remedies were alone used: the convulsions, as a matter of certainty, ran their course unchecked; and apoplectic coma followed!"

The correspondent proceeds to say, that in this state of unconsciousness the patient gave birth to a child and sank; and, he adds:—

"I am sure you will say, with me, that any tyro, who had attended one course only of midwifery lectures, would have known every symptom in this case, and been able to determine on the necessary, and (in all probability) successful treatment. A story was circulated immediately after the event, that a fright occasioned the convulsions: this caused a fear of the coroner. The rumour was then changed, and a post-mortem examination was made. *Report*—Softening of the brain; a large tumour; and more water than usual in the ventricles.

"Your readers may wish to know who examined the head? Dr. Hahnemann's disciples!"

A reply has been sent to the above statement by one who similarly conceals his name, and who declares the account to be a mere fabrication. Mr. Barnes, the accoucheur, and Mr. Fincham are named as attending the autopsy, neither of whom, it is affirmed, is an homœopathist (tant mieux pour eux). The first attended the whole accouchement. It is then bluntly denied, that at her former confinement her ladyship was attended by an homœopathist—that she was "of a plethoric habit"—that watching a plethoric habit during gestation is against the principle of Hahnemann—that the medicines did not check the convulsions—that the homœopathists spoke at all confidently of recovery—and that any coma at all supervened. It is, moreover, asserted, that "the medical man of some eminence" by chance present, was Mr. Barnes. The cause of death is stated to be beyond art; and the following are given as the appearances observed on the post-mortem examination:—

"Very little blood in the head. Dura mater rather congested, but without inflammation, and more adherent to the bone than usual. Great thickness and opacity at the back part of the longitudinal sinus, at its junction with the lateral sinuses. A small tumour, half an inch in diameter, and about a quarter of an inch thick.

"Base of the brain congested, particularly about the medulla oblongata, with a small quantity of fluid; the whole of the cerebellum softer than natural, with here and there a portion soft like paste. This state of the brain was the result of disease of considerable standing, and could not be remedied by any particular treatment.

"(Signed) G. Fincham.
Harris Dunsford, M.D.
A. B. Barnes.

"December 16, 1842."

Now, the conclusion we draw from these premises are—first, that "the medical man of some eminence," Mr Barnes, has been in very bad company, and should explain to his brethren on what principles he acted in forming so suspicious an association; and secondly, that M. D. has disgraced his cloth by an accusation against empirics, made in utter ignorance of the circumstances, and which, by its falsehood, throws discredit on his brethren; or else, that the homœopathic physician replying to him, is a pretty bold specimen of the class of liars. If better data be furnished us for less *conditional* conclusions, our readers shall have the benefit of them.

TREATMENT OF SPRAINS BY STARCHED BANDAGES.

(From a Correspondent.)

Sprains, as is well known, are generally produced by great force applied to a joint, or by a smaller degree of force awkwardly applied when the muscles of the limb are unprepared for it; the result of which is, that the ligaments, tendons, and their sheaths, which surround the joint, are violently stretched, and in some cases torn. After a short time, sometimes almost immediately, great tumefaction and stiffness of the affected joint takes place, from effusion of blood and serous fluid. Such cases are of very common occurrence, and are familiar to every practitioner. They are universally classed among the most tedious and troublesome cases which fall under the care of the surgeon. The treatment adopted by different practitioners is extremely various; some apply leeches, others cold evaporating lotions, others warm fomentations, whilst some trust to stimulating frictions: and, perhaps, it is a general fault among medical men to resort too much to *one* method of cure, to the exclusion of other means. The treatment of such cases, which we have been in the habit of following for some time past, has certainly been attended with more decided success than any one which had formerly come under our notice. Not only is the patient saved much suffering, but is enabled sooner to attend to his duties, and to take that exercise in the open air, which is so congenial to health and convalescence. By means of the following treatment, our patients may (even after having suffered a very severe sprain) be enabled to go about their usual avocations in six or eight days. Upon being called to a case where a sprain has occurred, the extremity must be elevated and kept at rest. Cold evaporating lotions, or warm fomentations, are to be applied according as the one or the other is more agreeable to the patient's feelings, and also according as we see the case immediately after the injury, or some time after its occurrence; in the latter case, warm fomentations are always most beneficial, and most relished by the patient. It may be necessary, also, to use local blood-letting, when symptoms of inflammatory action make their appearance: this, however, we believe, will seldom if ever be required, if the accident is seen at an early period. After the swelling around the joint and in the course of the tendons has nearly subsided, under the use of such, or similar applications, the starched bandages, first recommended by M. Larrey, and afterwards by Dr. Lentin, of Brussels, in fractures of the extremities, are to be applied. In the employment of these bandages, it is of the greatest consequence not to apply them so long as the limb continues very painful or much swollen; at the same time, it does not do to wait until the pain has altogether subsided, or the swelling entirely fallen, for this is seldom accomplished until a considerable time has elapsed, and until a bandage is applied. In applying the bandage, we always follow the plan of Dr. Lentin, of Brussels. Two or three pieces of broad stout cloth, well covered with starch, are to be folded and applied on each side of the limb, across the affected joint. One or two rollers, also well starched, are then applied over these, not very tight, but still of sufficient tightness to give gentle compression to the whole of that portion of the limb. These dry readily in twenty-four or thirty-six hours, on exposure to the air. It has been recommended to facilitate the drying of the starch, by passing a heated smoothing-iron over the bandages, but we have found that this has a tendency to render the limb more painful, and to increase the inflammatory action of the parts. The size and length of the bandages are always to be proportioned to the joint over which they are applied. Sprains most commonly occur in the wrist and ankle-joints, and then it is advisable to use bandages which will reach respectively from the middle of the fore-arm to the palm of the hand, and from the middle of the leg to the digito-tarsal articulation. The advantages resulting from this plan of treatment are obvious; it exerts a comfortable and most beneficial degree of pressure upon the injured parts, while the moisture of the starched bandages acts as a temporary fomentation, and when dry, the stiffness which they acquire, and the continued and regular pressure which they exert upon every point to which they are applied, completely prevent every kind of motion of the injured joint, even although the patient may be using the rest of his body very actively. It may be well to mention, however, that it is sometimes necessary to apply a couple of strong pasteboard splints on each side of the injured joint until the bandages dry. Out of 100 patients lately treated on this principle, 92 got well in six days—at least, when we say well, we should have said able to go about without any assistance; 6 in 12 days, and the remaining 2 in 30 days—the two last being very severe cases, and being much *bruised* besides sprained.

SPINA BIFIDA.

To the Editor of the 'Medical Times.'

Sir,—If the correspondent of the *Medical Times* who made inquiries respecting cases of *spina bifida*, under the signature of R. A., had looked, as indeed he ought to have done, into the various medical journals of this country before he asked his question, or supposed his case of that disease to be either curious or singular, he would have found more than one case of it recorded in those repositories of medical facts which, it is to be regretted, are so little consulted by the young practitioners of the present day, who frequently bring forward as new, observations and operations that have been made or performed over and over again before.

On the present occasion, R. A. will be satisfied, perhaps, with a reference to a really extraordinary case of *spina bifida*, related, as then living, by E. Jukes, Esq., surgeon, in the 47th vol. of the "London Medical and Physical Journal," page 106, accompanied by a drawing of the patient, (an adult young woman) with the tumour *in situ*, a cast of which is in the museum of St. Thomas' Hospital.

The admeasurements of that tumour being made the basis of calculation during the life of the patient, by the Editor of the Journal, Dr. Granville, it was found that its fluid contents amounted to one gallon, three pints, and two ounces.

The editor has likewise added a note in which he alludes to five other cases of the disease occurring in his practice, one of which had been carefully dissected by him in the presence of Dr. M'Leod and Mr. Hutchison of the Westminster General Dispensary, where the preparation was deposited. In a second note, the same editor refers to an interesting memoir on *spina bifida*, with some very remarkable cases by a Russian physician, contained in a volume of Memoirs of the Imperial Academy of Sciences of St. Petersburg, published in 1821.

Mr. Jukes' patient died a few years after the date of that gentleman's paper, when a preparation of the disease, with a portion of the pelvic bones, was made by Dr. Granville, which is now in the possession of Mr. North, surgeon, lecturer on midwifery.

It would puzzle, by the by, both Dr. Mar-

shall Hall, and his competitor, Dr. Carpenter, to account for the integrity of the phenomena, organic as well as functional, in Mr. Jukes' patient, notwithstanding so serious a deficiency of that nervous development which regulates the growth and functions of the abdominal extremities in man.

MEDICUS.

London, 2[illegible] January, 184[illegible]

TO CORRESPONDENTS.

We are able to express a confident hope of giving our readers a complete account, from the very best quarter, of the late Mr. Drummond's case in its medical and surgical aspects. We expect to do this immediately after the trial of the assassin; before that it would be perhaps not perfectly decorous.

Philos *is sincerely thanked. He is prayed to remember first, that a* class *work differs from one made for* general *circulation (as is well shewn by the high prices usually charged for a* merely *scientific journal or book) secondly, that "new brooms sweep clean." The same artist made the praised and condemned woodcuts, though certainly not with equal skill.*

S. R.—*The Berlin University is now in high repute from the distinction both of its surgical and medical professors. For pharmacy, Giessen is now usually preferred, from being the scene of Liebig's labours.*

A Friend.—*Gentlemen with degrees from Foreign Universities are not, therefore, exempted from serving on juries. Fellows or licentiates of the College of Physicians, Surgeons of one of the three national colleges and apothecaries have that privilege in England. Our Correspondent will find his other questions answered in previous numbers.*

M. R. C. S.—*The society of Apothecaries give medical journals no facilities for publishing the names of the new members. The circumstance is expressive of the general wisdom and liberality of their management.*

Medico-Chirurgus *has been, as he will see, anticipated in his suggestion.*

Bright's Farina.—*This article has been submitted for our judgment, and it gives us pleasure to speak of it as an elegant and delicate species of food, free, we think, from any tendency to produce acidity, and as far as our own experience goes, easy of digestion. This notice will make the invalids who profit by it our debtors; we wish, indeed, our editorial judgment were always invoked on subjects offering so pleasing a treat in the ordeal.*

M. D. sends us an authenticated *case of poisoning by Morison's pills. The patient (a lady) took by orders 6 pills at night, and 7 in the morning. "The consequence was hypercatharsis, with irritability of the stomach, and great debility of the constitution. diarrhœa followed, with great exhaustion of strength, and by means of stimulants and astringents she was kept alive until the evil effects of these pills was carried off." Our correspondent very properly expresses a hope that such cases should lead persons in authority to pay attention to the practical evil of quackery.*

B. N. *The possession of a diploma from any College is no conclusive proof that the possessor's scientific skill is sufficient. In any action, therefore, on incompetency that circumstance can only be made matter of presumption for the defendant in the hands of the jury.*

The Doomed Journal.—*A contemporary states on good authority that a respectable bookselling firm in Dublin, the name of which it mentions, was accustomed to sell four or five hundred Lancets weekly, and now sells but seven or eight altogether. A feather shews which way the wind blows.*

A Subscriber *to a fund for presenting that distinguished surgeon, the late Sir Charles Bell, with a tribute of respect from the medical profession, on the occasion of his leaving London for the metropolis of Scotland, desires to learn "the amount that was collected, and in what manner it was disposed of. Also if there be a portrait of him—by whom executed?—and its price?*

M. N.—A Chemist—R. W. S. Cottonus—Mr. S. P., Edinburgh—Musa—*declined with thanks.—Our other Correspondents next week.*

ERRATA.—In our last number in the second column, page 275, *dele "falsa,"* for "*ritue*" read *rigil*, and in page 280, at the end of article on consumption, for "*economy*" read *enemy*.

THE MEDICAL TIMES.

SATURDAY, FEBRUARY 4, 1843.

Salus populi suprema lex.

It is something to alleviate sickness—it is better to remedy it: it is best to prevent it. The two less social advantages are not of unfrequent occurrence. The scientific labours, the self-devotion, of our medical brethren, have done nearly all that human powers can avail to do, in detecting and combating death in every case where he is expugnable. The third duty—the duty, not theirs—but the duty of highest importance, viz., to *prevent disease*, has not yet been performed; and it becomes the necessitated office of our profession—still continuing its unfamed but noble mission of utility—to make known again and again to our rulers, the evils originating in the present system of public neglect of health, and to point out the best means by which this greatest of social boons—prevention of maladies—may be secured.

However neglectful public authorities have been in purveying for their subjects' protection from disease, we may still congratulate ourselves, as upon one of the results of advancing civilization, that they no longer pretend to excuse their inattention, in any silly faith that the spread of diseases is to be looked upon as solely the result of a supernatural power immediately interfering with the operation of its ordinary physical laws. The public writer, in these days, has only to prove that certain given causes, producing disease as their necessary effect, are allowed (to gratify some private cupidity or indolence) an unchecked range of action, when they might be removed by a due interposition of law, and the ruler resisting a change stands self-convicted, either of gross incompetency for his duties, or of a very wicked apathy in their discharge.

Now, while we admit that *much* has been recently done, favourable in certain directions to public health (and we derive from the fact of the increased value of human life that has thence arisen, a strong argument for making that *much* more), it cannot be too prominently shewn forth, that there are numerous widely spread agents in daily operation against the sanatory condition especially of the humbler residents of our towns, which, while only to be checked or removed by the governing power of the State, find in that governing power sometimes active support, frequently countenance, always impunity. We advance this statement in the boldest and most comprehensive words we can use; for, however startling it may be to those who, while aware of the injury to human life it infers, do not reflect that with our cumbrous, piece-meal system of sanatory law-making—and our inefficient system of sanatory law administration—no one of our thousand injuries to public health has, in ordinary circumstances, a chance of remedy in a *merely* POLITICAL senate, until the injury has grown to the height of an universal and unbearable nuisance, we have only to refer to the present horrible state of British sepulture—to our deficiency of town drainage—to the filthy condition of our supplies of water—to the squalid, dirty, and over-tenanted state of dense metropolitan neighbourhoods—to the absence of open spaces, in towns, for popular exercise and recreation—to the unnoticed condition of our slaughter houses and meat markets—to the adulterations which, encouraged by certain profit and impunity, take place in every article of food, and even of medicine—and to the thousand nuisances erected for any knave's or lunatic's convenience or pleasure, which no public officer ever feels it necessary to abate: we have, we say, only to give a moment's thought to all this, to see that the accusation which lies at the door of our laws, might have been couched in terms still stronger than any we have used, and yet be far from outstripping the truth.

A work, doing great justice to our views on this subject, and which does high credit at once to the feelings and abilities of the author, Mr. Curtis, has been recently placed in our hands. As the writer—a member of our own fraternity, we are pleased to remark—was among the first who publicly called especial attention to this great department of social improvement—the first edition of his work appearing four years since—we may, in whatever observations we wish to give, fairly give him priority to his able successor, Mr. Chadwick, the author of the "Report on the Sanatory Condition," &c.. Indeed, in following out our desire to call public attention to the question of Hygiene, we know of no better plan than to follow Mr. Curtis, step by step, through his principal positions.

The first subject touched upon, is the mode in which London is supplied with water: in reference to this, Mr. Curtis observes:—

The Thames is the principal source of the supply; and its water, if drawn from a proper spot, would be as good as could be desired; but, strangely enough, the companies which monopolise the sale of this important element, take it from a part of the river which receives all the impurities of the mighty city, and where it is asserted that fish cannot exist. This is the first evil to be removed. The wants of the metropolis could not be supplied without resorting to the Thames; but there is no necessity for using its corrupted waters. Why should not we go a few miles above London, and draw the needful supplies from the river before it reaches the city?

A project recently set on foot would, if executed, do much to obviate the inconveniences of the present system: I allude to the plan for forming a vast receptacle for the contents of common sewers, &c. &c. along the whole banks of the river; this would doubtless improve the

quality of the water: the other part of the project, viz. the construction of open walks and terraces by the river side, would also be a great change for the better, improving the appearance and increasing the healthiness of the city

But supposing the water to be derived from an entirely unexceptionable source, much would still remain to be done. The mode of its distribution to, and of its reception in, dwelling-houses, has an important effect upon its quality. It is at present conveyed by leaden pipes either into leaden cisterns or wooden casks. Water contains carbonic acid gas; this acting upon lead forms carbonate of lead, a white pow. er, which being conveyed in small quantities with the water to the stomach, acts as a slow poison, affecting first the digestive organs, producing dyspepsia, and finally terminating in ne vous apoplexy, or paralysis.

Also—

It is an established fact, that the best material for forming vessels to contain water is iron. Iron tanks have for several years been used in ships, with the greatest advantage: and there is no reason why iron cisterns should not be substituted on land for lead cisterns and wooden casks.

Of whatever material the receptacles for water may be formed, they should be often emptied and carefully cleansed. The purest water must frequently contain clay and other earths; these are deposited, and in time, if suffered to remain, become animalised; hence, be the water supplied ever so pure, it must speedily be contaminated. For the same reason, it would be better that a fresh supply should be furnished every day, even though each supply were smaller than at present. rather than (as is generally the case now) only twice or thrice a-week.

It ought to be added that filtering does not purify water, as it can only remove the impurities which are mechanically suspended in it, and not such as are in a state of solution. When water comes fresh into cisterns only two or three times a-week, as is the case with the New River water, filtering cannot much improve it, nor be successful in depriving it of its deleterious properties; we might as well attempt to remove the poison from a solution of arsenic by filtering. To prevent any injurious effects from its use internally, there must be a *chemical* process.

There is another mode by which an abundant supply of the purest water could be obtained, at least for drinking in any form, as for making tea, coffee, &c. which at the same time would greatly add to the beauty of the metropolis. I mean, the erection of ornamental fountains, which, giving out constant streams of spring-water, would impart an appearance of coolness which is very refreshing in the sultry summer months, and would materially assist in keeping clear the sewers, into which the superfluous water would fall. Every person who has visited the Continent must have admired the pleasing effect produced by the fountains with which most cities there abound; and it is truly surprising that so obvious a source of beauty and ornament has been so long neglected in this country. Let us hope that in this respect we shall soon imitate our neighbours; who, on this point at least, have certainly set us an example well worthy of imitation.

The erection of pumps is strongly advocated, and the state of the Continent in this respect is compared with that of England. Mr. Curtis states that in Berlin alone there are upwards of 2,000 public pumps. The sewerage is the next point adverted to, and the production of fever for want of sufficient drainage is pointed out: for instance, "in the fourth and fifth reports of the Poor Law Commissioners, it was stated that out of 77,181 cases of claims to relief during the year ended March 1838, 13,972 arose from fever in various forms, prevalent in certain localities distinguished by want of drainage and other causes." Such being the fact, the author might well say "few persons would have imagined that there was no sewer either in Cheapside, or Aldersgate Street; and yet such, till lately was the fact, sewers were recently, for the first time, constructed in both these leading thoroughfares. In the Old Kent Road, in Bethnal Green, and in some parts of Westminster, these indispensable requisites of a healthy residence are almost entirely wanting. The importance of drainage and sewerage is strikingly shown in the Report of Dr. Southwood Smith, respecting the causes of febrile affections, (which have for a considerable period been prevalent in Bethnal Green, and Whitechapel,) appended to a Report of the Poor Law Commissioners.

Provincial towns appear to be far worse off in this respect than London. Thus, in Mr. Chadwick's Report, a communication from Mr. Baker informs us, that in Leeds, out of 586 streets, only sixty-eight are paved by the local authorities, and of these twenty-nine are either not sewered at all, or only partially so. Dr. Duncan, of Liverpool, states that he is doubtful whether there is a single court in that town which communicates with the street by an underground drain. Manchester is quite as bad, and no where do the regulations, respecting sewerage, appear to be such as not to require amendment. At this season of the year. there is a periodical outcry respecting the cleansing of the streets, but no improvement has yet been made, yet it would seem a comparatively simple affair. Mr. Curtis says, "the inefficiency of the arrangements for cleansing the streets of the metropolis, has lately attracted considerable attention, and there can be no doubt that this is a crying evil, the removal of which would greatly contribute to the salubrity and comfort of London, and would be the more easily accomplished through the abundance of water. Not only the more crowded streets, but also the back courts and narrow alleys, wherein the poorer classes reside, should be cleansed, at least, once every day. The present condition of the public streets is decidedly injurious to the health and comfort of all classes. In no department of civic police is improvement more imperatively required. A self-loading cart, or street-sweeping machine, has been lately invented by Mr. Whitworth, of Manchester, which it is to be hoped will be speedily introduced into all populous towns. According to the description of it, given to me by its inventor, it is drawn by a single horse, and carries a series of brooms hung behind, which receive motion from the cart wheels, and successively sweep the surface of the ground, carrying the soil up an inclined plane into the body of the cart. The operation of sweeping, loading, and carting away, are thus performed simultaneously; and one horse, besides drawing the cart, does the work of twenty men."

The atmosphere of large towns is exposed to many causes of vitiation, from which that of the country is free, and our author gives many curious extracts from a rare work of the famous John Evelyn, (temp. Charles the Second), showing that this evil had attracted attention nearly 200 years ago; Evelyn proposed as a remedy for it a legislative measure for compelling the removal of all manufacturing establishments to some distance from towns. However practicable this may have been in those times, it is now, Mr. Curtis observes, impossible. "The advance of science, however, has put other and more simple means within our power for removing or abating the nuisance in question; all that is necessary, is an act compelling all factories, breweries, gas-works, *et hoc genus omne*, to consume the smoke which they generate, and not to pollute the vital element with their refuse. This measure I conceive to be of the utmost importance, and essential to the success of any other plans for improving the public health. Parks, and other places of public resort and amusement, derive the chief part of their utility from furnishing opportunities and inducements for exercise in the open air; but, if that air be tainted and rendered unwholesome, this becomes an evil rather than a good. The means to which I allude as enabling us to get rid of the nuisance in question, is the patent smokeless or argand furnace of Charles Wye Williams, Esq., which is an invention of considerable importance. Mr. Williams is the author of an elaborate treatise on the "Combustion of Coal and Prevention of Smoke, chemically and practically considered;" in which he gives an excellent exposition of the chemical theory of combustion, and ascertains the mechanical arrangements that are best calculated to burn with the greatest effect on the grate-bars, the carbonaceous fuel and its gaseous products. To the improper and imperfect combustion of the latter, are to be attributed those thick, fuliginous particles which, in the form of smoke, contaminate our atmosphere. Mr. Williams's agents, Messrs. Dincks & Co., of Manchester, have built a specimen furnace in that town for public inspection, and they have informed me that it has been visited by several of the nobility, as well as by the most intelligent engineers and manufacturers in that district. The novelty of this invention is, that the coals are burnt on the large scale of common engine-boiler furnaces without producing smoke; so that, as has been stated, there is literally no smoke to burn; and, indeed, Mr. Williams in his work, ably and most scientifically combats the opinion that "smoke" can be burnt, that is, with heat-giving effect; and, on this, he grounds

the want of success that has attended "smoke-burning" inventions generally for the last twenty-five years." Mr. Williams's may be called a system of prevention, and depends on a chemical knowledge of the due quantity of air requisite for combustion, and the best mode of regulating its admission. This plan is in use in many large establishments and public works, especially in Manchester and Liverpool, and has met with the approbation of several of the most distinguished chemists, and civil engineers,—among others, of Professor Brande, Dr. Ure, Dr. Kane, Dr. Brett, Mr. Parkes, &c.

There are several practical suggestions for affording greater facilities and inducements to the inhabitants of the metropolis for taking exercise in the open air, well deserving of the attention of the authorities, for instance.

Great satisfaction has been given to the lovers of out-door exercise by the occasional playing in Kensington Gardens of the band of the Horse-guards, stationed at Knightsbridge barracks; and it is to be regretted that this amusement is so scantily furnished to the inhabitants of the metropolis. In most country towns the regimental bands play frequently; and surely London ought not to be worse off in this respect than the country. It would add much to the charms of the Regent's Park, and induce many more persons to take exercise in it than at present, were the band of the regiment stationed at the Park Barraks, directed to play in it at stated times during fine weather. The band of the regiment stationed at the Wellington barracks might, in like manner, be directed to play in the enclosure of St. James's Park. If each of these three excellent bands were to play twice a-week, from three till five in the afternoon, a most agreeable recreation would be furnished to the inhabitants of the metropolis.

The Parks are not so useful to the public as they might be, partly because there is no means of getting refreshment in them, except milk, and cards and whey, which may be obtained at all the lodges. Were a casino allowed to be established in each of the Parks, where visitors could be furnished with breakfast or tea in the open air, in fine weather, the novelty of the thing would attract many, and thus induce some to leave their beds an hour or two before the usual time, and inhale the fresh morning air before it is impregnated with smoke. This measure would not cost the government one farthing, as a large rent might easily be obtained for the casinos, the greatest portion of which might be devoted to the improvement of the Parks. As a proof of this, I may mention that the rent received for the refreshment room in the Zoological Gardens defrays more than one-half of the annual rent paid to government for the whole of the grounds occupied by the society.

Although much has been done, there is still room for improvement. On the Continent greater attention is paid to procuring places of exercise and amusement for the inhabitants of towns than in this country. There are, however, indications that give us reason for hoping that our inferiority in this respect will not be suffered long to continue.

It would be very gratifying to the public were the gardens of Buckingham Palace thrown open at those times when the Queen is not residing there. Both at Paris and Vienna, the author observed that the grounds attached to the royal residences were at all times freely open to the people: and he feels assured that our amiable Queen would not, were the matter properly represented to her, refuse to grant this boon to the community, especially after the noble example given by William the Fourth, in admitting the people to his beautiful private garden at Windsor, which is directly under the windows of the Castle.

Again:—

The gardens of the numerous squares in the metropolis are not nearly so useful as they might be, owing to the exclusive spirit in which they are managed. Why should they not be opened at stated times to the public generally, in the same way as the Temple and Lincoln's Inn Gardens? Such a measure would be of great benefit. Gardens like those of Lincoln's Inn Fields or Russell Square might become pleasant places of resort to thousands of young people who scarcely ever see a green field. I am aware that, these gardens being private property, and intended for the use of the inhabitants of the squares, this plan could only be carried into effect with the permission and consent of the parties interested: but I should hope there would be no obstacle on their part. The number of persons frequenting these grounds is very small; those at present exclusively entitled to do so appearing to neglect them altogether. There need be no fear, I think, that this indulgence, if granted, would be abused, or lead to the damage of the gardens.

There has been much talk lately, both in and out of parliament, about providing places for the recreation of the people. Would Government object to pay a small sum for the purpose of keeping in order all the gardens that might be thus opened, and for making seats and other accommodations for the public? I should also like to see the Zoological Gardens, and all the Exhibitions, opened gratuitously two or three times a-year, on the anniversaries of great national events.

In connection with this subject, we may refer to the part taken by our author in the question respecting the shortening of the hours of labour,—for of what advantage is the throwing open of Parks, &c. &c., to those unhappy persons who are doomed to toil so long, that they have neither time nor strength to participate in the enjoyment of them. On this point Mr. Curtis says:—

There can be no doubt that most occupations are injurious, more by reason of the excessive length of the time of labour, than of any inherent unhealthy tendency; and that if men generally were acquainted with the laws of the animal economy, and applied their knowledge to the counteraction of the morbific influences to which they are daily exposed, they would escape many of the miseries which they now too frequently endure. Such would be the results if, for example, persons engaged in business devoted the time during which they are released from labour to the invigorating of their frame, instead of spending it in practices which aggravate the complaints occasioned by their employments, and convert functional into organic disease.

The proposal for shortening the hours of business, now so generally supported in London and other towns, is one, the adoption of which would prove highly beneficial to the health of a very large class of the community, and would not, I think, be any detriment to trade. The class in question has of late years improved so much in its habits, that there is little reason to fear that any additional time placed at its disposal would be mis-employed. The plan is certainly deserving of a trial.

We understand that Mr. Curtis has been personally exerting himself to prevail upon the employers to agree to some such plan, having called on many of the principal bankers and linen-drapers, who have expressed their willingness to forward this important measure. The last point to which we can at present advert, is that of Cemeteries, on which our author remarks:

The salubrity of the metropolis would be increased, if the practice of interring the dead within its boundaries were abandoned. For this reason, I rejoice to observe that the number of cemeteries round London is rapidly augmenting; and in a few years they will, I doubt not, entirely supersede vaults and church-yards—a result highly desirable on many accounts. Of the moral benefits arising from the use of cemeteries, and the admission of the public into them, much might be said—the advantages in regard to health must be obvious to all. It is highly desirable that interments in towns should be prohibited by act of parliament; or, at all events, that no new burying-ground should be set apart within their precincts, nor vaults constructed in any of the numerous new churches now in progress of erection. The Kensall Green, the North London, and the Norwood cemeteries are beautifully laid out—indeed, they are all admirable places.

The great difficulty in reaching any of the improvements we have been advocating, are the private interests more or less vested in every abuse. But a great public good is not for ever to be postponed to a petty personal interest. If it were, we know of no class who would be more justified in resisting a change of our present system than our own profession. The great mortality of children in the lower classes, evidenced by statistical research*—the constant presence of *spreading* fever in dirty districts of our towns—the high rate of mortality among certain classes of our artificers—and a thousand well known facts like these, are only to be thought on to convince us that one-third of our practice depends on causes which wise laws and a vigilant administration, might reduce to nonentity. Yet, if any class be found resisting this great improvement, or seeking to encumber public benefits by demands of private indemnity, we think we may pledge ourselve it will not be ours: and the circumstance leads us to a consolatory reflection, with which we shall conclude:—The age is not wholly worthless which presents medical men demanding the prevention of disease—and lawyers enacting the simplicity of litigation.

REVIEWS.

Practical Observations in Midwifery, with cases &c. By JOHN RAMSBOTHAM, M.D., Late Lecturer on Midwifery at the London Hospital, &c., &c. Second Edition: London, Churchill.

WHEN an individual offers to the public a compendium, or general system on any science, he provides no sinecure for his reviewer, who has to peruse the whole carefully, in order to find out what parts are his own, what theoretical problems he has solved, what practical hints he has offered, and what new suggestions he has held out, more than others on the same subject. But a very different task is presented to us in the work of Dr. J. Ramsbotham, when we have to deal with the practical experience of a practical man on a *few special* points, to which he has peculiarly devoted his time and attention. Such subdivisions of labour, (as they may be justly called) are eminently calculated to advance science, and dispose us to hail with cordial welcome all works, which, like the present, come recommended to us with so favourable a letter of recommendation.

To begin with the beginning, we cannot pass over the preface without a remark. Dr. Ramsbotham states that "he was for some time sceptical as to the effects of the ergot of rye in labour, but that he is now convinced of its efficacy; still he doubts on a general principle, whether its introduction ought to be hailed as a boon, or reprobated as an evil." Now a similar remark might with equal reason be made use of in reference to many of our most valuable remedies in medicine; all are evils if injudiciously used; shall we therefore cease to use them at all? Dr. Ramsbotham does not appear to have noticed those newest discoveries in connexion with the ergot of rye, which fully prove in it the existence of two distinct principles, a narcotic irritant, and a simple stimulant. When thus given combined, the ergot will of course be highly injurious; when separated, the stimulant powers will be as highly useful.* Before dismissing the preface, why let us ask did our author include in it the quotation from Dr. Dewes in praise of the work? As a matter of shop policy, would it not have been turned to better account if left for his publisher's advertisement?

Coming now to the work itself, we shall follow the subject in due sequence. The introductory observations on general principles are exceedingly well written. They are free from that prolixity observable in most recent authors; the principles are clearly laid down, and explain adequately the meaning of the author; and taken as a whole, are calculated to convey much information. We feel, however, disposed to hold contrary views on one or two points. First, we certainly did not expect to encounter so long, we can hardly say so strong a list of objections to the non-muscularity of the uterus, from the pen of an experienced practical accoucheur. In our opinion, the able arguments of Sir Charles Bell are conclusive. Dr. R. explains "of what muscle consists," and because the uterus does not present a strict analogy in *every particular*, he considers it *no muscle*. Now we humbly conceive that his definition *may be wrong*, and secondly, that there are other precedents for supposing that more than one species of muscle exists. In denying the muscular fibre of the uterus, the Doctor admits "that fibrous appearances are shown when a section of it is "*artfully made*." In the pursuit of science, we do not admit the term "*artful*," but think it easy to conceive that such may be the arrangement of the uterine structure, that no section would shew the fibres as the Doctor wishes them to appear, *and that after all they may be present.* With respect to the analogy which has been admitted by most authors between the uterus and bladder, the Doctor does not deny the muscularity of the latter, because (when inflated) it may be seen; and proposes to do the same by the uterus when inflated. The bladder is not stimulated to contraction by the *quality*, but *quantity* of the urine. If it were by the former, it would not retain the urine at all; as it is, the *quantity is regulated by habit*, beyond which, it becomes difficult to retain it. In our opinion, the uterus is more decidedly a muscle of powerful action within itself than the bladder. The latter can do but little towards emptying its contents if unassisted by the abdominal muscles, a fact proved by the sections made into the parietes of the abdomen when they have become incapable of voiding urine. It may be said the parietes abdominis assist the uterus in labour. Yes; but in a much less proportion. It has peculiar properties, differing from other muscular structures, the most remarkable being increase during gestation, and decrease after parturition. *We ask the question, therefore, if not muscular, what is it?* Being an organ strictly analogous to no other, and yet in most particulars resembling muscle in its functions, what are we to conclude but *that it is a muscle of a different species?* Because the only one of that character in the animal machine, it does not therefore cease to exist. But is not the Doctor a convert to muscularity after all? (Vide 3rd paragraph, page 5, beginning "I admit that")

The size, shape, and practical situation of the gravid uterus are well described, the particulars respecting the placenta are also well given, and afford us a good opportunity of presenting a specimen of the author's style.

THE FUNCTIONS OF THE PLACENTA.—It is an organ found for, and appropriated to, the absolute service of the fœtus; attached by the funis umbilicalis, it is the only means of communication between the mother and the infant within the womb; it is, therefore, the sole medium through which the principles of nourishment and growth can be conveyed from the mother to her child. The fœtal blood distributed by the branches of the umbilical arteries to their extremities in the placental mass, and deciduous membrane, is there exposed to the influence of the maternal blood brought to the uterine openings abovementioned, and is impressed with certain benefits necessary to the continuance of fœtal life. The fœtal blood thus replete with that nourishment and vivifying *something*, which it has acquired in its passage through the placenta, is returned to the body of the child by the umbilical vein, and is then quickly circulated over every part of the child's body. The blood of the child, under this state of improvement, may be assimilated to that of the adult after its circulation through the lungs and its return to the left side of the heart. If interruption to the free return of the fœtal blood from the placental circulation should be induced by any cause, the life of the fœtus will be as certainly destroyed, as if the free passage of the air into the lungs were prevented under breathing life. When the placenta is partially separated from its uterine attachment, a loss of blood, proportionate to the quantity separated, and to the development of the uterine vessels, is a necessray consequence. The blood lost under such circumstances is maternal, not fœtal; and if after such an occurrence, the fœtus should be deprived of life, its death is produced by, *in the first instance*, the diminution, and at length by the entire deprivation of that vital impression which is communicated to the blood of the child by its passage through the placenta. But when the mass of the placenta itself is ruptured, as, for instance, by the passage of the hand through its structure into the uterus, under a case of implantation of the placenta over the mouth of the uterus, the blood of the child will be discharged through the lacerated vessels.

The author speaking of uterine action says, "the child whether it be alive or dead is wholly passive." This may be true, but during a long experience we have invariably found dead fœtuses to produce protracted labours. This is a fact known to many, and it seems to prove that a *living child* in utero is a stimulus to that organ tending to shorten labour.

On Natural Labour.—The author's observations are lengthy and valuable; it would be impossible to follow him through them all, but we recommend attentive perusal. We shall only touch upon those parts which appear to us to differ from other opinions, or on which some doubts may arise. Dr. Ramsbotham says, "the pressure of the head of the child on the soft parts proves an increased stimulus to uterine action, and expulsive efforts are the consequence." This is not sufficiently explicit. We believe most obstetric writers are unacquainted with the fact, that there are two distinct actions set up in the structure of the uterus during labour; the first is dilatatory, during which no expulsive efforts are present, and which are confined to the cervex uteri, and its immediate neighbourhood; when this is completed, a second action is set up (*expulsive*) by the uterine structure of the upper walls and fundus uteri. The head of the child passes the os uteri, and presses on the soft parts, producing by that pressure, what? A sympathetic action of the diaphragm and abdominal muscles *hitherto inactive*, but now *powerfully assisting expulsion.* We have noticed these interesting phenomena for many years, and as illustrative of them may mention that if two fingers be gently introduced into the vagina, and pressed on the perineum, the diaphragm and abdominal muscles will be excited to action. A similar influence is produced by fæces in the rectum, causing propulsion. We have here a valuable adjunct in labour when used with due caution. Though this fact has long been known, a writer in the *Lancet* claims it as a discovery. He explains the action on the principles of Dr. Marshall Hall's theory of nervous distribution.

On the expulsion of the head, shoulders, and the body, there is often an intermission of pain, and our author recommends waiting "however long the intermission may prove." We think gentle friction by *grasping the integuments of the abdomen with the hand, and*

* See the experiments of M. Bougeen, M. Bodin, and Dr. Clay, of Manchester. Med. Times, vol. 6th, page. 355.

moving the mass over the uterus can do no harm, it generally produces the required pain, and in our opinion is better than waiting long. The Doctor's remark 'the child should be rather entirely expelled, than even partly extracted," is excellent. As to the time for bringing away the placenta after delivery, the author's arguments favour a greater length of time than seems to be strictly necessary. And we are disposed to dissent from him entirely, when he states in respect to the placenta "deferred as long as it seems consistent with professional duty so to do, or the clamours of the attendants will permit," and again as to manual extraction of the placenta, "The friends of the patient and even the patient herself, should also in most instances be apprised of the intended operation, that their *complete sanction and permission may be obtained*." Surely we misunderstand the author; if not, we are bold enough to say the rules are bad. For ourselves, we would eject all *clamorous attendants* from the chamber, *sans ceremonie*; though to the patient we should think it right to state what we were about to do; but when our author speaks of *asking permission to do our duty* of those who can know nothing about its requisitions, he compels us to ask what *could* have been his meaning? Should the patient or her attendants object to what is required, there is an end of the matter. In that case the accoucheur had better make his bow, and give way to those in whom they can confide. The directions of the author (page 38) on proceeding to extract the placenta appear to us remarkable. In conducting examinations, or rendering manual assistance, &c., *the patient*, we perceive, *is laid on the left side*, and Dr. Ramsbotham uses his *left hand* for introduction, and the *right* for application over the parietes. If this work was intended merely for a record of the Doctor's *own experience*, it would matter little, but if intended for the instruction of others, he should have prefaced these remarks by informing the reader *that he was ambidexter*. The profession as a whole *are not so*, and to say the least of the instructions they are not the most decent. We have always understood, when the patient lies on her left side, (the more proper) the *right hand* ought to be introduced, and *vice versa*. If there be anything in the nice discrimination of the organ of touch or in physical power, the right hand should have the preference. Suppose the accoucheur sitting at the bedside, the patient on her left side, the right hand is easily and most conveniently situated for introduction, and the left, under cover of the bedclothes, can as easily command the parietes. Indeed the left hand cannot be used for vaginal introduction without placing the patient most indecently across the bed, with the nates almost in the lap of the practitioner.

The following paragraph deserves especial notice in reference to febrile diseases arising from the suppression of the lochial discharge after delivery.

The sudden disappearance of this discharge within a few days after delivery, with an enlarged uterus, is usually a prelude to dangerous disease, with febrile symptoms. *It is not to be supposed* that this sudden disappearance *produces these symptoms, it is the mere indication* of the accession of disease, of which such symptoms are the necessary attendants. We, therefore, pay little attention to the present interruption of the lochial discharge, except *as a symptom*, and use no specific means for restoring it, or, for *obviating* its supposed bad effects; we apply our endeavours to the removal or relief of that cause, by which the temporary interruption is produced.

We know this to be the opinion of many writers, but long experience has convinced us of its fallacy; too little attention has been manifested towards the missing lochia, and too much to the consequences (fever). We think it easier to restore the lochia by hot fomentations, hip baths, camphor, and opium, and thereby check the febrile symptoms; than to lose sight of the lochia, and treat a fever, which, if it once fairly sets in, we have great difficulty in controlling. We repeat it; the suppression of the lochia *is the cause*, and not the consequence of fever, at least that is our opinion.

On adhesion of the placenta, the author is decidedly at home, and we would recommend his observations to the perusal of all obstetricians. Much benefit may be derived from the practical illustrations by cases appended to them. Simple retention of the placenta from want of uterine action, and also from irregular contraction of that organ are ably treated. If anything, we think the Doctor waits a little too long on the average before he attempts extraction.

We had proceeded thus far in our remarks, when our attention was arrested by the uncertain statement as to the ultimate result of many of the cases illustrating this work. All cases on so important a subject should assuredly end in a manner to leave no doubt of their ultimate result. Many are of this uncertain character.—"Case 6th. She began to revive from her fainted state; [illegible]th. This woman was left under a state of great exhaustion, but in a few days she had so far rallied as to *promise to do well*; 16th. I left the poor woman under a state of great exhaustion, but in a few days she had so far rallied as to *promise hopes of her recovery*; 17th. I was permitted to leave the house about one in the morning, and the *next day* she was *as well* as after any of her former confinements; 19th No result; 22nd. The next morning I was informed this patient had passed a tolerable night, and that, *upon the whole*, she seemed in a more comfortable state than, from her preceding sufferings would possibly have been expected."

On disruption of the placenta, we certainly agree with the author that it ought seldom or never to occur. It is almost always the offspring of ignorance or mismanagement. We do not, however, coincide with him when he states "that after failing in the first attempt to remove the adherent portion any further, manual assistance is inadmissible." The first attempts are generally by inexperienced or ignorant practitioners; and when a second person is called in, the least *he can do is to try and satisfy himself whether it can be effected or not*. The serious and often fatal results of cases left to medical aid only, is sufficiently alarming to warrant a little more manual assistance than the author advises; two cases out of five, of his own illustrations, being fatal. His medical treatment—it must be said, however,—is well conceived.

Cases of relaxation of the uterus after delivery productive of internal hæmorrhage come next under notice, and however much we may admire the candour of the author, we certainly feel some surprise at not finding any allusion to *padding* and *tightly bandaging* the uterine region *most valuable adjuncts in obstetric practice*. We smile to find the author fixed for many hours together applying mechanical pressure with his hand, when a *full* dose of *good* ergot and a *well applied bandage* would have effected the purpose much better; the warmth of the hand having a tendency to increase hæmorrhage. *Collapse after Labour* the author attributes to the too sudden removal of pressure, arising from the want of accommodation of the abdominal viscera, or from the impression, or shock on the mind, from having a dead child, &c. The only hint we see of bandaging in this chapter, is conveyed in the following words. "I recommend a proper degree of pressure on the abdomen *by the hand or otherwise*." Indeed, the omission of bandaging seems to us, of the most serious importance throughout the work. We have seen many cases of progressing collapse immediately arrested by *a bandage*, and all obstetric practice must be deficient without; for if collapse arises from the too sudden removal of pressure, what better means can we suggest than artificially to restore the pressure.

On protracted labours the author is lengthy, classing all under that heading if more than of twenty-hours continuance. We have, 1st. Those of mere lengthened duration as to time; 2nd, Those requiring more than natural efforts; 3rd, Those in which the child's head and pelvis are slightly disproportionate. The first or lingering, he accounts to arise, 1st. From undue resistance given by the soft parts; 2nd, From the diminished energy of actual efforts; 3rd. From malposition or direction of the head in the pelvis. With regard to the undue resistance given by the soft parts, the author's description, treatment, &c., are worthy the importance of the subject. He very justly condemns any attempts to hasten labour by irritating the os uteri, artificial dilatation, exhibition of stimulants, frequent examination, or that very pernicious practice of rupturing the membranes, in which we fully agree. We do not, however, see any hint in this chapter to the effect that very many of these cases (among the working class particularly) arise from over exertion, and bring on what may be termed premature labour, when the secretions are absent, and the soft parts not fitly prepared for the purpose. Very many cases have we witnessed of this nature, where, instead of interfering or waiting for nature to work out the problem when she is ill prepared for it, we have given a *powerful opiate*, enjoined quiet, and prohibited stimulants. Such cases have been days, nay, some four or even six weeks before natural labour came on, when there being an abundance of mucous secretions, and the parts being well prepared for the transit, the accouchment has been of the usual character. In all cases of protracted labour *one enquiry is imperative*. Is the patient at the full period of gestation? If there is any reason to suppose she is not, labour ought not to progress if it can be controlled by any reasonable means. As means of relief, the author proposes five classes,—opiates, venesection, clysters, fomentations, and placebos. We think the division useless; the whole being medical, would have done as well under one head as five. To opiates the author is unfavourable. Now we hold them valuable when used judiciously. As stimulants only, we consider them inadmissible. In controlling uterine action when premature, they are, in full doses, highly valuable; and we are warranted by experience in declaring that females under such circumstances will bear much larger doses than at any other time. We quite agree with the author that no relaxation of the soft parts, or increase of their secretions takes place from the exhibition of opium. On blood-letting, he speaks more favourably, but with becoming caution. Great discrimination is requisite in bleeding, particularly in habits previously of delicate stamina. Clysters being harmless, may almost always be used with advantage. On fomentations, Dr. Ramsbotham offers no experience, although practitioners in other countries speak highly of the warm bath. With regard to the last division, (harmless fraud or placebo medicines) we must at once declare them unwor-

thy of any practitioner of high standing as an accoucheur.

In considering the second class of protracted cases, viz., those from diminished energy of natural efforts, the author says nothing of opium. Now if the parts are not duly prepared, and a cessation of pains occur, it should be remembered, that a good opiate procuring a few hours rest, will bring on pains afterwards, fully capable for every purpose. If the soft parts are well prepared, and the os uteri well dilated, the ergot is the best and only resource. The author, however, speaks of it cautiously and evidently as a late convert to its powers. He says, sometimes it is found almost inert. So is opium, and why? Because the cupidity of druggists (favoured by neglect of selection by the practitioner) induces them to vend old specimens which of course are inert, and the failure should be attributed to the drug, and not to the idiosyncracy of the patient. In cases of protraction of this nature, the author states there is often trouble with the placenta, for want of uterine action. We should say scarcely ever if the ergot is properly used. As to asphixia of the child, we have an impression, that giving the ergot in substance will produce that state; but that if the infusion be given, no asphixia, or at least, only an asphixia of a very trifling nature will occur. The author, we regret to observe, appears not to have paid due attention to the late discoveries on the ergot

The author's remarks on protraction from malposition, or direction, are both cautiously and judiciously written. The person given as an illustration (45) in our opinion, would have had her anxieties sooner relieved by a bold opiate and quiet, than by the perambulations recommended to her; the pains would in all probability have returned much sooner. The next subject of enquiry—"protracted labour, under a natural presentation combined with a slight degree of difficulty;" in other words, "forceps and vectis cases" is an ably written chapter, shewing to considerable advantage the capabilities of the author. It would be impossible to follow him through the whole of this excellent part of his subject, there being no less than fifteen heads or divi ions, establishing the necessity for instrumental interference, but with every deference to the author, we think case 51 more adapted to the long forceps than the vectis, and that case 55 exhibited a great waste of time. While admiring the author's candour, we beg to assure him that the application of some unctuous substance would have improved the process a little. In protracted cases combined with *greater difficulties*, the author is feelingly averse to cephalotomy, except under the most urgent necessity. He then uses the common crotchet, but speaks highly of Dr. Davies' forceps for craniotomy. In the section, "preternatural labours," the author endeavours to establish a diagnosis for ascertaining breech presentations before labour, which we think not sufficiently conclusive.

On shoulder presentation the author makes the following valuable remark:—

> Every case in which the presenting part does not come within range of the finger, especially after the establishment of pains, and relaxation of parts, ought to receive an unusual share of watchful attention, for that fact alone ought to excite a justifiable suspicion, and some other part of the child except the head may be placed at the brim of the pelvis.

The author is particularly desirous that the practitioner should not lose the favourable moment for "turning with advantage by any inattention or absence, &c.;" and the directions are so well given, that they cannot be studied without advantage.

On uterine hæmorrhage, a subject of immense importance, the author is much more brief than we expected. The fact of spare and thin persons bearing loss of blood better than those of corpulent habit, has often been asseverated, and is confirmed by our author, who is averse to bleeding in hæmorrhage, because it is generally passive; speaks also cautiously of ergot, but in other directions and applications of manual assistance, is more decided. Uterine hæmorrhage the author divides into "accidental, and unavoidable." On "rupturing the membranes, turning, &c.," there is nothing new; the same may be said of "unavoidable hæmorrhage" with one exception. We think some degree of caution is required in proceeding to deliver, where the placenta is attached over the os uteri, particularly when the os uteri is a little *dilated and rigid*. We have seen powerful opiates allay the pains, and consequently the hæmorrhage, very frequently. The inference is, that the process of labour is premature, and the case has gone on for days or weeks longer, pains have again occurred, and even hæmorrhage, but under the more favourable arrangement of the os uteri in a dilatable state. This should be borne in mind, and if practicable tried rather than rupture, when the os uteri is rigid and scarcely dilated. Parturient convulsions previous to, and subsequent to labour, is a part of the work well worthy of perusal. With regard to the first 'on venesection," the author observes, "if the lood does not flow out in a powerful jet, little good arises from it." Indeed he goes so far as to say," if it flows lazily from the orifice, it would have been better not to bleed." Now here we do not fully accord; we know the value of a rapid abstraction of blood, but think the form of the incision may often prevent the blood rushing out like a jet, and yet the abstraction be quick. Copious and repeated bleedings, powerful evacuants, &c., are almost the only means in convulsions *previous to labour*, with delivery when it is practicable. Should convulsions continue during delivery the same means must be resorted to, more energetically applied. On the still more intractable *convulsions after* delivery, opiates and stimulants are jus ly condemned, and enemas of assafœtida, and ol. terebinthinæ recommended.

On multiple births nothing very remarkable occurs. The author is of opinion that conception is simultaneous in cases of twins, &c., but gives no reason for so thinking. There is no certain criterion during pregnancy to indicate twins The children are generally smaller, and the mother larger, but we do not think with the author that in such cases there is less chance of arriving at the full period of utero-gestation, although the probability is generally acknowledged to be smaller in triplets, or quadruplets.

The article "*abortions*" is exceedingly interesting, but somewhat unconnected. The treatment of abortion by bleeding he justly condemns; he might have included astringents also. We think opium in full dose the *sine qua non* of practice, in preventing abortion, a remedy on which he is silent. The Doctor's candid statements in respect to *rupture of the uterus* are deserving of great praise; he appears to have no wish to hide his unsuccessful cases, of which he has recorded thirteen. Three successful ones shew most clearly that rupture of the uterus is not necessarily fatal; indeed, we are convinced after so many cases recorded by Douglas, Murphy, Mitchel of Dublin, and others, that such should not be given up as hopeless. The modern operation, peritoneal section, sufficiently proves to what extent we may go with safety, and how much females will bear in the hope of relief, and recover fter the most extraordinary extent of injury.

With respect to *retroversion of the uterus*, a subject of much importance, it would be better (in our opinion) not to wait; but at once replace the organ in its normal position, if possible. We must name our dislike to the position chosen by the author for his patient. Might not an equally effective and more delicate one be chosen? His observations on the attention to be paid to the bladder by the catheter are most important.

In polypus of the uterus (which is sometimes mistaken for long standing inversion of the uterus) the author advocates the removal by ligature in preference to the French mode by curved knife. When polypi are connected with os uteri and cervix, authors (generally) have added more to their importance than they deserve, making their extirpation a tedious process (as the ligature). We have without loss of time frequently removed the mass by twisting when the pedicle will give way, and the tumour has come into our hands without hæmorrhage, or the slightest bad symptom. By this mode the pedicle is most likely to give, way at its origin, and less likely to returns We do not say this summary practice is always advisable, but when the pedicle is slender, it saves much pain and offensive discharge. The volume concludes with a case of sudden death during pregnancy, after considerable excitement. The autopsy confirmed the author's idea that death arose from disruption of some vessel in the uterine structure of considerable magnitude, which he supposes to have had the same effect on the gravid uterus as blood effused on the brain.

In conclusion, we must be permitted to say, that we have felt great pleasure in the perusal of this work. It contains much practical information, great candour in the relation of experience, without a wish to hide the unsuccessful portions. The reader will profit by it if he use his powers of discrimination There are, as in all works, some faults visible, as we have very freely noticed; but its good points are many, and make it a valuable addition to our obstetrical literature. The points on which we differ are few and our readers have our objections at their judgment seat. On the valuable portions of the wor we have freely descanted, and with our bes wishes for future success, we cordially take our leave, hoping that others imitating his good example, will record *their own experience* more, and other people's less; and not give themselves so much trouble in extracting our hard-earned fees from our pockets by presenting us in new type, and under new fancy covers, learning which has long reposed between the parietes of every decently lined medical caput in the kingdom—a professional theft on our money, and time, which should make such meddling carriers of other men's wares as hateful to men—as by their hopeless poverty they seem to be to Gods.

An Essay on the Nature, Causes, and Treatment of Deafness, &c. by W. Thornton, M.R.C.S.L., late Surgeon of the 97th Regt. —Churchill.

Before expressing an opinion on the merits of this small work, we must, as a warning, in justice owing to our readers, acknowledge some personal predilections for the gallant author. Though unknown to us, personally, he has been good enough to inform us of the pleasing fact—so favourable a *prima facie* evidence of the goodness of his taste and the extent of his good sense—that he is a weekly subscriber to our "highly valuable periodical."

he has favoured us once or twice with cases of ' deafness, arising from morbid conditions of the mucous membrane of the stomach," or of some other part equally connected with aural disease—in which cases the "successful treatment" was a very prominently exhibited feature—and we have, finally, to acknowledge the gift of the book before us, with a very courteous request "for the honour of a notice," accompanied with the outshadowing of an indistinct hope to us of a voyage to that El Dorado of Journalists—"Advertisements." Thus weighed down by a gratitude which is not the less lively because it has a deligtful reference to favours yet to come, our readers will be pleased to take our commendations with some little distrust, and give us credit for no mean sum of impartiality, if by any accident we so far conquer our prepossessions as to reach the length of an occasional censure.

Some time since, it was our painful duty, in reviewing a brochure on the Ear, to express a rather marked disapprobation of another Aurist—a very general favourite of our hebdomadal contemporaries—we mean that very, very active gentleman—Mr. Yearsley. As we have peculiar notions of the duties of reviewers, we not only criticized, but *read* his book; and as the impression was rather an unpleasant one, that greatest of human traitors, memory, which so remorselessly lets slip any delightful reminiscence, retains to this hour a tenacious grasp of almost every word, nay, every syllable, imprinted during that afflictive visitation. This freshness of recollection, this mental malady of an ill-fated editor, ought to be no offence in either Mr. Yearsley or Mr. Thornton—but it is certainly an unfortunate circumstance for one of them; for the coincidences, nay, the identity of opinion and of expression, on professional subjects, which the two authors exhibit in their different books are so perfect, as to justify the notion that the two gentlemen have joined together to keep up two aural establishments on one stock of trade. They appear to exhibit an economy of the "raw material," a saving of that priceless commodity, knowledge—for which the scientific world owes them the deepest obligations. Let us present a few examples:—

THORNTON.	YEARSLEY.
Sudden transitions from heated assemblies to the *cold air*, or *vice versa*, are much more likely to occasion *cold*, than exposure either to an uniform high or low temperature, and should, therefore, be avoided. As the mucous membrane is the chief point affected by *cold*, or injurious influences, all causes that act upon it prejudicially should be held in apprehension; and cold and humidity being by far the most frequent of these, and affecting the ear in the greatest variety of forms, should be guarded against with the most sedulous care.	As the mucous membrane is the chief point affected by injurious influences, all causes that act upon it prejudicially should be held in apprehension, and cold and humidity, being by far the most frequent of these, and affecting the ear in the greatest variety of forms, should be guarded against with the most sedulous care. Sudden transitions from heated assemblies to the cold air, and *vice versa*, are much more likely to occasion cold than exposure either to an uniform high or low temperature, and should, therefore, be avoided.
In these diseases the mucous membrane is the first tissue affected, though the continuance of the disease in either form often leads to disease of other structures, especially the osseous and muscular contents of the cavitas tympani. Suppuration of the ear, through the membrana tympani, may justly be regarded as the termination of inflammation of the mucous membrane, the tumefaction of the membrane having closed up the minute opening of the tympanic extremity of the eustachian tube, had the pressure exerted by the closed cavity upon the inflamed membrane occasioning pain resembling that which happens when the pulp of a tooth inflames within its osseous envelope. In the chronic form of disease the same thing happens, but in a less marked degree.	In these diseases the mucous membrane is the first tissue affected, though the continuance of the disease in either form often leads to disease of other structures, especially the osseous and muscular content of the cavitas tympani. Suppuration of the ear, through the membrana tympani, may justly be regarded as the termination of inflammation of the mucous membrane, the tumefaction of the membrane having closed up the minute opening of the tympanic extremity of the eustachian tube; and the pressure exerted by the closed cavity upon the inflamed membrane occasions pain resembling that which happens when the pulp of a tooth inflames within its osseous envelope. In the chronic form of disease the same thing happens, but in a less marked degree.
In the first, the discharge comes from the cavity of the tympanum, with loss of continuity in the membrana tympani; in the second, the discharge is secreted in the external meatus alone. *Internal Otorrhoea* is always the result of inflammation of the mucous membrane, or *otitis*, and generally of the acute form of this disease. External otorrhoea generally comes on in consequence of irritation of the membrane within the tympanum. Sometimes it occurs in cases where there is no sign of disorder on the intended side of the *drum*, appearing *per se* from the lining of the meatus. But even granting this to occur oftener than I believe to be the case, I consider the pathological characters of disease of the lining of the meatus to be altogether different from those of the skin, and closely resembling, in this respect, mucous membrane. The cuticular lining, as it is termed, and the sebacious follicles which secrete an unctuous matter in sufficient quantity to keep the canal and external surface of the membrana tympani in a moist state in the progress of otorrhoea, gradually passes from the natural secretion to the copious discharge of mucus, or even pus, without the intervention of suppuration;—circumstances which never occur in the common integument.	In the first, the discharge comes from the cavity of the tympanum, with loss of continuity in the membrana tympani; in the second, the discharge is secreted in the external meatus alone. Internal otorrhoea is always the result of inflammation of the mucous membrane, or otitis, and generally of the acute form of this disease. And in a little pamphlet, which, including title-page, index, and preface, numbers but 44, pages we have 16 in which the similarity, or rather the identity, is equally singular. Now, we are credibly informed that there really does exist no partnership between the two authors, that on the contrary, Mr. Thornton disclaims, with much *hauteur*, any and every connection with Mr Yearsley, and we further know from our publisher's circular, and from our own announcements, that the book first *openly* published (though both appeared in 1842) was Mr. Yearsley's. Under present circumstances then, and until we are differently advised, we may make bold, we hope without injury to a modesty—which we suppose not to be more maidenly than suits a professional aurist—to compliment the gallant army surgeon on the Napoleon-like daring with which he walks into the very camp of the enemy, and despoils it of its richest stores. Surgeon Thornton has evidently not campaigned for nothing,—and the dexterity, the unflinching ease, with which he beats his rival with his own troops, entitles him incontestibly to rank as generalissimo of the aural army. The *Lancet*, a *very* high authority, declares Mr. Thornton, "to be well versed in the diseases of the ear," and we may venture to add, that, however versed in diseases, (happy, critical expression!) he is not less well versed in the treatment of that class of them which appertains to the *res angusta domi*. If candour were one one-half as profitable as boldness, we should have a new reading in his next edition,—"diseases of the pocket" would substitute "diseases of the ear."

But one word more to Mr. Thornton, before leaving him to the tender mercies of the College of Surgeons, who, after this enumeration of his merits, will no doubt find it convenient (the envious Council!) no longer to be overshadowed by the dazzling radiance of his professional daring. "Let him that hath ears to hear—hear." You tell us, in your book, "of *pretended* aurists"—you declaim against their ignorance, which, you asseverate, has not been profitless of good only, but instrumental of injury; and you hopefully prophecy an era of aural wonders, from the competition arising from your appearance in the professional market. Now, you have sent the journals, cases of "cured deafness"—why was the name and address of the patients invariably omitted? We have at this instant in our hands, your MS. relating a case of "successfully treated" deafness, sent to us this week. How happens it that the imaginary girl having but disease of *one* ear, ("the other being perfect") you yet speak of obstructions in the eustachian *passages*—evidently demonstrating ignorance of the elementary anatomy of the ear? How is it that you talk of an "*elongated* tonsil," and of giving a lady forthwith three notes, by touching it with lunar caustic? How is it that you tell us the cure was effected by bougies and iodine, and mention, as your reason for publishing it, the wish to illustrate by it the importance of the vapour douche? In fine, who is the professional singer?—where does she live? When all these questions are answered satisfactorily, we shall allow you to encourage hopeful expectations of what science may expect from you—to declaim against your brother-aurists, as mischievous wrong-doers and pretenders—and to put yourself forward to your fated patients, in the worthy *Lancet's* words, as "well versed in diseases." Till then, we must brand you as a living, moving, mischief-making disgrace to the profession you encumber by your membership, and hold you up as a warning of what one medical journal, at least—the only medical journal not in bookseller's hands—will do for men who think they can publicly contemn decency and virtue—rush into the vilest kinds of empiricism—and yet carry with them, through all their filth, the support of what *should* be the profession's guardians—its own press—if they but enter themselves as subscribers to the publishers, and talk about advertisements to the proprietor

Absorption of Iodine.—M. Leon Brousse has tested the urine of several patients who had been treated for hydrocele by the iodine injection. In every instance he was readily enabled to discover the metalloid in the urinary secretion by the third or fourth day after the operation, and in one instance, at least, as early as the second day. In this case, that of a Spaniard, forty years of age, the scrotum continuing swollen, and evidently containing fluid five weeks after the operation, it was punctured with a lancet, and a sanguinolent fluid evacuated, which, on being subjected to the usual tests, yielded evident indications of the presence of iodine.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, Jan. 27, 1843:—

C. Withington, W. J. Preston, T. H. Benfield, A. Cartwright, S. Byles, J. Prowse, S. Singleton, T. Young, J. R. Lewer, T. Spencer, D. Coulter, C. H. Perry.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 10, Essex Street, Strand, in the Parish of St. Clement Danes, Westminster, in the County of Middlesex.—Feb. 4th, 1843.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs,

No. 177. Vol. VII. LONDON, SATURDAY, FEBRUARY 11, 1843. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

SUMMARY.—*On the principle of determinations in comparative anatomy—general facts on organogeny and embryogeny—anatomical philosophy of Aristotle—application of the idea of the final causes to the organisms of man and animals (Galen)—union of the method of Aristotle with that of Galen (Haller)—object of the general sciences; their modes of proceeding—the descriptive sciences—nature of the facts serving as the basis of these two orders of sciences—their inconveniences and imperfections.*

We may, then, consider the following propositions as established in organogeny and in general embryogeny.—That the organs are compound bodies; that the materials or elements which compose them are primitively multiple and disassociated; that it is, from the mode of their reunion, that the principal organic variations result and, perhaps, also the fundamental arrangement of the more inferior animals.

It is further established: That the more we descend in the animal scale, or the further we advance in embryonic life, the more do we find the division of the organisms increased; that, consequently, these two states of animality correspond in the lower animals, and in the course of the embryogeny of the superior animals; that this general fact being reproduced throughout the whole animal kingdom, it results that organogeny is but a transitory comparative anatomy, as in its turn comparative anatomy is in some measure a permanent general embryogeny.

Finally, it is established: That, from the complication of the organisms in embryos and animals, and from the evolutions which they undergo in these two states, result organic species, and, perhaps, also animal species, especially in the branch of the invertebrata. It therefore follows that, supposing organisms to possess a common point of origin, their differences become established by the greater or less number of evolutions which they experience in the course of their developments. It further follows, that to found upon positive results, either the scale of beings, or, what amounts to the same thing, the scale of their organisms, we must compare the two states of animality at the period at which they correspond; that is to say, the embryogeny of the superior animals with the fixed and arrested organization of the inferior animals.

These first principles, however, being established, new difficulties present themselves in the theory of the epigenesis of formations. We may readily conceive, from the foregoing observations, how difficult it becomes to preserve a correct line to guide us through these continual variations,—these so varied combinations of the constituent materials of organs, whether in the animal kingdom, or in the course of general embryogeny. These metamorphoses, in fact, so completely change the organs and the organisms, that, without a rigorous method of determination, we should be liable to combine organisms of a very inferior rank with organisms of a much more elevated character; to draw together organic elements which naturally repel one another, and to set apart other elements which have a mutual attraction; to compose, in a word, true scientific monstrosities. To avoid this confusion, which has already produced such grievous results in the determination of the organisms of invertebrated animals, it is more than ever necessary to lay down rules which may serve as a guide in this branch of science. Such, then, is the task which I propose to myself in the following observations.

To determine, in the anatomical sciences, is to fix the principles by which we may distinguish an organ, or a system of organs. Determination is the basis of the philosophy of these sciences, as facts are the basis of their material part. These are undoubted truths. But naturalists have hitherto attempted this determination of parts, sometimes by the simple consideration of the function, sometimes by the consideration of the form, and at other times by that of the form and function combined; position and connections were, in general, almost entirely neglected. This variation in the modes of determination is so perfectly bound up with the progressive advance of our knowledge in anatomy, that I think it necessary briefly to allude to its sources. The philosophy of the ancients, especially Platonism, soared above the level of nature. Aristotle was the first who, so to speak, made it descend into a sphere of utility, and rendered it applicable to the physical and moral wants of man. The spiritualism of Plato became in some measure embodied in the philosophy of Aristotle, who was thus necessarily conducted to the study of the organic forms so happily exposed in his *History of Animals*. This work, however, contained views only on the general characters of the animal kingdom; the descriptions were neither minute nor profound, nor was any necessity for such then felt. But the progress of medicine soon caused this want to be appreciated. Having discovered in disease a deviation from the normal action of organs, physicians soon became convinced that, to appreciate the disturbance of the functions which forms the essence of every disease, it is first necessary to understand the regular condition of these functions. Now the functions being merely the result of the action of the organs, their study necessarily led to that of the apparatus or organs themselves. The definitive object being the knowledge and appreciation of diseases, physiology was thus rendered subordinate to medicine, as, in its turn, anatomy was necessarily entirely subservient to physiology. The organic form was, then, what the function demanded.

But function is an absolute result; the least disturbance, the least change, leads to disease, and the latter to death; it therefore follows that the organism, subservient to the function, must be like it—immutable and absolute. Such was the conclusion to which Galen was inevitably and logically conducted in his remarkable treatise "*De usu partium*." Such also was the origin of the application of the final causes to the organisms of man and of animals. They were believed to be exactly what was requisite to attain the end for which they had been created. To suppose them different from what they are in the perfect being, enjoying the full exercise of his functions, would, according to Galen, have seemed like blasphemy against the Creator. Although subordinate, the form was, then, supposed unchangeable, and anatomy was entirely devolved to the service of physiology, as the latter was to that of medicine. Thus do we find in the works of Galen the origin of the doctrine of the immutability of organisms, and of their action at all periods of existence in organised beings, as afterwards proclaimed by the advocates of the system of pre-existences. Hence the cause of that exclamation of the founder of physiology, "*Function is the only determinator in anatomy*."

Galen had implicitly delineated the functions in man; he had defined, conformably to his views, the arrangement of the apparatus. To touch this system, was to shake his physiological edifice and to attack his hypothesis of the final causes; it was, moreover, a sure course to draw down the anathemas with which his followers overwhelmed their adversaries. Vesalius attacked it and paid with his life his audacious temerity. Vesalius dissected the human being, which Galen had not done; Galen was mistaken—such was the simple fact; Vesalius said so,—but Sylvius, in reply, asserted that it was better to believe that nature had deviated from her ordinary laws, than to place in doubt the infallibility of the physician of Pergamos. This decision solved the difficulty for the moment. But to believe is not to demonstrate in anatomy; so said Beranger, Eustachius, Fallopius, and all the followers of Vesalius in their turn. However great might have been the genius of Galen, how could he deduce with precision the form and arrangement of the human organs from the disposition and form of the organs in animals? But science now marched onwards; by the process of dissection, the various parts entering into the composition of man were separated one from another; this separation accomplished, they were studied singly and collectively, by considering them under all their aspects, and from this immense labour finally arose the descriptive anatomy of man—that wonder which had been for ages hidden from human observation. Man once reduced into his diverse elements, it became necessary to distinguish these elements one from another, to attach to them their especial names, and to divide them into groups, so as to facilitate their examination and apply to each their proper attributes. It was thus that the *distinction of organs* and of tissues was formed, from a comparison of their characters—their nomenclature, from the attribution to each of a name implying its individuality—and their classification, from combining into one group all the organs possessing general and common characters. Never was scientific movement more rapid, or marked by more numerous or positive discoveries, or by such as were of more immediate application to the wants of man; the natural sciences also, which formed a part of the study of the physician, pressed forward in the steps of human anatomy towards the determination of their several objects. *Botany, zoology, comparative anatomy, mineralogy, geology, chemistry;* these are, as it were, but the aids of human anatomy, which kept in advance of them all. Thus—to determine an *organ*, a *body*, or an *animal*, to give to it a name, to describe it in all its details, and to range it in its place or under its proper classification,—such are the characters of the descriptive sciences, the base and essence of which, so to speak, are constituted by form and its variations.

This rapid sketch suffices, then, to show, on the one hand, how descriptive anatomy detached itself from physiology—and, on the other, how, in organic determinations, the consideration of form was substituted for that of function. The method of Aristotle, essentially descriptive, neglected the function for the form; that of Galen, essentially rational, neglected the form for the function. The first of these methods carried in its train the descriptive sciences; the second led to the general sciences; the truth thus lay in their combination, and to Haller we owe the merit of first discovering this fact. He founded the determination upon form and function combined; thus, embracing in his method, the descriptive as well as the

general sciences. Without repeating what we have already said on this subject, I shall merely remark, that man, as well as nature, would be but ill-appreciated with regard to the collective characters, the harmony and the final object of his organization, if our knowledge were limited to the facts disclosed by the descriptive sciences. However indispensable may be the truths of detail composing these latter sciences, we perceive that these truths are not detached one from another; we see that they are united and bound up together by various and numerous relations; by something in common which serves them, in some measure, as a principle or point of origin. The study of these relations and principles constitutes, then, a new series of general facts, the discovery of which goes far to explain all these particular truths, and thus form a useful body of doctrine. Such is the object of the general sciences.

Here, again, anatomy has opened a route to the other natural sciences. For, as we have already seen, we find the principles of the method in Aristotle and Galen. But in general as in descriptive anatomy, they could be but of imperfect application. The cause of this is in the very nature of the general sciences. If the descriptive sciences are composed of facts of detail, the general sciences are constituted by facts of a collective nature. In the descriptive sciences, we are constantly seeking the differential characters of facts. In the general sciences, we search for their relations. In the first, we decompose nature—we isolate facts. In the second, we combine them—we connect them together by the force of analogies. The study of the analogy of organised beings forms, then, the essence of the general sciences; as that of their differential characters forms the essence of the descriptive sciences. Hence arise their differences, their subordination, the simplicity of the descriptive sciences—the complication and extent of the general sciences. I may here remark, that to ascertain the differential characters of a body, of an organ, or of an animal, we must study it solely at the period of its complete development. The descriptive sciences thus include but the history of a given period of organised beings,—as the adult age, in human anatomy; the corresponding period of animals, in comparative anatomy and zoology; and, in botany, that period of vegetables when they are arrived at the term of their increase. While, on the other hand, to appreciate the analogies of bodies, of organs, of animals, or of vegetables, we must embrace all the periods of their existence, by following all their changes and metamorphoses: we must form a complete history of the life of organised beings: and hence the extent of the general sciences. As the purpose of the descriptive sciences is merely to discover some given object, a series of organs or of bodies, their labour is in some measure entirely mechanical or material; the system is the same in all. Hence, the simplicity of the descriptive sciences. While, on the contrary, the general sciences, purposing to establish the conditions of existence in the organs of beings, to show how they become what they are, whether considered in themselves or in reference the one to the other—their labour is necessarily more elevated, more intellectual; it requires the full exercise of reflection and comparison. To the genius of observation should be joined that profound sagacity which, by the comparison of natural bodies, rises from one relation to another, until it embraces all within its grasp. Such were the minds of Aristotle, of Galen, of Harvey, Malpighi, Haller, Bichat, Meckel, Geoffroy Saint-Hilaire, Cuvier, Blainville, &c.

The descriptive sciences take bodies such as they are, without inquiring into their nature, their intimate, microscopical or molecular constitution; whilst, on the contrary, the object of the general sciences is to unfold this intimate composition of organised beings. Hence it follows, that the descriptive sciences are in themselves sufficient for their special purposes, whilst the general sciences indispensably require the aid of all the others. Undoubtedly, the details of the general sciences is formed by facts, as is that of the descriptive sciences; but these facts differ in their nature. The facts of which the descriptive sciences are composed are simple; those constituting the general sciences are removed to a second, a third, or a fourth degree; on both sides, however, the certitude is equal. But although there may be a proportionate degree of certainty in these two orders of sciences, we must still acknowledge that the causes of error are much more numerous and powerful in the general than in the descriptive sciences. These latter have merely one rock to avoid—that of saying too much. From a disposition to descend into details, we become prolix; we hide the prominent points under a heap of insignificant characters; we describe, without making ourselves understood. This is a fault into which the descriptive anatomy of man has often fallen. Hence the dryness of this study; but, from the same cause, its constant certitude. Now, the contrary is the fact with the general sciences: immediately that the mind has seized on some relation, some character common to several facts, it aims at extending it to all; it conjectures instead of translating facts. To render generalities useful to science, we must be able to contain them within limits. Thus shall we remove the abuses to which the general sciences have become so liable. Now, we may readily conceive that the abuse of details which may have crept into the descriptive sciences, will necessarily have less grievous results than the abuse of generalities in the general sciences. The progress of the former has, therefore, been regular, constant, and uniform; whilst that of the latter has been irregular and unequal: hence would the variability of the general sciences, as compared to the fixity of the descriptive sciences, have presented a sad contrast, were it not more apparent than real. But when we search its causes, we shall find that these sciences are constantly tending towards the same end: and, on attentively considering their means, we shall find that they constantly progress according to the same logical and inflexible principle—that of analogies, or organic conformities. Such is the constant principle which we find pervading these sciences, from the time of Aristotle and Galen down to the present day.

How then is it that the general sciences, invariable in their principle, have become so varied in their applications? The cause is in their very nature. If the general sciences are composed only of relations between particular facts, and consequently of general facts, it is evident that they must follow the descriptive sciences. Without the just knowledge of particular facts, the establishment of true relations is impossible. The imperfection of the general sciences has, then, at all periods, depended on the imperfection of the descriptive sciences; the one has merely been the result of the other. Thus, the imperfection of the general anatomy of Plato, of Hippocrates, and of Aristotle, was evidently owing to the few fixed notions acquired at that period upon descriptive anatomy; and, on the contrary, the progress made in the general anatomy of Galen, evidently had its source in the strong impulse which he gave to descriptive anatomy. We must also remark, that the notions of the ancients on general anatomy, being founded much more on the outer aspect of animals, than on their internal conformation, were necessarily more of a zoological than of an anatomical character. Thus, their observations on the analogies of the different animals, were founded on the teeth, the relations of the limbs, of the head, &c.; these observations were, however, correct, inasmuch as they were confined to what was placed beneath their eyes. But, on the other hand, when from the exterior they pass to the interior, we perceive at each step that they are reasoning upon what they had not accurately observed, and often upon what they had not observed at all: thus are their views frequently but vague ideas, which go completely astray in their application; abundant proof of which is found in the views which they have left upon the development of animals, as well as on the origin of parts.

OBITUARY.—Dr. Malachi Blake, at his house in Taunton.—Mr. T. W. B. Kirkby, Surgeon, on the 28th January, at Pimlico.

FOTHERGILLIAN MEDAL.—This has been awarded to Dr. Lever, of Guy's Hospital, for the best essay on organic disease of the womb

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM.

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c. &c.

(LECTURE VI., Delivered December 14, 1842.)

GENTLEMEN.—I purpose to bring before you today the subject of apoplexy. Now apoplexy is divided into two kinds:—in the first place, you may have congestion of the brain without a rupture of a blood-vessel; and in the second place, you may have it with a rupture of a blood-vessel; and you will see that throughout this lecture it will be a very important distinction with which we begin.

I must first detail to you the preliminary symptoms of apoplexy, and I will begin this subject by just adverting to what I have always considered very important, and that is,—that many subjects are not to be learned in the hospital, but they are only to be learned in private lessons, and this is one of them:—you can never learn to detect the premonitory symptoms of apoplexy in an hospital. You know that patients with such symptoms never come into an hospital, therefore, you never have an opportunity in an hospital of observing such a case. This may be said of all such diseases.

Now with regard to the premonitory symptoms: these occur in many subjects. In one set of cases you find a patient of a sanguineous temperament; he looks florid, is robust and muscular, and it is obviously a case of fulness. In another set of cases, the patient, instead of being sanguineous, is one of the most phlegmatic you can meet with. You may, perhaps, think this distinction is merely a scholastic one, but it is not so by any means. In order to prove this fact, I will detail to you a case that occurred to me but a year or two ago. A member of parliament came to me describing attacks of giddiness—attacks attended with symptoms which seemed to indicate a degree of apoplexy. He had been under treatment, and he had been repeatedly leeched and cupped, he had been leeched from the beginning, and had been cupped and leeched into a state of anemia. The symptoms had very much subsided, and he might have been anemious from the beginning. But there might have been merely a deranged state of the stomach and bowels, and the repetition of blood-letting only led to an aggravation of the symptoms, by aggravating that state of things that is commonly associated with the state of anemia. I put him under a different treatment, and I went so far as to prescribe preparations of iron for the anemia, and a frequent and moderate supply of meat, to which I added a little wine. From that moment he recovered.

This suggests an important distinction with regard to the premonitory symptoms of apoplexy. Sometimes they are altogether those of a flow of blood to the head, or a state of plethora, and on the other hand, there is the opposite state, namely anemia. This state does not show that there is not congestion within the head, as is proved: for if an animal be bled excessively, that animal becomes comatose, as if all the muscles were reduced extremely by the loss of blood. In that state, which is a state of reaction, many persons become affected with a state of things approaching to apoplexy,—that is to say, a little disposition to coma, and coma goes on, and then you have apoplexy.

Now with regard to the symptoms; they usually relate to the head. Vertigo, flashes of light, and noises in the ear, and a momentary loss of memory; this is the most diagnostic mark of all. The most diagnostic sign of an attack of apoplexy is a momentary loss of consciousness. In several instances in which these attacks come on, you find a momentary loss of memory, so that the patient has forgotten those things he used to know; and there is a momentary loss of consciousness, so that the patient has forgotten where he was, and what he was about, and so on. I think this more important than headache, and more important than vertigo, though that is very important. However,

all affections of the cerebral functions may be considered as relating to apoplexy, unless you can at all trace them to a disordered state of the stomach and bowels, or something of that kind. An attack of apoplexy leads you to suspect such things to take place.

Another diagnostic mark is very important. How is it in a real attack of apoplexy, a patient, generally speaking, is better from having the head very much raised? In general, when a state of inanition takes place, that must be the case. A relative of mine, frequently on coming down stairs was so giddy as to be obliged to take hold of a chair or sofa. This state of things came on generally in the morning, and it would lead you to the idea that there was plethora, so much so, as to lead to a state of inanition of the whole system. Suppose you are called to a patient with some of these symptoms. Look to the countenance, and see whether the features are sanguineous or flushed; inquire into the habits of the patient, and consider the constitution of the frame, and so on, and see whether the patient is apoplectic. Now suppose you come to the conclusion that there is really an attack of apoplexy; your only safe-guard in such a case is this:—throw the patient into a state of exhaustion by placing him in a chair, upright, with his face looking towards the ceiling, and let blood flow. This important fact was impressed upon me by an individual case, which I will now relate. A gentleman some years ago, a most active person for his days, fond of sporting and hunting, and who seemed altogether to be quite a *bon vivant* when young, complained of symptoms which seemed to be those of apoplexy. He was bled until an incipient state of syncope was produced. I observed that the patient lost ninety ounces of blood, and did not faint at all, and I have to add to this remark what I have added on former occasions, that he never suffered from the loss of blood. Remember you have two things, one is merely incipient syncope, and the other, the remote effects of the loss of blood. He did not suffer from the remote effects of the loss of blood, though he lost ninety ounces. What do I mean to shew by relating such a case as this? Why, simply to shew that this is a case of all others in which the patient bears the loss of blood best. I do not bring this as an example; but if you follow the measures adopted in this case, you must place the patient in an upright position, and bleed until you have produced some impression on the whole system. I do not recommend you to take ninety ounces of blood, for I hardly think the human frame can spare so much blood. However, this patient did, and he escaped every symptom of the remote effects of the loss of blood. At any rate, before adopting this measure, you should acquire a vast deal of information respecting the individual case. In the first place, you learn whether the brain is affected; then, if you find that the patient is robust, and bears the loss of blood, you may generally come to the conclusion, that this is a state of things that requires it, unless you find by your diagnosis that the symptoms will be followed by a more serious attack.

I now pass on to attacks of apoplexy. Attacks of apoplexy must be divided into two, invariably; for practice sake and for the sake of the prognosis, and everything interesting in such a case. The two states into which apoplexy has been divided are, the case of mere fulness or congestion, and the rupture of a blood-vessel. These two cases, you see, are different. The one is a case in which it is important to use active remedies, and the patient is almost sure to recover; in the other case, in spite of all the remedies you may employ, the patient may not recover. I do not say that a patient does not recover from a state of rupture, but he is never in the same state that he was before. Now in a violent attack—I am going now to state what I have observed in an actual attack of apoplexy—a case which is not one of rupture but one of mere fulness—the patient in such a case, is taken with apoplexy like a thunder stroke; just like a thunderbolt strikes a man, and he falls down, and is perfectly unconscious. No impression can be made on his mind, or any of his senses. You see him ...

nance, and laborious breathing. If the symptoms are confined to the cerebral system, they are infinitely less important; but there is danger the moment you find the symptoms begin to involve the symptoms attached to the spinal marrow. Suppose a man in a state of deep apoplexy, so that you can hardly produce any sensibility by pinching him, or shouting in his ear; still, if he breathes well and swallows well, and there are no spasmodic symptoms, that man is sure to recover. But the danger comes on when there is choking in swallowing, and the spasmodic affection is just in proportion to the violence of the symptoms.

Gentlemen, the danger is in proportion to the violence of the symptoms, and in proportion to their duration. For if you bleed a patient, and he is rendered better, and the symptoms are mitigated, I need not tell you that your hopes revive; if you leave him, and he is no better, I need hardly tell you that your hopes are cast down. Not only is the violence of the symptoms important, but also the duration. These symptoms, when continued, in spite of active remedies lead to a terrific prognosis, which is worse as these symptoms are gradually increased. If you have a violent case, and it subsides a little on letting blood, then your patient will most probably recover; and if you have a violent case, in which the symptoms do not subside at all, then your patient will die. If you have a moderate case at first, and the symptoms greatly increase, that is always fatal.

I may mention a case now while I think of it. A patient had the symptoms of apoplexy, and he could not swallow. I asked the question, "is the swallowing any better?" I was told "no," and I said "your patient will surely die," and he did die. You see what I mean then; that if the symptoms are not mitigated, the patient is not in a state of hope; even if they are not violent, and the symptoms augment, there is danger still. There is another case I may mention; it is that where a patient has had a slight attack, and in the midst of the treatment he comes to have another, and perhaps a third. That is almost sure to prove a fatal case.

So far, then, with regard to the symptoms, and with regard to the prognosis. In this cure, the remedy is, as I said before, blood-letting; and all I can say is, that you must adopt the measure I recommended to you, that is the common mode. You must place the patient perfectly upright, and bleed until some impression is produced upon the system. You must continue this until the cheeks become a little less livid, and until you have induced an alteration in the state of breathing, and you begin to see only a few dew drops are on the forehead. I mention these symptoms because you are to seize the very first of them, and then you will not have to let blood any further. Blood-letting is the remedy, and it has the effect of leading you not only to determine the diagnosis in the case, but any one can tell whether the case is one of apoplexy or not. The object of the diagnosis is to ascertain whether it be a state of apoplexy, and then to lead you on to the prognosis.

Now I want to pass on to a case of rupture of the vessels which is a totally different affair. If then, there is rupture, and there are violent symptoms, and the patient is taken with apoplexy, do you know what is the diagnostic of rupture? How do you determine it? The diagnostic mark is congestion and paralysis. If you pinch the foot and hand, on one side or the other, and find the foot withdrawn, and the patient is in a state of utter insensibility, which may occur, you may hope there is only congestion. I give this to find the diagnostic mark, whether there is rupture or not. I do not know whether I am pressing too strongly on this subject, but practically, with, perhaps, some exceptions, this is true; however violent the apoplexy may be, if you find the limbs retract on being pinched or pricked, or touched, you may merely hope that it is apoplexy without rupture. But if you find that instead of this being the case, there is distinctly on one side paralysis, you may be perfectly certain that, violent as the form of the disease is, the case is hemiplegia, and the patient can hardly be said to have any chance of recovery. But suppose you find there is hemiplegia; ...

be this. You have got hemiplegia:—look to the degree and violence of the apoplectic symptoms, —the cerebral symptoms:—there is danger or there is hope, according to the violence of the symptoms. If there is no violence, if the symptoms be slight, and there be hemiplegia, it is always a very serious case. The patient may recover, for a time, but he cannot live. Then you may have violent hemiplegia in a state of apoplexy, or you may have it without any apoplexy at all. A patient, with a brother of mine, was attacked with hemiplegia. All at once he fell down as if shot; he could not move one side, yet his senses were entire. It was quite obvious that even without apoplexy he had a violent attack of hemiplegia. With this hemiplegia there was a difficulty of swallowing, and when these two things go together, you may be sure that something has occurred, and that nature cannot recover from such a state as that. I have a preparation here, that of a cyst extending into the ventricle, and I need not tell you, that when a cyst extends into the ventricle, recovery is next to impossible. If there is violent hemiplegia with a cyst extending into the ventricle, respiration can scarcely take place. The attack is marked by complete hemiplegia, and hope scarcely exists in such a case as that; when the hemiplegia is complete, the prognosis is exceedingly low indeed, and exceedingly fatal.

Now I want to bring a few remarks before you, relating to the degree in which you are to hope or fear the recovery of a patient. Now suppose there is hemiplegia; if hemiplegia be confined to the arm and leg, even if it is very severe, still there may be a degree of hope, because a cyst in the hemisphere of the brain, not communicating with the ventricle, may produce this state of hemiplegia. If there is hemiplegia in the arm or leg, and with this, paralytic affection of some other part, I need hardly tell you, the disease bears a more aggravated character. Now what other parts are to be affected to produce this? In the first place, the eyelid is affected. Tell a patient (I am supposing the patient is not in a state of deep apoplexy) to close his eyes, and he does so, but you find that one is much better closed than the other. If the left side is paralysed, and the patient is told to close that eye, the corner of the mouth is raised, and the other side of the mouth falls a little. Another remarkable diagnostic is that the tongue is drawn to the paralytic side. The angle of the mouth on the paralytic side is drawn upwards, and on the other side it is allowed to fall down.

I may here make an interesting remark, that in no case of hemiplegia I have ever seen, have I ever seen the eyelid not closed. But it is a very different thing when you have paralysis of one side of the face from disease of the *portio dura*, or seventh pair of nerves; for then the eye does not close at all. But here you have complete hemiplegia of the voluntary part of the nerve, the eyelid closes with every part of the opposite side, though not as it were, on the principle of association, as it has been made out recently by Professor Muller.

I will first now explain to you, that you may be aware of the fact, why the tongue is drawn to the paralytic side. You have seen the *sterno-cleido mastoideus* muscle, and you are aware of the division of the fibres of this muscle. If one side of the tongue is paralysed, the tongue will be drawn to that very side on account of the direction of the fibres. Now suppose you have paralysis, it is quite plain that here the head will be drawn a little to the paralysed side, because the *sterno-cleido mastoideus* has oblique fibres passing from a centre to a point more distant from the others. When the muscle contracts, the direction of the head is to the paralytic side. This may very often form the subject of question in an examination, and is very important.

Well then, I now go on to another set of functions, and those local symptoms which relate to the true spinal system. The state of breathing:—in a state of deep apoplexy the breathing very often becomes stertorous. If the state of breathing, under the influence of remedies, becomes mitigated, the patient will probably recover. Suppose that after having bled a patient to the utmost that you dare,—and that you ought to bleed a pa-

tient,—the symptoms are not relieved, the patient will almost surely die. So with regard to another nervous symptom, which I always regard with terror, namely, the difficulty of swallowing. There never is difficulty of swallowing with apoplexy, but it is a fatal sign. It is a sign of great danger, and if it continues in spite of remedies, the patient is almost sure to die; but if it becomes mitigated, he is almost sure to recover. If this state of things comes on after the first attack, then all I have to say is, that it is a worse sign, according to the rule given at the beginning of this lecture. Here, then, the true spinal system is involved. How is the true spinal system involved? Simply because of counter pressure. Violent congestion of the brain, and therefore counter pressure of every part within the skull, and at the base of the skull. There exists a part of the true spinal system at the top of the medulla oblongata. If that be pressed upon, you will have difficulty of breathing, and there is difficulty of swallowing for the same reason. If then blood-letting does not relieve the patient, and this state of things continues, it invariably leads to fatal results. You may be sure it is a state of congestion.

Now, in congestion, generally speaking, the pulse is strong and moderately slow; on the other hand, in laceration, or the rupture of a blood-vessel, or the laceration of the substance of the brain, you may remark that the countenance becomes pallid, the pulse feeble, and at the same time there is some difficulty with regard to the capability of bearing the loss of blood. I have told you already that no disease bears the loss of blood equal to the state of congestion in the head, either before or after an attack of apoplexy, but especially before. In an attack of apoplexy, a patient bears the loss of blood extremely well.

But then there is laceration. This occurs when a shock is impressed on the whole nervous system on the whole system precisely like what we can observe by experiment. Take an animal of [illegible] and crush the brain, and you see the heart loses its power. By and by the heart recovers from the shock, and the circulation goes on. Just the same thing occurs in the human subject in a violent accident, or a violent convulsion, or a violent attack of apoplexy. Therefore, in that case, you have all the symptoms that I have detailed to you, to which I add the influence of the shock. Now I need hardly tell you, that under the influence of a shock, the patient cannot bear to lose much blood. Now I am perfectly certain that many a life—I do not say that many a death on the other hand has been caused—but many a life has been shortened by taking blood under the combined influence of an attack of apoplexy and the paralytic state, and the shock produced on the brain. Therefore in a case of congestion, blood-letting is attended with some danger, and so in the case of apoplexy, combined with laceration, you may bleed, but with extreme caution. If you do bleed, the patient [illegible] suddenly sink altogether; if that is the case, he does not bear the loss of blood well, and if the symptoms are not alleviated, perhaps the patient will never recover, but he gradually sinks and dies. I shall never forget a case that occurred in my early practice. I bled a patient [illegible], and to my [illegible] and astonishment, that patient, instead of being relieved, sank from that moment. I am persuaded that [illegible] blood-letting [illegible] to be deprecated, because there is the danger of precipitating [illegible] into the [illegible].

I have hitherto been talking on the subject [illegible] very [illegible] [illegible] [illegible] the rupture be confined to one part of the brain and is not extensive [illegible] that hemisphere, the patient [illegible] probably live, though he does not [illegible] perfectly [illegible]. Now it has been [illegible] by [illegible] French physiologists—I believe I may almost say established—that there is a certain effect produced, be the clot in this or that portion of the hemisphere—whether anterior or posterior. I need not tell you that a clot in one hemisphere paralyses the opposite side. There is always this effect:—if you have a complete cyst running along one hemisphere, you will have complete hemiplegia of the other side of the body. Now suppose the cyst is not so extensive and does not extend along the hemisphere, but is confined to the anterior lobe of the brain; I give you here a useful mnemonick, and if you comprehend it once well, you will never forget the effects,—there is an affection both of the right and the left side. There is a double cross effect, because when the anterior lobe is affected, the posterior lobe is also affected, and when the anterior lobe of the brain is affected, it is the anterior extremity that is affected, therefore there is a double cross effect from side to side, from before backwards, or from behind forwards.

Well then, the next question is whether any other part is affected. I must mention one matter. When the clot has been confined to the middle lobe of the cerebellum, it has been said that there is a peculiar effect upon the genital organs, so that Mr. S., on one occasion, passing round the wards of an hospital with me, accompanied with some friend, said, "what would you say, if I were to say that it is not the cerebrum that is affected, but the cerebellum that is affected?" I replied, "I should think you very bold;" and he said, "I am very bold then, and I say that the patient will most surely die." On the post-mortem examination, it appeared that it was not the cerebrum but the cerebellum. He asked for the diagnosis, and he observed on examination, that the abdomen was in a state of sexual excitement. It had been thought, according to Gall, that the sexual organs are more or less under the influence of the cerebellum, and this showed at once that the cerebellum was affected in this case. I do not give that as a proved fact, but certainly the inference, (not as to the diagnosis) that the cerebrum has not anything to do with it, is true. A case occurred to a friend of mine—a case of deep apoplexy. There was nothing particular in that case, and the usual remedies were applied, but he said the patient will surely die. He did so, and on examination, there was found a clot in the lobe of the cerebellum. The question came to be whether there had been any excitation or sexual efforts more than usual. Now it so happened, that the patient had been hitherto devoid of all sexual desires and power, and yet on the night previous to the attack, he for the first time manifested such power. I came to this conclusion, and you will see I was perfectly right, that the cerebellum was affected. But though this attack led to some manifestation of sexual affection in that patient, I am very far from coming to the conclusion that therefore the cerebellum is the centre of sexual affections. There are facts which lead to an opposite idea. In the first place, the lobe of the cerebellum is just over the medulla oblongata, and being in such contiguity, it may affect it by counter pressure, or in any other way. You cannot say, having two organs affected, which is the source of the function. You have these two involved, and therefore you must not conclude that it is the cerebellum, or the medulla oblongata that is affected without you know something more.

Now there are certain other effects. It has been proved, that where there is an injury of the medulla oblongata, there is a manifestation of the sexual organs, proving invariably that the medulla oblongata is connected with the sexual organs; and on the other hand, it has been proved, that where there has been an absence of cerebellum, there has been a manifestation of sexual power, and, in fact, the general conclusion is, that the cerebellum has nothing to do with the manifestation of sexual desire or power, but, in fact, that the function is one of the medulla oblongata. I dismiss this subject because it is one more of curiosity than of practical importance.

But there is another point I must bring before you, because this point is really important. Sometimes you find there is a case of apoplexy which terminates suddenly—in a moment. Formerly you heard of sudden death being traced to disease of the brain, disease of the lungs, or of the heart. But you find in all works on medical jurisprudence at the present day, that disease confined to the brain never leads to sudden death, —that is to say, disease confined to the brain itself. You may remove the brain without that operation leading to sudden death. An animal so mutilated continues to breathe, and swallows, and performs all the functions of the true spinal and ganglionic system. If then, you have a case of apoplexy in which there has been instant and sudden death, you may be sure that something else has happened. Now what are the symptoms? Such a violent congestion of the whole brain as to compress the medulla oblongata, and to cause its functions to cease. You may have a violent laceration of the whole brain, or of one hemisphere passing from the anterior to the posterior lobe, and passing into both ventricles, and that may produce sudden death in two ways. First of all, the violence of the shock impairs the action of the heart, and then the compression of the medulla oblongata annihilates the actions of respiration. A case occurs to me at this moment, where the patient died in a moment; and the question came to be, what was the disease? I should tell you, that previously she had had some paralytic affection, and on examination, a clot was found just between the median lobe of the cerebellum and the medulla oblongata. This, of course, pressed on the medulla oblongata, and produced sudden death.

Now remember the remarks I made. If you have such a disease, however severe, if it is confined to the brain, it will not produce sudden death. But if you have such a disease pressing on the medulla oblongata, or if there is a clot of blood situated so as to compress the medulla oblongata, respiration will cease, and the action of the heart will cease altogether. Sudden death may occur again in disease of the cranium, or disease of the head itself.

You see, then, so far as I have gone into the subject, the important conclusion to which I come, that disease of the brain will not produce sudden death, unless that disease of the brain be accompanied with such violence as to cause counter pressure on the medulla oblongata, or to produce such a violent rupture, as to cause the blood to escape not only into the cavity, but into the ventricles, or to form a clot pressing on the medulla oblongata.

I will now call your attention to what Cruveilhier has noted on this subject:—He says, that you may have apoplexy from an injury of the tissues, and not from rupture so that there is a clot of blood poured out, but there may be an enlargement of the capillaries—the blood thickening in the vessels. In the other case, you see the blood has actually escaped out of its channels, and found a cavity for itself. One case is capillary apoplexy, and the other is altogether apoplexy from rupture.

There is one other point I want to shew you, because it is important. I have told you that under various circumstances you may have apoplexy or hemiplegia. Now I need not tell you more than recall your attention to the anatomy of the base of the brain, in order to lead you fully to understand the variety of circumstances that take place in apoplexy, which you can hardly understand, without reference to the anatomy of the base of the brain. In case of compression of the medulla oblongata, you have cessation of the respiratory functions, and therefore speedy death. Suppose there is such a state of things in apoplexy or rupture, that you have a pressure on any of the nerves at the base of the brain, I need hardly tell you in that case you will have blindness and deafness; and in this manner I believe for the most part, you may explain those peculiar phenomena that sometimes occur in this case. Another important thing to bring before you is this. There is another kind of apoplexy in which the blood-vessels at the base of the brain are affected. A case is given at large in the *Annale de Medicale Societe, &c.* Now I want you to observe that in this case there is not anything very peculiar and my very excellent friend, Dr. Graves, of Dublin, has furnished a case having precisely similar effects.

I have now given you my views on the subject of apoplexy and paralysis, and I must conclude with a very few words respecting the mode of treat-

ing such an attack. In the first place, in an attack of apoplexy or congestion, I believe the remedy should be blood-letting. The patient must be bled first upright, and generally speaking, the blood should be allowed to flow until some slight impression is made on the countenance, or the breathing, or the pulse, or the skin. If you have hemiplegia, then, I say, beware of blood-letting: use caution, be watchful of the cause of the disease, and then I have nothing more to say on the subject. You remember the case I referred to, which occurred early in my private practice. I have held blood-letting since in *terrorem*. What is to done further? After blood-letting and cupping, we should resort to what will not harm the patient, for we dare not do anything further to the vascular system—I mean purgation. I recommend to you now croton oil. It was recommended by Dr. Abercrombie. There are other remedies of the same kind. It has this peculiar property, that it promotes the circulation of fluids by slow degrees. After this, all you have to do is to watch the patient, and to adopt such measures as the case may require. For instance, leeching or cupping may be adopted from time to time; the patient may be raised up in bed and counter irritation applied to the posterior part of the head. The patient may then be placed under the influence of mercurial powders, and when I say that, I want you to observe, that if a patient does not recover soon, he scarcely ever does recover. If the attack comes on in the early part of life, it may be felt under many circumstances. It may come on whenever a patient is indisposed, or in any way attacked with fever, then the old complaint comes on. I have a patient in my eye when I tell you, that he had an attack at the age of 25, from which he seemed perfectly to have recovered, but he felt it again at the age of 40, when fever came on; and whenever he had fever, or was in any indisposed, he always felt a weakness of the paralytic side. When he got into years he walked lame. Nothing, in my opinion, converts young men into old men so completely as an attack of hemiplegia.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE VII.

Articular Amputations of the Upper Extremity.

Gentlemen,—When all efforts to preserve a limb or an important part of it, are evidently about to fail, when the general health of the patient is suffering from the progress of local disease, or life is endangered by the temporary condition of a part which has been the subject of accidental injury, we in many cases are obliged to have recourse to operations which mutilate the body, for the purpose of prolonging the life. It is undoubtedly better to live with three members than to die with four—hence the propriety of removing one (or even more) where its amputation is essential to existence. Leaving, therefore, the elementary operations with which we have been hitherto engaged, we proceed to give an outline of the operative surgery of the different amputations of the extremities, reserving for an after lecture some general remarks on these operations, and on the circumstances in which they ought, or ought not, to be performed.

We will first speak of the operations at the joints, where contiguous bones are separated, afterwards of the more commonly performed amputations, where the bones are divided with the saw.

Amputation of the Fingers.

In these cases the stump of bone may be covered by one flap taken from the dorsal, or from the opposite surface, or by two smaller flaps taken equally from both; or instead of looking to the anterior and posterior surfaces for soft parts to cover the denuded bone, a couple of folds of integument may be obtained from the sides of the articulation, which may be cut so as to approximate evenly in the middle line; the practice of making a circular incision a little below the joint, and then a short and straight incision upwards on each side, so as to form two flaps, is troublesome and but seldom resorted to.

When two flaps are made in such small amputations the process is a tedious one, and occupies more time than we should like, beside which when the parts are subsequently united, the line of cicatrix crossing the middle of the stump either from side to side, or from the dorsal to the palmar surface is much exposed to accidental injury and contusion from various causes, which in some cases for weeks or even months after the healing, might be the source of considerable suffering; hence the adoption of methods of operating such as those which have been recommended by Lisfranc, passing the knife at once into the joint, dividing the lateral ligaments, thus opening largely the articulation, and lastly cutting a flap from the dorsal or palmar surface, or from that aspect of the finger which is opposite to the surface where the knife first entered. Suppose the middle finger were operated on, in either of its two middle joints, and the flap made from the palmar surface, the skin on the dorsum of the finger had better not be divided immediately over the articulation, but a line or two below it, this incision being a little convex downwards; cut in this way it would hang neatly over the dorsal border of the extremity of the phalanx to be left behind, merely just turning over its edge to meet the flap—brought towards it from the palmar aspect—the latter affording the main covering to the stump.

After this first incision is completed, the knife readily enters at the back of the joint, especially if the portion of finger we are removing be a little flexed on that which is to remain, (the finger operated on having hitherto been held in the extended position, while the remaining fingers of the same hand are bent toward the palm and rest on some firm support.)

The next step is the division of the lateral ligaments, which might perhaps be regarded as *one* of, if not *the* most important part of the operation; this should be done rather with the point than with the middle of the bistoury, so as to avoid cross-cutting that part of the integument from which the main flap is to be formed.

The last step of the operation is commenced by gliding the bistoury, which has already traversed the articulation, along the other side of the phalanx to be removed, keeping it close to the bone; it is thus carried far enough to obtain a flap which will cover the exposed extremity of the stump, and the operation is completed by bringing it outwards.

In terminating this operation, it is better not to cut out too suddenly, and without any previous and gentle inclination of the knife, for if we do so, a stunted flap too thick at the edge will be formed, which it is more difficult to manage or to join with the opposite portion of integument than where the knife has been brought out less abruptly.

It is easy to reverse this operation by commencing it on the palmar surface, and taking the flap from the dorsal. Operations on the corresponding joints of the other fingers and of the thumb may be performed in a similar manner.

Metacarpo-Phalangial Amputations.

In amputating the fingers at the joints away from the meta-carpus, the flaps to cover the stump are obtained from the dorsal or palmar aspect of the finger, as may suit the choice of the surgeon or the peculiar circumstances of the case, but in removing the entire finger at the joint with the metacarpal bone, the flaps are mostly obtained from the sides of the latter at its extremity, in other words from the web of the fingers.

Supposing the middle finger to be removed in this operation, the patient puts forth his hand, which is taken and held firmly by an assistant, who draws the little and ring finger on the one side, and the thumb and fore-finger on the other as widely apart as possible, thus affording ample space for the surgeon to attack the middle finger, all the set being extended; the finger has now to be removed at the joint, sparing the surrounding soft parts as much as we can; the bistoury is placed on the prominence of the knuckle, and thence carried through the web of the fingers to the palm, the incision terminating in that part where the cuticle becomes indurated and thickened in labouring people, or just above the upper of the two folds seen on the palmar aspect of the root of the middle finger.

The joint is now to be opened, it will be found behind the most prominent part of the root of the phalanx, and to this the surgeon may, as it were, feel his way, the bistoury being held perpendicular to the metacarpus; and entering the joint may, in some cases, be a little facilitated by making traction on the finger to be removed, while the assistant fixes and holds firmly the hand for in this manner the ligaments being put on the stretch, the line of separation between the bones is more easily discovered the ligaments divided, and the articulation traversed, the surgeon turns the edge of the bistoury towards the tip of the finger, and keeping it close to the bone on the other side of the root of the phalanx, takes care not to bring the instrument out too soon, but cut a flap corresponding to that made by the first incision.

In passing through the joint it is well to bear in mind the cupped form of the end of the phalanx, and the rounded extremity of the metacarpal bone articulated with it, and to guide the knife accordingly.

The neighbouring fingers being bandaged together with a little broad tape, the bleeding is in most cases soon arrested, especially if the operation be performed after accidental injury to the part; in those cases, however, where the finger has long suffered from the progress of chronic disease, the enlarged arteries occasionally require ligature: union by the first intention will generally take place if the flaps be kept in neat apposition.

When this amputation is performed by what is called the oval method, the incision is made completely around the root of the finger, commencing and terminating at the same point on the knuckle; the integument is then a little turned up and the disarticulation effected.

In another method called the circular, the dorsal aspect of the incision does not mount so high, for it is carried round the root of the finger on a level with the upper line of fold in the palmar integument; the joint being farther removed from the first incision, the disarticulation by this method is more difficult.

Of the three operations here noticed, the first with two flaps; the second by one oval incision, the third by one circular incision; the former, or the flap operation, is most frequently performed in this country. Some have recommended the oval method as interfering less with the integument of the palm, and leaving a cicatrix which does not encroach so much upon it; the circular operation not so easily performed as the others, and possessing no advantage over them, has had but very few advocates.

When a corresponding operation is performed on the fore-finger, or on the little finger, the radial flap in the former, and the ulnar in the latter instance, should be cut a little longer than when either the middle or ring finger is operated on.

So much for the removal of the fingers separately, sometimes, however, the four require to be taken away all together. Suppose we operate on the right hand; it is placed in a state of pronation, and the surgeon, as if for converting the four fingers into a one member to be removed, grasps them firmly together in his left hand; a narrow and strong bistoury is required, which is carried across the roots of the four fingers, cutting from the little finger to the index, (right side,) thus making a dorsal flap which is slightly convex downwards, one extremity of it corresponding to the ulnar side of the metacarpal articulation of the little finger, the other corresponding to the radial side of the metacarpal articulation of the fore-finger; but it is better that the incision should commence and terminate a little below these points, that sufficient of the soft parts may be left to cover the denuded bones.

The metacarpus being elevated and supported by an assistant, the fingers are now forcibly flexed towards the palm, the dorsal ligaments, and extensor tendons thus put on the stretch, being firmly touched with the point of the knife, are cut across, and the joints laid open one by one, the

lateral ligaments being divided and the ends of the bones set free, the surgeon proceeds to form the palmar flap by gliding the knife under the metacarpal phalanges, and at the same time bringing it from the little finger towards the index, each finger being taken by the assistant as the knife separates it from the rest; in completing the flap in the palm, the surgeon should take care that he obtain a sufficient piece from the root of each finger, for this joined with the integument from the opposite or dorsal aspect, will suffice adequately to protect the four-fold metacarpal stump; for this precaution is required, although in this operation the chief flap is taken from the dorsal aspect of the root of the fingers.

When the four fingers are removed together by what is called the circular method, the knife is passed over the roots of the fingers on both the dorsal and palmar aspects, the incisions corresponding to the folds on the palmar surface; the incision for each finger is turned a little on its side, so that the dorsal as well as palmar incision being semicircular, the course of the knife as described, suffices for completely dividing the integument, the joints are next opened and the fingers removed. By this plan a somewhat greater portion of soft parts is preserved to cover the metacarpal stumps; the circular method may also be employed when two or three only of the fingers have to be removed.

We proceed now to notice those articular amputations of parts of the hand which are performed between the carpus and the metacarpus, or the

Carpo-metacarpean Amputations.

We will begin with the borders of the hand, speaking first of the amputation of the thumb with its metacarpal bone, (not discussing at present whether this be a metacarpal bone or a phalanx,) afterwards proceeding to the amputation of the little finger with its metacarpal bone; we will next describe the mode of operating in removal of the index, the middle, and ring finger, with the corresponding metacarpal bones, and lastly, the operation for removal of all the four fingers with the metacarpal supports which belong to them.

Amputation of the Thumb.

The patient puts forth his hand, the assistant seizes the fingers, the surgeon seizes and forcibly extends the thumb, thus stretching the web between it and the fore finger; the edge of the bistoury is now applied to this web, and the instrument being kept close to the bone of the thumb, is carried onward to its articulation with the carpus, where it is stopped by the os trapezium, its edge is now directed towards the radial border of the thumb and the articulation traversed; the edge of the bistoury is next turned towards the nail of the thumb, and a flap is cut from the dorsum, the knife being brought out a little below the metacarpo-phalangeal joint; in cutting this flap the surgeon raises the integument with the fore-finger and thumb of his left hand, thus obtaining a full sized flap, or one sufficiently large to meet the opposite section.

The hitting of the joint and opening it may be facilitated by a method alluded to before, the surgeon making traction on the thumb while the assistant holds the hand firmly, thus separating a little the articulated surfaces of the bones, and bearing the thumb also away from the rest of the hand, which will put the inner ligaments somewhat on the stretch, and thus help the bistoury into the joint; the bistoury for this purpose should be strong and narrow, somewhat like a lengthened penknife, but very stiff.

It is more or less difficult to form the flap from the dorsum of the thumb in this operation, as in that region the soft parts are not abundant, in consequence of which it is occasionally recommended to complete the division of the soft parts before the disarticulation is attempted; the flap may, in this way, be formed precisely in accordance with the wish of the surgeon, and thus there will be a better prospect of neat cicatrization for the future; the dorsal flap being first cut, the knife next thrust down inside the thumb as far as the trapezium; and lastly, the articulation traversed and the part removed.

Amputation of the Little Finger with the Metacarpal Bone.

A bistoury similar to that used in the last operation should be employed; the surgeon directs his attention to the ulnar margin of the palm of the hand, between the fold of the wrist and the fold at the root of the little finger, which is, generally speaking, slightly convex inwards, or in the ulnar direction and more or less plump, with plenty of soft parts, muscle, and skin, whence to form a flap; an assistant holding the fore-arm and steadying the extremities of the fingers, the surgeon satisfies himself of the position of the hook-like process of the unciform bone at the ulnar corner of the palm of the hand, with which the metacarpal bone to be removed is connected; or to proceed with the description in language somewhat plainer, the operator seizes the fleshy border of the palm of the hand, at a point corresponding to the upper extremity of the metacarpal bone of the little finger, and squeezes as much of the soft parts as he can between the fore-finger and thumb of his left hand, and having got this firm hold of the base of his flap, the bistoury is stabbed through it, close to the root of the metacarpal bone, taking care to be as high as the joint; the instrument is carried downwards, keeping close to the bone to a point a little below the articulation with the phalanx, where it is brought out, the flap for covering the wound being now formed.

If the precaution here recommended has been sufficiently attended to, so that the flap now cut is of full size, there will be no difficulty in passing the knife through the interosseous space, close upon the radial side of the root of the metacarpal bone to be removed; the instrument thus passed through, the surgeon with the fore-finger and thumb of his left hand presses the soft parts whence the flap already made has been cut in the direction of the radius, while the knife is carried downwards to make its exit at the space between the little and the ring fingers, and thus the inner border of the hand, or the little finger with its metacarpal bone, is set at liberty, saving at the joint where it is tied to the unciform and to the next metacarpal bones, and this connexion is immediately overcome, first by thrusting the knife a little forcibly between the roots of the two metacarpal bones then bending forcibly backwards, (or in the direction of extension,) the metacarpal to be removed, thus putting the ligament at the inner aspect of the joint a little on the stretch, when a touch of the knife will open the articulation, by crossing which the part is removed.

It might tend to preserve more the natural form of the palm, its roundness at the inner border, and its breadth, if we could disarticulate the metacarpal bone, and take it out by a single incision on the dorsal aspect, the knife having also been turned round the root of the finger; this however is a more difficult operation than the former, but is nevertheless frequently preferred to it.

An incision is made corresponding to the course of the extensor tendon on the dorsum of the bone, and a ring incision is appended to it round the root of the finger, the sides of this wound are drawn apart at its carpal extremity; the surgeon gets his narrow knife inside the joint and turns its edge to the internal ligament which he divides; at the back the articulation is easily opened, and as in the former operation, the roots of the two metacarpals may be separated by pressing the point of the instrument between them; the little finger, with its partly loosened metacarpal bone, should now be bent towards the palm, by which the upper extremity of its metacarpal bone will be elevated, and the remaining ligamentous connexion put on the stretch; by another touch of the knife, the root of the bone will be liberated—the operation may be completed by passing the knife under the bone upon which it is closely kept, the soft parts all the while being held well apart, and carrying it onwards, to leave the part through the palmar half of the ring incision around the root of the finger, the attachments of the soft parts at the side of the metacarpal bone having previously been divided. In these operations, the extensor tendon should be pressed towards the thumb, and not divided by the longitudinal incision.

Bleeding is sometimes troublesome after these operations, and the arteries retracted into the dense tissue of the palm cannot always be secured by ligature, it is well therefore to allow the part to be exposed for some little time after the operation; or should bleeding afterwards occur, to plug the wound with lint, and make pressure by a bandage, which may remain for some hours, as recommended by Mr. Liston.

An operation, more or less resembling the last of the two described as applicable in the removal of the little finger with its metacarpal bone, has been proposed by Langenbeck in cases demanding the

Carpo-Metacarpal Amputation of the Index, Middle, or Ring-Finger.

An incision made along the dorsum of the metacarpal bone is turned round the root of either of the above-named fingers; the soft parts are separated at the sides of the metacarpal bone with the point of the knife, and the sides of the wound at its carpal extremity, being drawn apart, the dorsal ligaments are cut, and the knife passed through those on the lateral aspects of the bone to be removed; in this way the point of the knife may be got towards the palmar connections of the root of the metacarpal bone, which is the subject of amputation;—these being divided, its upper or carpal extremity must be forcibly elevated—the knife passed beneath it, and then carried onwards to make its way out by the ring incision at the root of the finger—thus completing the operation.

Operations of this kind are seldom required, and it has been remarked by Mr. Liston, that they are more frequently talked of than executed on the human body. And here we might observe, that the directions for removal of parts, as generally given, are evidently adapted to supposed operations, performed on the same parts in the healthy state, but that the effects of disease are often such as to oblige the surgeon to modify the proceedings, so as to suit the operation to the peculiarities of his individual case.

Having shortly noticed the carpal amputations of the thumb, of the little finger, and of the intervening fingers, we proceed to describe the

Carpo-Metacarpal Amputation of the Four Fingers.

Here a small flap is taken from the dorsal, but the principal covering from the palmar surface; but at the commencement of the operation, the knife is carried between the metacarpal bones of the thumb and forefinger, so as to separate the former from the greater portion of the hand which is about to be removed.

The roots, or carpal extremities of the metacarpal bones of the fore-finger, and little finger, are, in the first place, to be found, and their position and projections are such as to render their discovery tolerably easy: the former will be found more readily at the back—the latter at the ulnar border of the hand. The hand is placed in a state of pronation,—an assistant holds it firmly, extending, at the same time, the thumb, and thus opening the space between it and the metacarpal bone of the forefinger, where the work of the knife begins. We suppose the operation to be performed on the left hand, and that the surgeon has already separated the metacarpal bone of the thumb, by the incision above-mentioned. The knife is now passed across the roots of the metacarpal bones to be removed, dividing the integument, the extensor tendons, &c. A flap, a little convex downwards, is thus formed—the way to the articulations being cleared by the division of all fibrous bands in the neighbourhood, the surgeon bends the metacarpus forcibly towards the palm, and the dorsal ligaments thus put well on the stretch, yield to very gentle touches of the knife; by a little additional force the bones are now dislocated, the palmar ligaments then divided, and the knife carried close beneath the bones to be removed, prolonging the incision in the palm sufficiently to obtain a flap that will cover and protect well the carpal stump. The articulations which the bistoury has in this operation to traverse, may for practical surgical purposes be regarded as one which in its general outline is transverse, the main exceptions to this form being

at its two extremities, for the root of the metacarpal bone of the fore-finger has a somewhat zig-zag shape, and that of the corresponding bone of the little finger, is joined to the unciform in a slanting direction, the inner or ulnar border of the joint being the highest.

It is a much safer plan not to dress the wound in these cases until some hours after the operation, as bleeding is now and then troublesome, even after the surgeon considers that he has taken great pains in securing the arterial branches.

Amputation of the hand at the wrist-joint

Is a very easy operation, and may be performed either as a circular or a flap operation.

The surgeon feels for the styloid process of the radius, and for the corresponding process of the ulna, and observes the fold of the integument at the wrist, or the faint line which separates the hand from the fore-arm.

The wrist-joint is higher than might be supposed at first sight, and when we bend the hand backwards and forwards, for the purpose of discovering it, we must take care not to be deceived with regard to its position, by that degree of motion which the upper has upon the lower row of the carpal bones.

Circular Method.

An assistant retracts the integuments forcibly, another may steady the extremity of the fingers; the knife is now carried round the wrist as close upon the hand as possible, and the integument thus divided, which being further drawn in the direction of the elbow, the surgeon, by another turn of the knife, divides the tendons before and behind the joint, which last is next traversed, and the hand removed. There is no great difficulty in hitting the joint in the last step of the operation, for if its position should not be observed without such a precaution, one or two movements imparted to the half severed hand will shew where the knife should enter.

Flap Operation,

Performed more or less in the same way as in amputation of the fore-arm, a little higher up. A small catlin is passed across the front of the joint, and is brought out upon the commencement of the hand, dividing all the soft parts between the exterior of the fore-arm and the anterior aspect of the joint; in other words making a flap in this situation, which is slightly convex downwards. In making this flap, the surgeon will do well to get hold of the integument from the sides of the wrist as much as possible; it will afterwards be easy to include all the remaining integument and soft parts behind the joint in the next flap, which is formed in the same manner as the other, the knife passing close behind the bones.

The two flaps being formed, it does not matter much whereabouts the point of the knife first enters the joint. If the hand be a little bent back, or in anatomical phrase, extended, the anterior ligament being put on the stretch will easily yield to a touch of the catlin, and the articulation once opened, we need not employ more words to shew how the operation should be completed, although it may be well to remember, that the lateral and anterior ligamentous bands are stronger than the corresponding structure at the posterior aspect of the joint.

By the method of M. Lisfranc this operation is very speedily performed. Having cut the two flaps, they are drawn towards the elbow by an assistant. The operator then applies the middle of the knife on the lateral ligament of the radial side, and forcibly carries the instrument through the curve of the joint, and thus separates the hand from the fore-arm;—a brilliant proceeding, but an operation the results of which are regarded as less favorable than those of the circular method.

Amputation at the Elbow Joint.

To discover the exact position and direction of the elbow joint is also not quite so easy as might, at first sight, be supposed. The surgeon applies the fingers of his left hand to the projecting tuberosities of the humerus, inside and outside; the joint, however, is not, as we are all aware, immediately below them; but if a line be drawn between their most projecting points, and we suppose a line in the same direction somewhat less than an inch lower down, we shall have pretty nearly imagined the position of the joint.

In Lisfranc's operation at the wrist joint, a knife may easily be carried across the articulation, and will readily enter at either side; not so with the elbow: on the radial side, the instrument enters at once, as there is ample space for it (during extension) between the head of the radius, and the corresponding part of the humerus; the approximation, however, of the ulna, and the corresponding trochlea of the humerus, is much closer; along with which the winding course of this side of the joint refuses easy admission to the knife.

Hence two practical cautions,—1st, to take care that we do not mount too high in the bend of the arm in cutting the anterior flap; 2d, that we do not attempt to open the joint by commencing on its ulnar side. These are worthy of being remembered, although even Dupuytren could forget the former, and err as often in consequence.

Flap Operation.

The bend of the elbow is transfixed by a catlin kept close to the fore part of the joint: it is carried downwards in front of the bones, and a flap of about three inches in length is cut from the fleshy part immediately below the joint, which is sufficiently long to fold backwards, and cover the end of the humerus about to be exposed. The integument behind is now to be divided, on a level with the commencement of the first incision: the knife next enters the joint between the radius and humerus, where it is soon arrested by the ulna. The ligament at the ulnar side of the joint may now be divided, and the fore part of the joint completely opened: next, the fore arm may be a little flexed on the upper arm, by which the olecranon will, as it were, be brought down, and the point of the catlin carried around it, will divide its ligamentous connections, and sever the tendon of the triceps, by which the operation is completed.

It is not difficult to enter the knife at the radial side of the joint at the same time that we divide the integument at the back, and the surgeon may, if he think proper, pass a saw through the olecranon, and leave its extremity attached to the tendon of the triceps. In operating on the right arm, the catlin may be introduced from within, outwards—from without, inwards, on the opposite limb.

Circular Operation.

The integument is divided around the fore-arm, three fingers' breadth from the joint, and then dissected upwards. The catlin is now passed around the limb, through the soft parts, dividing the tendons of the biceps and brachialis anticus—the anterior and lateral ligaments: the joint is forcibly luxated—the point of the knife carried around the olecranon, and the operation completed.

If the integument, after the first incision, be dissected up as far as the articulation, and the muscles afterwards cut as high as the line of the joint, the humeral artery will be divided before its bifurcation, and the trouble of securing blood-vessels abridged; besides which, the flap will consist almost solely of integument, which will be favorable to the future healing by the first intention; hence some surgeons give the preference to this mode of operating.

Amputation at the Shoulder Joint.

The arm may be separated from the trunk at the shoulder joint, in several different ways, as it is evident that the contour of the incisions for effecting this object might be very much varied, for if a circular incision were made around the arm near to the joint, and the integument sufficiently dissected up, the knife might be got into the joint—turned round the head of the humerus, and brought out on the axillary side of the arm, and in this way, the limb removed: or, if instead of this mode of commencing the operation, which is the same as in the ordinary or circular amputation of the upper arm, the outer half of the division in the integument should be carried higher than the inner, so as to make an oval section of the skin—its upper extremity a little below the acromion—the lower at the inner aspect of the arm,—a kind of oval operation would be performed, and the soft parts, from before and behind, afterwards united in one line on the external aspect of the stump. Again, the operation may be performed by making one flap of the deltoid, carrying the knife through its base near the joint, and cutting outwards in the direction of its insertion. Or instead of one flap, we may make two,—one from the outer and fore part, the other from the opposite aspect of the upper part of the arm.

The operation by the oval incision, however, before-mentioned, would be rather awkward of execution, unless a single and straight incision were added to it, going from the middle of its upper part towards the point of the acromion, and this might be said still more of the circular incision; so that, in reality, the methods of operating which have been chiefly advocated,—are the single flap—the double flap, or method of Lisfranc, and a modification of the oval, or method of Larrey, although the circular operation, or method of Ledran, has been practised and praised by different surgeons—English, French, and German.

The flap operations are easier of execution, but the oval or circular methods leave better stumps—hence some surgeons prefer the operation of Larrey to all the others which have been proposed; but it will be readily understood, that we are not often called to amputate at the shoulder-joint, except in cases where the neighbouring parts of the arm have suffered from the progress of disease, or are shattered by accidental injury, so that the method of operating will often, as it were be dictated to us by the state of the parts, or by circumstances over which we have no control: hence in cases where the integument, at any part near the joint, has suffered so much that it would be in vain to attempt its preservation, we must seek to cover the glenoid cavity about to be exposed, by a flap from an opposite aspect. In the

Single Flap Operation.

A catlin is passed through the outer side of the arm, close upon the head of the humerus, carried downwards towards the insertion of the deltoid, and a flap of sufficient length cut from the body of the latter muscle; next, the capsule of the joint is opened on the outer side, the point of the knife carried round the head of the humerus, which being set at liberty and dislocated by moving the elbow, the knife is again applied on its inner side and the limb separated from the trunk.

The first flap is raised by an assistant as soon as it is formed, who continues to hold it over the top of the shoulder, and the same assistant may, with the fingers of the other hand, seize and compress the artery in the axilla before the last stroke of the knife is effected.

Double Flap Method.

The first flap is formed in the same manner as the flap in the operation just described, save that the catlin is introduced at a point nearer to the hinder aspect of the axilla, so as to make a flap in this direction, by passing the point of the instrument over the head of the bone, at the same time elevating the handle so as to get round the head of the bone easily, and complete this first transfixion at the anterior margin of the deltoid.

This flap being raised the joint is freely opened, the arm carried across the chest, and the head of the humerus dislocated. The knife is next passed behind the head of the bone, and brought out through the remaining soft parts, so as to form a second flap, in size corresponding to the first. When the second flap is being formed, an assistant follows the back of the instrument with his fingers so as to secure the axillary artery.

We have described the operation as performed on the left arm. When the right has to be removed, the knife enters at the anterior border of the deltoid, and passes on near the posterior margin of the axilla, the surgeon, placing himself accordingly. The length of the flaps in this operation must be regulated in some measure by the bulk of the limb to be removed, and the extent of the surface afterwards to be protected.

Oval Operation.

Imagine a longitudinal section (through the middle) of a pear with its foot stalk attached, and you will have a tolerably good idea of the contour

of the incisions in this operation: the foot-stalk part of the section corresponds to the point of the acromion, the broad and rounded end passes under the arm. In the operation as performed by Larrey, the foot-stalk, or first incision, is a longitudinal section through the middle of the deltoid down to to the bone, commencing over the head of the humerus, immediately beneath the acromion, from this incision two others are carried, one on each side, which tend towards the inner or axillary aspect of the limb where they meet.

The first incisions in this way formed their sides are forcibly separated by an assistant, the adhesions to the bone on each side having been set free by the knife, the surgeon next carries the catlin into the joint, which he freely opens, and then passes the instrument behind the dislocated head of the humerus to complete the operation in a line corresponding with the preliminary section of the integument underneath. In the

Circular Operation,

the knife is turned round the arm four fingers breadth below the acromion, and the integument thus divided, is next dissected up, the surgeon now cuts obliquely through the deltoid, divides the tendon of the biceps, and opens the joint, the head of the humerus being partially dislocated, the catlin is passed behind it, and brought out inside to complete the operation.

Having already occupied some time in describin the amputations at the shoulder joint, this account of the circular method is made somewhat short: but it is to be remembered, that the difficulty of dislocating the head of the bone in this operation is very considerable.

Some surgeons have recommended, instead of the oval—or what we have attempted to illustrate as the pyriform incision with the foot-stalk attached, an incision of the inverted **Λ** kind, the two free extremities being joined below by a curved incision which would pass under the arm, the point of the **V** approaching the acromion: the main objection to this method is the chance of the bone projecting afterwards for want of an adequate covering from the soft parts.

Sir Charles Bell, in his work on operative surgery, recommends us to be aided in this operation by assistants, stout and strong, capable of compressing the artery above the clavicle, and against the first rib (which may be done with the aid of a key or boot-hook, the end being coated with linen), and having sufficient surgical knowledge to manage the blood vessel as soon as it is divided, that the patient may suffer as little as possible from hæmorrhage, and this you may rely upon it is a very valuable caution; for I well remember, when very young, and not very strong, having to compress the subclavian artery with a key, and the fatiguing effort which it required, but no other assistant being present, I was obliged to prolong the exertion despite the inconvenience. In such a case, however, it is desirable to save one's strength as much as possible until the latter part of the operation.

During this operation the trunk should be well steadied by an assistant on the opposite side, who holds a jack-towel which has been passed closely under the axilla of the affected side, and two other good assistants should also be present.

TO CORRESPONDENTS.

Will Z. give [illegible] that [illegible] of the value of his remarks?

Argus *writes us a [illegible] article on Medical Reform, a subject on which all observations at the present moment are of little use, [illegible] a name adds some authority. [illegible] decline the paper.*

The Crichton Institution, Dumfries.—*We have [illegible] an article relating the [illegible] performance of [illegible]'s farce of "Raising the Wind," by the [illegible] inmates of this asylum. [illegible] thing went off [illegible] and the [illegible] of pleasing excitement [illegible] is the [illegible] great [illegible]. We are glad to hear of the [illegible] experiment, and [illegible] Dr. Brown [illegible] cordially on its success.*

M. R. C. S. *complains that we or our aids have done Mr. Yearsley injustice in our demonstration of Mr. Thornton's plagiarisms. We do not deny that the first opinions expressed leave the matter unsettled as to who was the real plagiarist, for that question was not reached till we came to the consideration of the facts, which all but conclusively proved Mr. Thornton to be the gleaner. The word* openly *was merely used as intimating a remote possibility that Mr. Thornton might be able to allege something in his defence we were not acquainted with. The offers made to us are very obliging, but we beg to decline them. We observe by the way, that the "Medical Gazette" has innocently published the deplorably incorrect case of Mr. Thornton, to the reception of which we referred in our critique*

Mr. Luce.—*We have given the answer several times recently in our notices to correspondents.*

M.N.P.—Hibernicus—A Medical Reformer—J.H.—An Enquirer—*declined. The last correspondent is informed that we encourage no such Paul-Pry-ism.*

A Correspondent calls our attention to Dr. Lindley's assertion in his Introduction to the Natural System, that the fruit of the umbelliferæ is in no case dangerous, and to Dr. Pereira's recent declaration before the Pharmaceutical Society, that a gentleman was really poisoned by an infusion of anise, in which some seeds of conium maculatum were discovered. The extractum conii according to Paris is much more powerful when the seeds are included. Is Lindley therefore right?

The Hunterian Oration will be given by Mr. Arnott on Monday next at 2 o'clock. Our readers will be as fortunate as the hearers.

THE MEDICAL TIMES.

SATURDAY, FEBRUARY 11, 1843.

> Eripere vitam nemo non homini potest:
> At—mortem! Mille ad hanc aditus patent.
>
> SENECA.

As Sir James Graham is pledged to introduce his new Medical Bill early in the session, we hasten, before he stands compromised to a serious and ruinous defect, to invite him to a re-consideration of that part of his measure referring to one of the most practical of our grievances—Empiricism.

If we are to believe numerous concurring authorities — among whom is a recent Quarterly Reviewer—he proposes to content himself with restricting all public medical employments to the duly-qualified, stripping the unqualified of exemptions to serve as jurymen or parish-officers, and making their certificates useless in courts of law. If this statement were not authenticated, we should take it for the invention of a political enemy. As it is, however, did homœopathist, in wildest imagination, ever reach to such infinitesimal doses for lightest malady, as those prepared by the Home Secretary for the deadly gangrene, Empiricism? We regret to say it—but truth in an independent journalist must out—the malady our State physician would cure, he has caught, and the quackery he would suppress, is sanity, wisdom, to the quackery that pretends to its suppression. Sir James will restrict to *us*, public medical employments—but are they not so restricted already? Quacks shall serve as jurymen and parochial officers—but who shall be bettered by that but the quacks, whom, so serving, they may favour? Their certificates shall not be taken by magistrates—and what magistrate takes them now? If this be your discouragement, this your suppression of quackery, permit us frankly to tell you, Sir James, that we prefer to leave it its present impunity; for you do worse than leave wrongs as they are: interposing the law, you enact them a legalized standing, which gives them the gloss of right!

But there are reasons, we are told—grave and convincing reasons—why the Profession is wrong, and Sir James Graham right. Some of our titled surgeons and physicians, who, despite their success, feel yet the rebellious remains of early salaciousness in the cause of a sly bit of quackery, and whose evil communications reach occasionally higher than the council board of a College, these have exercised, of late, no little ingenuity in the discovery of sage reasons why their amiable *chere amie* should remain unmolested under their unpublished protection. One of them has been fortunate enough to get leave to speak through the last number of the *Quarterly Review*, and as his argumentations are intended to halloo on the Home Secretary in his proposed course, it may, perhaps, be some little service to the public, no less than to ourselves, to give the singular and occasionally ambiguous text, the benefit of an elucidatory commentary.

The writer has three reasons why the suppression of quackery should not take place: it would be, first, impracticable—secondly, improper—and, thirdly, inexpedient. We are told, that on the occasion of a royal entry, a certain pragmatical mayor having to apologize for the non-presentation of the city keys, and commencing a long categorical enumeration of the causes, with the declaration, *imprimis*, "there were no keys to present," was stopped with the good-humoured assurance that that cause proved, the rest could be spared. Now, though the *impracticability* of a given course, be, like the mayor's deficiency, a tolerably settling sort of argument, yet as we can have no objection to hear any still more conclusive, which the author may feel it necessary to add, we will, with our readers' permission, give our mayor of the *Quarterly* the liberty of going through the whole of his category *seriatim*:—

First,—We are convinced that the thing is impracticable. It may be made penal for a man to call himself a physician or surgeon, or apothecary, who has not obtained a licence; but how is he to be prevented from giving advice, and medicine too, under the name of botanist, hygeist, homœopathist? Or he may put doctor before his name on the door, and say, probably with truth, "I am a doctor, for I purchased the degree of doctor of philosophy for £5 at Heidelberg." Moreover, the experiment has been already made, and without success. The College of Physicians of London are armed by their charter and Acts of Parliament with ample powers for the purpose, but they long since abandoned the exercise of them in despair; and in France, where the legislature have done all that they could do to suppress it, quackery flourishes as much as in any country in the world. But, secondly, even if the suppression of unlicensed practitioners were practicable, we are far from being satisfied that it would be either proper or expedient. If the art of healing had attained perfection, if physicians and surgeons could cure all those who apply to them, we grant that the case would be

otherwise; but, as matters now stand, would not such a proceeding be a very tyrannical interference with the right of private judgment? Let us see how such a system would operate in a particular instance. A patient labours under an incurable disease. His case is hopeless. His medical attendant complains in a court of justice, or some one complains for him, that the patient has placed himself under the care of an unlicensed practitioner, who has never studied medicine, who treats all who consult him with the same remedies, and believes that most of the diseases to which mankind are subject arises from cows eating buttercups; and therefore he requires that the interloper should be punished. But it turns out that the remedies which this individual administers are innocent; and as to the theory of buttercups, it is as good as Cullen's theory of fever, and it can do no harm. It is a comfort to the patient to try this new scheme, and wherefore should he be prevented from doing so?

It is really something amusing, to see a medical man, and one, if we are well informed, of no mean standing among the ruling authorities of the profession, thus talking of such a thing as the impropriety of the suppression of quackery. Quackery dealing with human life, either for good or ill, can be a thing of no negative character; and he that declares its suppression improper, has done more than declare it no evil—he has put it in the class of good. In his creed of virtues, Empiricism finds a place as much as Patriotism: they may differ to him in extent, but in kind their qualities are the same. Now did the writer of this implied eulogium reflect that Empiricism, and the Profession he is a member of, being opposites, he cannot declare that the former should *not* be suppressed, without affirming that the latter *should!* There can be no medium point for extremes: if the order of quacks be good, ours must be bad, and *vice versa*. The penalty of either's malpractice is pain or death to some one: the class of the two, therefore, whose opposed principles are wrong, lives by the injury, the assassination of the community. The question comes—Is that class ours, or the Empirics? Whichever it be, it imports that that class cease to be.

But let us consider "the impracticability." The argument takes this form: "You may punish pretenders to *regular* titles, but not pretenders to irregular titles. You cannot even prevent the assumption of regular titles by pretenders. The College of Physicians, and France, have tried, and failed, to suppress quackery.—*Ergo, &c.*" Now, all the assertions here made, are either wholly or partially false; and were they *all true*, they are yet considerably too narrow to justify so wide a conclusion. There are a thousand ways of suppressing quackery, besides interfering with quacks' assumption of this or that name; and there are a thousand systems which might *be introduced*, besides those tried in London and Paris, which plainly owed their want of success to *inherent* deficiency. To give one plan—our own—Why shall there not be a broad legal distinction at once drawn between the class of Doctors and that of Quacks? Why shall not the real and the counterfeit be distinctly badged by the State with the insignia of their distinction before the people? Why may not the quack be compelled to register himself as a quack, and—if he must be permitted to practice his nefarious calling—be at least obliged to buy an expensive license, yearly, from Government? Who does not see how the public badging would diminish the prestige of his reputation?—how the annual tax would lessen the attraction of his calling? Why, further, shall not magistrates, and especially coroners, be endowed with powers of summary but moderate punishment, for every case where health or life may have suffered through malpractice? But we shall be told that all this, while it would elevate the high standing of the professional man, and lower the position of the pretender—while it would reduce quacks to the more respectable of their number, and terrify them into moderation and decency—would not totally suppress Empiricism. What evil is totally suppressed? Is dishonesty, drunkenness, assassination? Suppression of quackery, like suppression of every other wrong, is but a relative term—and as we call him perfect who has least vice, we may call that suppression which exists in the smallest shape compatible with the exigencies or powers of a society which must always be, more or less, imperfect.

The failure of the College of Physicians, and the French Government, to root out all Empiricism, may be admitted: and accounted for by the clumsy machinery and limited powers by which they acted. But does any one doubt that the French laws,—imperfect as we know them to be, and as the Academy of Medicine has lately declared them to be—have stopped much Empiricism? A single reference to Paris and London, with one further thought to the extensive practice of five-sixths of our druggists, furnishes a ready answer, and makes us wonder how France could have been cited by a writer of ordinary reading or observation, as proof that laws do not avail in counteracting Empiricism.

The "impropriety" of legal interference is proved by this valuable argument: accomplished physicians cannot cure all patients; therefore, there should be ignorant quacks, whom *curables* and incurables may consult. And, in further support of this reasoning, it is affirmed that quacks are harmless—and that to prevent their practice is to infringe individual liberty. The plain analysis of the argument is its complete refutation. We have, throughout it, nothing but false facts and unsound logic. The non-curability of certain patients, by an accomplished practitioner, is an argument, *a fortiori*, *against* the usefulness of a quack. If the incurable cannot be made better, he can be made worse: and it is surely no unlikely thing that the ignorance which blindly rushes to do more for the disorders of so delicate and complicated a piece of machinery as man, than the most practised skill has been enabled to effect—will terminate its rash meddling by leaving the derangement still more disordered. The writer, to acquire even a scintilla of force for his argument, must have two things believed, which are the very opposites to fact,—first, that the consultants of quacks are all incurables; and, secondly, that all quacks are harmless. Is one word more necessary, to prove the exceeding absurdity which may be perpetrated for reasoning, by even a sober Quarterly Reviewer? If the writer be Sir Benjamin Brodie, as some assert, our pity for his powers of ratiocination turn into real alarm for his unfortunate patients. The plainest symptoms must be lights that only shine to mislead, to one whose psychical education leaves him so utterly incompetent to deal with the plainest and commonest reasoning *data*.

The author tells us, that to suppress quackery is to interfere with personal freedom. Of course it is. So is the suppression of thieving. So would be the exercise of the discretion of the *Quarterly's* editor, which would prevent the worthy writer's again befouling the work's pages with such inconsequential reasoning. But it would be a good interference: it would prevent quacks who are *not* "harmless," injuring curable, and killing incurable patients. If we were ill off for a proof of this, we should turn, oddly enough, to a part of the writer's own statements. He tells us:—

"A man may run the risk of ruining himself if he be pleased to do so, by embarking his money in a Cornish mine, but he must not enter into such a speculation with the money which he holds in trust for others. In like manner, each individual has a right to manage his own health in his own way, and to consult whomsoever he prefers about his own complaints; but it is quite different when he has to provide for the health of others."

And has not the State, as one of its highest duties, "to provide for the health of others,"—the others being the whole people?—and if, on that principle, the State be bound, as the reviewer states, to ward off empirics from soldiers, paupers, and felons, shall it take no pains in guarding that other portion of its subjects who are certainly not less worthy of special protection? But taking the depreciating term, money, as a point of comparison with health, does Sir Benjamin Brodie think that the State should encourage hell-keepers, pickpockets, swindlers? If not, on what principle shall it encourage quacks and charlatans? The one class of scoundrels are certainly not more dangerous to the valuable, than the other are to the priceless boon.

We would earnestly warn Sir James Graham against being misled by Court surgeons and physicians, who are too apt, in the glow of their young elevation, to overlook the *useful*, in their confused zeal for the *respectable*. It is a pretty and a genteel thing to say, "*We* have none of that vulgar narrow-mindedness of class which makes some of our brethren so intolerant of irregular competition:" but we would beg such liberal-minded and affluent prac-

titioners to remember, that though the ground, that empirical interference with the claims of an impoverished profession is wrong, be very tenable; our brethren, with ourselves, mount to the higher position—that, however bad to the profession, it is infinitely worse to the public. It is on that ground, and that only, that we have felt it necessary to prove that that removal is not impracticable nor improper, but the contrary; and to call on Sir James Graham, if he wish for the shadow of success for his Bill, to pay no heed to medical advisers who neither know the public nor their own profession—and to do at least as much for the quacks of England, as Napoleon thought it politic to do for those of France.

MESMERISM.

We are happy to be able to present our readers with the results of the maturest deliberations of the *Lancet* on mesmerism. The opinions of so high a scientific authority given at two distinct epochs, cannot but throw a light upon this once very obscure branch of psychical medicine, which will leave little for further researches to achieve.

Lancet, (*First Serious Notice*), Oct. 29, 1842.

Mesmerism is too gross a *humbug* to admit of any further *serious notice*. We regard its abettors as quacks and impostors. They ought to be hooted out of professional society.

Lancet, (*Second Serious Notice*), Feb. 4, 1843.

Of Mesmerism we are too sick to descant upon it at any length, and there are but few members of the profession so utterly devoid of reasoning power as not to know that the Mesmeric Phenomena, in so far as they are true, form merely a heterogeneous mass of materials for the study of psychical medicine, and are wonderful (phenomena!) *only* to those who are unacquainted with the aspects of disease. When we continually see patients labouring under hysteria, and analogous forms of nervous disease, falling suddenly into various states of stupor, trance, and convulsion, without any assignable cause, why should we wonder at similar states being induced by so slight a cause as the pawing of a mesmeriser? And, knowing, as we do know, the remarkable power of habit in facilitating the repetition of nervous actions which have once taken place, why should we wonder that an effect which, a few weeks ago, it took half an hour's handy-work to produce, is now occasioned by two minutes' application of the same graceful process? In *these* things there is nothing either new or wonderful."

It is truly distressing to witness such an exhibition of low-bred and unscientific lunacy as is here displayed, in a journal, which, though cast off, and on the streets, still pretends to be connected with a gentlemanly and educated profession. The gross humbug of four months since, unworthy of serious notice, whose abettors were to be hooted out of society as impostors, is *now* the admitted source of *phenomena*—the creator of *a mass of materials* for the psychical philosopher! To crown the heap of absurdity, we are told that stupor, convulsions, trance, produced in two minutes by the mere movement of a second party's fingers, (those results which, from their incredibility, were, once, imposture and humbug so gross, as to admit of no serious notice) are *phenomena*, it is true—but phenomena neither "wonderful nor new!" The *Lancet* knows of phenomena not *wonderful!* In the same article we find the ingenuous editor expressing his "belief that the information of the medical profession generally, on matters of natural science, was very little greater than that of the people at large;" adding, "this is an extremely humiliating fact!" And what a happy illustration of its truth is furnished by the editor! How happy must the worthy scribe be, while writing on professional ignorance and incapacity! He has his practical and undeniable proof always conveniently near at hand! But, with such exhibitions, is it wonderful that the house of Longman and Co. sell less than one-third of their former number of *Lancets*, or that Hodges and Smith, of Dublin, sell seven or eight copies in the place of five hundred? *Quem Deus vult perdere dementit.*

CASE OF PUERPERAL CONVULSIONS ANTECEDENT TO, DURING, AND SUBSEQUENT TO LABOUR.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Piccadilly, Manchester.

Puerperal convulsions are, at all times, cases of considerable interest to the medical reader; the following one, though it offers nothing very remarkable, yet may serve to encourage junior members of the profession, and convince them that such cases cannot be treated too energetically to ensure a successful result. Mrs. Pomfret æt 21, first child, asthmatic tendency, short in stature and rather thin, commenced having slight labour pains on the Monday morning, at the early hour of 1 o'clock, Jan. 23, having experienced a slight fit the day before, which did not alarm the family so as to take any very particular notice of it, considering it hysteric; severe purging followed the fit, and as before stated, slight labour pains took place soon after midnight. On visiting her I made an examination, and found the os uteri dilated to about the size of a shilling, thick and rigid, membranes as yet entire, pains trifling but frequent, with very short intervals between; after encouraging my patient I left the room, promising to return in about an hour, ordering a little gruel. About an hour after I ascertained the progress; the os uteri dilated to little more than half a crown in size, still rigid and thick; pains frequent, with scarcely any intermission. I waited for half an hour longer, and determined to bleed if the progress was not more satisfactory; at the end of that time I was summoned hastily up stairs, my patient being in a strong convulsion; I opened a vein in the arm, and abstracted as rapidly as possible about twenty five ounces of blood, when the fit abated. The os uteri was but little altered from last report. Pulse fell considerably after bleeding, and became very soft; I therefore deferred delivery, in the hope no further unpleasant symptoms would occur. The uterine pains had now left her entirely, consequently little additional alteration in the os uteri, within half an hour of the bleeding, however, another convulsion came on, *no further time was to be lost*, I abstracted about fourteen ounces of blood, and then proceeded to deliver, first emptying the bladder by the catheter. On examination I found that during the last convulsion the membranes had ruptured, and the face presented. The wild and incoherent expressions, and turbulent conduct of my patient, convinced me every moment was big with importance. I endeavoured to pass the long forceps, but the difficulties attending their introduction occupying too much time, I determined on lessening the head, but had the mortification of finding my perforator missing from my obstetric case; situated thus awkwardly I commenced operations with the crotchet, fixing it as firmly as I could in the cheek bone, and after severe exertion succeeded in getting the head partly into the pelvic cavity, during which time two convulsions occurred, requiring the loss of about twenty ounces more blood. By this time my hold with the crotchet had become very precarious, I sent to a medical gentleman (living close by) for a perforator, but the messenger mistaking the name of the instrument, the gentleman arrived himself, to render me what assistance he could, of which I was glad to avail myself from the unruliness of my patient; the forceps were now applied, and the head finally delivered; she was now allowed a few moments rest before the body of the child was born, and in about twenty minutes after that the placenta came away easily. A bandage was applied, the pulse soft and compressible. I now retired to wash, but was immediately sent for, another strong convulsion had seized her, the vein in the arm was again opened, and about eight ounces of blood with difficulty abstracted, when the fit left her, and after a considerable lapse of time nothing indicated a return of the spasm; face very pale, pulse languid, breathing free; I left her with instructions how to act if any fit returned, and ordered her half a drop of croton oil, in a pill of castile soap, every two hours, until the bowels were well cleared out: it was now about 7 o'clock A. M. I had scarcely, however, arrived home, before I was again sent for; the fits represented as more violent; she was in one when I arrived; I endeavoured to get more blood from her, but could not obtain more than six ounces. The spasm however abated. An enema, with ol. terebinthinæ was administered, and a second in half an hour after the first; soon after the bowels were relieved of a large quantity of dark grumous fluid, mixed with blood, with little or no smell of fæcal matter. I continued in close attendance till half-past 2 P. M., up to which time she had had sixteen convulsions since the delivery, two during actual delivery, and three previous. During the forenoon she lost about sixteen ounces more blood. From half-past 2 P. M. no further convulsions took place. At half-past four she had slept a little, and awoke conscious for the first time, expressed herself perfectly ignorant of all that had taken place even from the Sunday afternoon when the first attack was observed, thus accounting for her unruly conduct. At ten P. M. she had again rested a little, felt free from pain, had voided urine, and had had a copious motion of a more natural smell and colour; no lochia. Tuesday, nine o'clock A.M., no return of convulsions, felt comparatively well, had rested well, no lochia; six o'clock P. M., bowels not moved, pulse rising, face slightly flushed, urine high coloured; ordered a saline purgative draught, no lochia. Thursday, quite as well as could be expected, bowels moved. Friday, remained well. Saturday, continues well. Sunday, the same. Monday, the same further close attendance unnecessary.

OBSERVATIONS.

The quantity of blood taken in these cases is often enormous; in the present about ninety ounces proving not only that an additional quantity is in the system during pregnancy; but also that nothing less than the most extensive

bleeding offers any chance of a favourable result. The absence of lochial discharge is not uncommon where bleeding (on an extensive scale) has been resorted to. Convulsions commonly give way on the birth of the child, it being rare that they extend to the three periods here stated. In conclusion, a few words may not be amiss on the cause of puerperal convulsions, on which authors differ considerably. I think the immediate cause appears to be, that more blood is contained within the system during utero-gestation. The uterus has the character of a reservoir, by its great vascularity; and when that organ is in a state of almost constant contraction, the extra blood rushes into the general system, and the brain, as the most sensitive organ to any increase in its circulating system, first exhibits its effects in the form of convulsion from compression; and the stertorous breathing subsequently, sufficiently confirms it. When there are long intervals between uterine pains, the blood re-assembles in the uterine mass, and no mischief ensues: when once the mischief has been produced in the brain it is not immediately relieved, though uterine contraction may be absent, as in the case just related. First labours are most liable to convulsions, and least liable to hæmorrhage, from the greater energy displayed in uterine action. On the contrary, after many labours, they are most liable to hæmorrhage and least to convulsions, from the want of a proper degree of uterine energy. The absence of after pains in general, in first labours, is accounted for by the energetic contraction immediately after the completion of labour, whilst the almost certain occurrence of after pains, in subsequent labours, shews that uterine energy is wanting, and the uterus is, therefore, longer in completing its contracted state after labour.

LECTURE ON STARCH.

Delivered January 27th, at the Royal Institution.

By Professor BRANDE, F.R.S., &c. &c.

The lecturer commenced by stating, that the old mode of preparing starch was by steeping grain in water until it became soft, when it was subjected to pressure, and a milky juice exuded, which passed into water, and gradually subsided. The precipitate was starch mixed with impurities.

If grain be powdered, that is, reduced to the state of flour, and washed with water, it will be separated into two leading parts: that which is removed by the water, although not soluble in it, is starch; the other principle is gluten. It possesses the property of elasticity, and aids materially in the manufacture of bread, by causing it to rise. There are some other matters in wheat of minor importance. Wheat contains—

Starch	70.84
Gluten	12.10
Sugar	4.9
Gum	4.6
Water	8.0
	100.44

There are a number of interesting particulars connected with gluten, which have been recently investigated,—one of the most important of which is, that its ultimate composition is identical with that of animal fibre. When it enters into fermentation, it passes readily into the putrefactive stage, on account of the nitrogen it contains. When rubbed with soda or potass, it gives out ammonia. Its composition is as follows:—

	Marcet.	Zenneck.
Carbon	55.7	45.80
Hydrogen	7.8	3.37
Oxygen	22.0	33.33
Nitrogen	14.5	20.50
	100.0	100.00

It is a very common, in fact, almost a constant ingredient in many vegetables, which consequently form fitting nutriment for granivorous animals. It dissolves readily in weak alkaline solutions, from which it is precipitated by acids. Certain acids easily dissolve it,—among these is vinegar, or the dilute acetic acid. In either case, if the process be carefully and properly effected, the starch remains unaffected.

Starch is now prepared in the following manner:—the wheat is ground into flour, mixed with water, and fermented. The liquor becomes sour, either acetic or lactic acid forms, by which the gluten is separated, and partly dissolved. The fecula is then washed in hair-sieves to separate the bran, and afterwards allowed to subside. The dirty liquor is next poured off—the serum scraped off the deposited starch, which is washed, and again strained through a fine sieve, and purified. The next process is, that of stove-drying, after which the scum is again removed: it is then boxed, and again stove-dried. On the completion of the process, it is no longer an homogeneous mass, but when a paper is opened, it breaks into columnar pieces, exhibiting a tendency to crystalization.

In this process, the object to be attained by inducing fermentation, is the removal of the gluten. An acid is formed, by which it is in part dissolved, the other part being precipitated upon the starch, from which it is removed by scraping.

Starch, when thus prepared, is white, and is coloured with cobalt, or indigo blue, for the market, and for the various purposes to which it is applicable.

In the process for obtaining starch, which has been just described, wheat only can be used, and large quantities are annually employed for that purpose. Mr. Jones has taken out a patent for obtaining starch from rice; by effecting which a double object is gained,—by increasing the demand for rice, its cultivation is necessarily advanced, while the more valuable grain previously used is economized. The theory of his process consists chiefly in the separation of the gluten—not by fermentation, and the formation of an acid, but by means of a weak alkaline solution. The rice which is employed is that called Patna rice. It is impure from adhering substances, and from a little lime which is always added, to prevent injury by insects. To get rid of these, the rice is dusted, and steeped in a weak solution of caustic soda. The success of the process necessarily depends on a due adjustment of the strength of the alkaline solution. Mr. Jones prepares it with 200 grains of caustic soda to the gallon of water. The rice is then rendered softer and whiter, and can easily be crushed. It is then ground into powder. This first application of the alkaline solution removes some gluten. The powder should then be mixed with a fresh alkaline solution, which readily dissolves the gluten. It should be steeped for 24 hours each time, and on the second occasion afterwards allowed to deposit. A very curious circumstance now takes place: there are two distinct sediments, the nature of the first is not fully understood; it is supposed to consist of fibrous matters, and is quite distinct from the starch which falls gradually on it. The starch is collected, washed, and boxed, in the usual way; the mass is dried to a certain extent on porous brick or chalk, and then stoved, when a crust forms on it, which must be scraped off. The mass is next put up in paper, and then resembles that procured from wheat. It is white also, and is colored precisely as the wheat starch. On opening a paper, and breaking the mass, it separates into columnar pieces, which have their bases externally, and appear to shoot towards the centre.

The old and new processes differ in no case more than in the mode of removing the gluten. In the one it is effected by fermentation; in the other, by means of an alkaline solution. The chief advantage consists in the time saved in not waiting for the fermentative process, and in the economizing wheat by the substitution of rice.

Having thus got rid of the principle containing nitrogen, we shall find that starch consists of carbon and the ultimate component of water.

	Wheat-starch.	Arrow-root.	Potatoe-starch.
Carbon	42.80	44.40	44.25
Water	57.20	55.60	55.75
	100.00	100.00	100.00

There are several varieties of starch, which are used as articles of aliment. Among these are the different forms of sago. The granulated form of sago is entirely artificial—it results from its mode of preparation. Sago is obtained from the pith (improperly so called), i. e., the fibrous matter in the centre of certain palms. This material is ground up, and washed in cold water, by which the sago is extracted from the pith, and afterwards deposited. It must be obtained before the fruit is formed, as, otherwise, a large portion thereof is extracted for the purposes of nutrition. From five to six hundred pounds weight have been procured from a single tree.

The other varieties of starch are, the Otaheite sago, or arrowroot, which is prepared by the natives converted by the missionaries; the Tous les mois, prepared at St. Kitt's, from the canna-coccinea, arrow-root, the Portland arrow-root, from the arum maculatum, the Brazilian arrow-root, from the Jatropha manioc, and potatoe starch. There is an article sold as maize, or Indian corn starch, which is nothing else than potatoe starch. This latter is obtained by grating the potatoe, and washing it in water, when the starch will be removed, and deposited.

100 lbs. of potatoes will yield in the month of

August	10 lbs.	of starch.	
September	14½	do.	do.
October	14¾	do.	do.
November	17	do.	do.
March	17	do.	do.
April	13¼	do.	do.
May	10	do.	do.

100 parts of potatoe contain, in the average,

Starch	15
Gum	2
Fibre	7
Water	76
Total	100

The chemistry of starch has assumed, lately, a very important aspect, as it seems to be the first form from which the other substances of the plant are produced. Starch is not soluble in cold, but it is so in hot, water. In water at a temperature of 160 deg., the globules break down, and a part is dissolved in the water, the remainder forming a gelatinous compound. By long boiling, the whole is dissolved. The action of iodine upon it constitutes a very valuable characteristic, by which it can at once be distinguished. A very weak solution of iodine will impart a blue tint to starch, and an iodide thereof is formed. If, however, the starch be dissolved in an alkaline solution, instead of water, the blue color will not be produced, and the blue tint of an already formed iodide of starch will be destroyed by the addition of an alkali. Iodine, to act thus on starch, must be in a free state: if the hydriodate of potash (iodide of potassium) be added to a solution of starch, no apparent effect will be produced; but if, with this, some solution of chlorine be then mingled, the iodine is set at liberty, and its effects on the starch are speedily visible. This may be exemplified by exposing a paper, written on with a mixture of starch and hydriodate of potash, to the vapour of chlorine. The letters which, previous to the exposure to the gas, were totally invisible, soon become legible. The blue color of a solution of starch and free iodine, disappears on the application of heat, and returns as the liquid cools. These tests may be similarly applied for the detection of iodine, the starch in solution being added to the suspected liquids.

Under certain circumstances, starch appears to be the source of the other vegetable products: at certain periods, there is pent up in plants a large quantity of starch, which, in process of time, is called upon, and used in the formation of gum, sugar, woody fibre, &c. These processes can be imitated by art: by a high temperature, starch can be converted into gum; here, in London, this process is carried on, and the resulting article is

sold as British gum; in Paris, it is called dextrine and is used as a substitute for gum-arabic. If the gum thus produced be boiled for a long time, with a very weak acid, it will be changed into sugar,—and by analyzing these, and woody fibre, they are all found to belong to the class of compounds of carbon and water; so that all that is done in the operation of the various changes previously enumerated, is, the adding a portion of water. These processes are also effected in brewing. In the preparation of malt, a substance called diastase is produced, which converts starch into gum, and then the gum is changed into sugar by fermentation with heat, to the formation of sweet-wort.

The ugar, thus produced, is not the crystalline variety, but that known as the grape-sugar.

Potatoe starch is very cheap; and there is now a large manufactory in London where it is converted into sugar, for the purpose of adulterating the moist sugars. It is possessed of a certain degree of sweetness, but is weaker than cane sugar, and more is consequently required to effect the desired purpose.

MR. THORNTON'S PLAGIARISMS.

(To the Editor of the 'Medical Times.')

SIR,—In your spirited exposé of Mr. Thornton's literary delinquencies in your last number, you omitted to point out his more recent appropriation of Mr. Yearsley's language and opinions. The identity of the cases lately sent to your journal by Mr. Thornton, and those related by Mr. Yearsley in his work "On the Enlarged Tonsil and Elongated Uvula" (barring on behalf of Mr. Yearsley the distorted and garbled condition in which you got them from Mr. Thornton) is most striking. Permit me to make it manifest to you. In your last number but one (Jan. 21) appears the following case.—In Mr. Yearsley's work, published some months ago, you will find the passages quoted, at the pages and lines indicated in the margin. May I beg that you will cause the quotations to be placed side by side?

Enlarged Tonsils affecting the Voice and producing Deafness, Successfully Treated, by W. THORNTON, Army Surgeon, M.R.C.S.L. (See Med. Tim. Jan. 21)	Extracts from Mr. Yearsley's work "On Enlarged Tonsils and Elongated Uvula, &c.—page 72
A young gentleman residing in London, of strumous constitution, nine years of age was brought to me, delicate and pale.	"M. A. C. a girl of strumous constitution, fourteen years of age was brought to me, pale, weak, and of stunted growth."
He complained of distressing symptoms such as confirmed tonsillary disease can alone produce.	"She complained of a variety of painful and distressing symptoms, such as confirmed tonsillary disease can alone produce."
His hearing defective, the voice thick and nasal, and the articulation so indistinct, as to be almost unintelligible to strangers.	Page 79, line 22. "The hearing was extremely imperfect, the voice thick and nasal, and the articulation so indistinct, as to be almost unintelligible to strangers."
I prescribed frictions of the ointment of iodide of mercury upon the external fauces, and small doses of iodide of potassium dissolved in dec. sarsæ. concent. internally, also a rhubarb aperient administered twice a week. A tonic powder composed of carbonate of soda, rhubarb and calumba given alternately with the hydriodate of potash. The topical treatment of the tonsils were argentum nitratum applied by a pencil brush three times a week. In the course of a week, the tonsils felt quite soft, and began to diminish very rapidly; they were reduced to their natural size. I was anxious to give these remedies a fair trial before I had recourse to excision.	The identity of treatment is not a little remarkable. At page 44 of Mr. Yearsley's work he says, "When debility is present, a powder composed of calumba, sesquicarbonate of soda and rhubarb ni equal parts, is the est combination that can be given." At page 45. "Occasionally great benefit accrues from alternating the use of the tonic powder with the hydriodate of potash." It appears to have answered Mr. Thornton's purpose to cause the arg. nit. first to soften the tonsils, and then reduce them to their natural size. Here we find him at variance with Mr. Yearsley, who declares, that the arg. nit. will *not* reduce enlarged tonsils.
The effects of the combined treatment were most gratifying, and all the impeded functions were gradually restored, and the general health improved, and cured in the course of a month!!!!	Page 73 line 18. "The effects of the combined treatment were most gratifying." Page 72 line 8. All the impeded functions were gradually restored."
	I have looked Mr. Yearsley's book carefully through, and cannot find that he ever "improved and cured *the general health*."
The persevering medical treatment and dietetic restrictions are of paramount importance in the management of enlarged tonsils, especially when they occur in youth.	The two concluding sentences may be found at pages 43 and 47, omitting the words "the persevering." In the original it runs thus:—"medical treatment and dietetic restrictions are of paramount importance in the management of large tonsils, especially when they occur in childhood or youth."
When these remedies fail, it i only then necessary to resort to the operation, which is safe and painless.	"When the means now recommended fail to reduce the enlargement, it is necessary to resort to excision."

Now, Sir, I think you will admit that this extraordinary mode of fabricating a case is without a parallel in the annals of medical literature, and not doubting that you wish to do justice between man and man, I trust that you will give insertion to this communication, in your forthcoming number.

I have the honour to be, Sir,
your obedient servant,
Q.

PERISCOPE OF THE WEEK.

PATHOLOGY OF CHOLERA.—Dr. Fife of Newcastle states it his belief, that the heart and lungs being mainly influenced by the same system of nerves, are in cholera simultaneously involved, the morbific impression whatever it may be being made on that part of the nervous system. The condition of the blood also, is perceptibly changed, both physically and chemically. Drawn from a vein it exhibits a dark tarry appearance, and flows very slowly, owing to diminished fluidity, and the small proportion of serum it contains; which deficiency clearly arises, says Dr. Fife, from the large quantity poured off by the intestines—an effect inattributable to mere increased secretion from the alimentary canal. An increased quantity of mucus is certainly discharged, but the increase bears no proportion to the immense quantity of serum and water in the evacuated matters. The analysis of Dr. Shaughnessy and others, have proved that the blood in cholera is invariably deficient in its soluble saline, and aqueous components. Doubtless, the morbid absence of these will account for the remarkable—we had almost said miraculous—effect of saline injections in restoring the powers of the patient in cholera, though this restorative effect is but temporary.

STYRACINE.—A crystallisable matter was discovered by M. Bonastre in storax, to which he gave the name of styracine. The following is the process to obtain it with facility:—The storax of commerce should be treated with cold hydric æther, which is to be poured off after several day's contact, and the filtered liquid set aside for spontaneous evaporation. The dried residuum is then acted on by boiling alcohol at 40 deg., and the filtered liquid also set aside for spontaneous evaporation; when about three-fourths have been evaporated, the remainder is poured off, the crystals adhering to the sides of the capsule are washed with a little cold alcohol, and dried in joseph paper. The styracine may be obtained properly crystallised, and sufficiently pure, by being dissolved again once or twice in boiling alcohol at 40 deg. It may aslo be obtained by treating the storax several times with alcohol of commerce, allowing part of the liquid to evaporate each time spontaneously, and pressing the matter left between leaves of filtering paper, &c. But greater difficulty is always experienced by this process in getting rid of a green coloring matter, which always stain the crystals.—Styracine presents itself in the form of small needles, almost always agglomerated, of a very white color, without any sensible savor, and of a light, agreeable, balsamic odor. It is completely insoluble in cold and boiling water; it floats on the latter in the form of oily drops, which have a greater degree of consistence on the cooling of the liquid. Alcohol at 33 deg. dissolves very little, but it is more soluble in alcohol at 40 deg., and still more so in æther. Its alcoholic solution does not redden litmus paper; the addition of water render it milky. Concentrated ammonia has not any action on it, nor is it soluble even in strong solutions of potass or soda. Cold sulphuric acid carbonises it; the reaction is still greater if heat be applied. Hydrochloric acid has no influence neither when cold nor hot. Nitric acid transforms it into a very friable yellow matter, without any sensible taste, and a very marked odor of bitter almonds is generated, from which it is probable that styracine contains some cynnample.—M. Lepage gives the following as the result of the analysis of purified storax:—A neutral crystallisable resin, a green coloring matter, benzoic acid, and perhaps cinnamic acid.

ALBUMINATE OF IRON.—This preparation, better known in France than England, is usually prepared by the following method:—Albumen, or white of eggs, is diluted with distilled water; the mixture is filtered, and a solution of persulphate of iron is added until precipitation ceases, the deposit is then washed and dissolved in alkalized* alcohol. It is very evident, however, that this solution does not answer to its name, and in this state, from the amount of alkali it contains, will prove unfit for administration, in many cases where chalybeate tonics are indicated. It has been my endeavour to remove this objection, and after some experiments for that purpose, I find the solution of albuminate of iron is best made by dissolving its hydrous oxides in the newly diluted and filtered white of egg, which

* Caustic potassa must be used.

takes up a considerable portion of both the freshly precipitated protoxide and sesquioxide. The liquid may be filtered, and will be found by tasting to contain a large proportion of metal. In the case of the sesquioxide in particular, the solution will keep for some time without decomposition, and its permanence may be further increased by adding a little alcohol, with which it will mix without precipitation. In this respect it resembles many other preparationsof the same oxide. I have now before me two four-ounce phials of this preparation—the one with spirit, the other without any. The simple solution was made about ten days since and placed in a temperate situation, loosely corked, for the purpose of ascertaining its conservative powers. It is barely so clear as it then was, but differs in no other particular. The other phial, to which a little alcohol was added, has kept nearly three weeks without any visible alteration. When tested for iron, they both yield precipitates as before. It may be further remarked, that this preparation s compatible with caustic solution of potassa, and no doubt the other alkalies and their carbonates. As a therapeutic agent, the albuminate of iron is highly spoken of by M. Lassaigne and other high authorities, who recommended it s a preparation etpecially adapted by its nature, on theoretical grounds, for combining with the tissues of the body. It will no doubt, ere long, take a prominent situation mong the most esteemed of our chalybeates.

Marking Ink that requires no Preparation.—Mr. Rowland, of Liverpool, gives the following formula as of very superior merit:—℞. Argenti Nitratis Crystallorum, ʒiij.—Liquoris Ammoniæ fortissimi, ʒij. Solve. —℞. Cupri, ʒss.—Acidi Nitrici, q. s. Solve, tum adde Liquoris Ammoniæ fortissimi ad saturationem.—℞. Pigmenti Indici [*vulgo* Indigo], gr. iij.—Levigatur cum Aquæ Destillatæ, ʒi. et adde Carbonis Puri, gr. vi.—Pulveris Gummi Acaciæ, ʒi. Mix the whole of these ingredients together, and add a sufficient quantity of ammonia to form a bright mixture, and when a gentle heat has been applied to drive off the excess of ammonia, the fluid will be ready for use. He adds that "the combination may be more curious than chemical, but I have found that the copper exerts a great influence over the silver in preventing its liability to blot when written with. It is, however, necessary to observe, that although the proportion of ammonia should be sufficient to keep the fluid clear, yet there must be no uncombined excess, and I find the best method after the ingredients are mixed, is to put the fluid in a small evaporating dish over a lamp, and keep up a gentle heat for ten minutes, to disengage the free ammonia.'

Use of the Colutea Arborescens.—Dr. Colla attributes to this plant contra-stimulant purgative properties, and has derived advantage from its employment, especially in cases in which it was necessary to purge patients whose stomach were refractory to drastics, and whose constitutions were enfeebled, and when it was necessary not only to free the intestinal tube from its contents, but also to strengthen it. The analysis of the fresh leaves of the *colutea arborescens* gave albumen, a bitter substance of a resinous nature, tannin, malic acid, a yellow coloring matter, a green coloring matter (chlorophylle) a gummy substance, malate of lime, chlorides of calcium and potassium, and sulphate of lime. This plant readily yields many of its principles to water, at all temperatures; but the use of the leaves without heat is preferable, or, better still, the tincture arising from the lixiviation of the powder. The aqueous decoction of the leaves appears to be very active. The plant does not contain any alkaloid to which its powerfully bitter taste and cathartic action can be attributed; but there is a bitter principle, of a resinous nature, similar to that of rhubarb and other plants, to which this action is owing. The absence of alkaloid from the *colutea* makes this plant resemble senna, whose purgative action is not due to a vegetable alkali, but to a mixture of deliquescent salts, bitter resin, and coloring matters. Finally, the infusion and the aqueous tincture, made cold, contain the resinous principle, separated from the gummy matter, which accounts for the greater activity of these preparations.

New Treatment of Itch, by Dr. Dornbluth.—The patient must first, at night, cleanse the whole body by means of careful ablution with a warm solution of green soap; then rub with the following liniment:—℞. Black soap, 125 grammes.—Powdered root of white hellebore, 60 grammes.—Warm water, q. s.—M. and F. S. A. a mixture of syrupy consistence. This liniment is applied with the palm of the hand, or by means of a brush, and care should be taken to spread it over all the parts of the body which present the slightest traces of exanthemata, especially on the articulations of the four limbs, on the hips, the back, and the abdomen Moreover, the force of the friction ought to be proportioned to the degree of sensibility of the skin. As soon as the rubbed parts commence, after the second, third, or fourth application of the remedy, to redden and become the seat of a burning sensation, instead of the itching which was previously felt there, and when no more pimples are seen to appear there, the application of the liniment is ceased. The day after the last friction, the whole body is rubbed with 125 grammes of black soap, then carefully washed with warm water holding in solution the same quantity of the same soap. It is only necessary afterwards to give clean linen and fresh clothes; the old ones must be submitted, before being again used, to washing and disinfection with sulphurous acid gas, because, without this precaution, they might reproduce the disease. Very soon afterwards, the skin dries and scales off. In this way cure is obtained in six or eight days, without leaving any bad consequences. With this mode of treatment, there is no necessity for resorting to any internal administration of medicine: Dr. Dornbluth, who at first prescribed medicines to be taken internally, was ultimately convinced of their utter inutility. Dr. Dornbluth has cured about six hundred individuals of all ages, by following this topical treatment, and he regards it as preferable to all others for the following reasons:—1st. It certainly cures the itch in the shortest possible space of time, and without giving rise to any bad symptom. 2nd. It has the valuable advantage of not betraying, by its odour, the nature of a disease which it is always important to conceal; and in this respect it has a marked superiority over the sulphurous preparations, &c. 3rd. Finally, it has the advantage of being very cheap.

Ferruginous Preparations in various Affections.—Dr Pitschaft, of Baden, prescribes iron in the following form in the treatment of chlorosis:—℞. Klaproth's ethereal tincture of acetate of iron, 8 grammes.—Tincture of vanilla, 30 grammes.—Tincture of orange peel, 30 grammes. M. S. A. Twenty drops, in a teaspoonful of water, every three hours. During the use of this medicine, it is advisable continually to administer a tonic purgative composed of aloes and rhubarb. In some cases of cyanosis in adults, Dr. Pitschaft has employed, with much advantage and with great relief to the patients, the following mixture, but by continuing its use for a long time:—℞. Klaproth's ethereal tincture of acetate of iron, 15 grammes.—Tincture of digitalis purpurea, 8 grammes. M. S. A. Twenty drops every two hours in a teaspoonful of sugar and water. Moreover, the patients want to go every day to the water-closet, and it is advisable to watch them in this respect. The same practitioner considers carbonate of iron, associated with the extracts of bitter plants, one of the best medicines that can be employed in chlorosis; if the patients complain at the same time of very violent palpitations, it is as well to join with it small quantities of digitalis.

Hydrated Peroxide of Iron.—Mr. W. Proctor, jun., in the *American Journal of Pharmacy*, gives the following conclusions:—1. That hydrated peroxide of iron, even when kept under water, gradually decreases in its power of neutralizing arsenious acid.—2. That if kept in the form of a thick magma, it will retain its properties longer than when mixed with much water.—4. That this decrease in power is probably due to a change in the relative proportion of the oxide, and the water chemically combined with it, as well as to an alteration in its state of aggregation.—4 That from the experiments of Otfila, and others, the dry hydrated oxide possesses the power, to a considerable extent, of neutralising arsenious acid, and it should be used in the absence of the moist and recent preparation.—5. That hydrated peroxide of iron may be obtained in a state fit for use in ten or fifteen minutes, by using a solution of the persulphate of iron. And, lastly, that the recent oxide should be used in all cases where it is attainable, in preference to that long kept.

Diabetes Mellitus cured by Hydrochloric Acid.—(By Dr. Gennaro Festeggiano.)—A seaman, after remittent fever, with gastric and rheumatic complications, became affected with an increased flow of urine, which gradually assumed the character of Diabetes Mellitus. His urine was passed in great quantity, and had a sweet taste; he had a ravenous appetite, constant thirst, became thin, and had the other symptoms which usually attend that complaint. Dr. Festeggiano prescribed a drink acidulated with hydrochloric acid, to which small doses of ipecacuanha were added. At the end of eight days, the peculiar symptoms had notably diminished, the morbid characters of the urine had disappeared; and in a month the patient left the hospital cured.

Green Cataract.—M. Cuvier of Brussels' notices, that this form of cataract is often confounded with glaucoma, and no attempt is accordingly made to afford the patient relief. Out of eight cases affected with Green cataract, at the Ophthalmic Dispensary of Brussels, within his memory, seven had been restored to sight by the ordinary operation.

Cure of Ectropion by Nitrate of Silver.—M. Magne was consulted in the case of a child, where the use of the scalpel being interdicted by the parents, Dr. Magne was compelled to depend for the local treatment solely on caustic. This he applied with great decision to both the palpebral and ocular conjunctiva; and to combat the inflammation apprehended from this treatment, ordered free foot-baths, and compresses moisture with fresh elder flower-water, to be applied continually to the eye. The process of cauterisation was renewed daily for a fortnight, at the end of which period the granulation had disappeared, leaving only a few whitish eschars on the conjunctiva, and child was soon afterwards sent away for change of air. Three months afterwards M. Magne again saw his patient, and

their rutting season. Among these the ovarian vesicles are found to increase gradually in size during the interval between the rutting epochs; and they ultimately escape altogether at these epochs without congress of the male. The spontaneous detachment of the human ovum at the end of the menstrual epoch naturally renders that period the most favourable for impregnation, and readily yields a reason for the fact that conception is most commonly referred to that epoch by pregnant women. "Of 15 women (says Dr. R.) who specified accurately the period of their latest menstruation, as well as the dates of the connubial act, 5 evidently conceived from coitus taking place from two to four days previous to the period at which the catamenia were due. In 7, conception dated from coitus occurring two or three days after menstruation; in 2, it took place at the actual period of the catamenia; and in one only so long as ten days after the latter had disappeared. Considered with respect to her generative function, woman holds a place intermediate between rutting animals, which are capable of impregnation only at fixed seasons of the year, and those animals in which a coitus only is required to produce impregnation at any season. She, however, approaches much nearer in point of this analogy to the former class, her power of reproduction being infinitely the more active at her menstrual periods, to which the rutting time in brutes bears a strict physiological resemblance.

MEDICAL NEWS.

Royal Medico-Botanical Society, Jan. 25, Dr. Sigmond in the chair.—Mr. Foote, the senior secretary, read a paper by M. Guibourt on the Ceylon Moss, from which it appeared that it had been described and figured by Turner under the name of fucus lichenoides—by Agardh as the sphærococcus lichenoides—and by Lamaroux as the gigantina lichenoides. This moss, or alga, is in whitish, ramifying filaments, about three or four inches in length, and about the thickness of strong sewing thread. It appears to be cylindrical to the naked eye, but under the microscope it offers an unequal, and, as it were, nervous or reticulated surface. Its branches are either dichotomous, pediculated, or simply alternate. It has a slightly saltish savour, and is scarcely, if at all, soluble in cold water. Iodine colours it of a blackish-blue colour, mixed with a red tint; it therefore contains amylaceous matter. The Ceylon moss affords by boiling, an abundant nutritious jelly, well suited for invalids. The residue of the decoction may be employed as food; it may be prepared in the same manner as the leguminous vegetables, and is occasionally eaten raw. Such, in fact, is its principal use in the countries where it is indigenous. Some fine specimens of native medicinal plants were laid on the table by Dr. Houlton, among which was the prunus lauro-cerasus. With respect to this, Dr. Houlton observed, that a patient of his, who had been engaged for several hours collecting it, was, after a time, seized with all the symptoms of poisoning by prussic acid, from which he recovered by the use of medicinal and dietetic stimulants.

Ethnological Society.—A meeting of gentlemen engaged in scientific pursuits, was convened on Tuesday evening at Dr. Hodgkin's, in Lower Brook Street, for the purpose of forming an Ethnological Society, on purely scientific principles, for investigating the natural history of civilised, as well as uncivilised man. Mr. Greenough presided on the occasion, and Mr. Richard King acted as the secretary. An essay by Dr. Ernest Dieffenbach, pointing out the advantages of such a society, and the course that ought to be pursued in carrying out its objects, was first read, after which Dr. Granville moved—that it was expedient that the Ethnological Society be formed. Dr. Hodgkin seconded the motion, which was carried unanimously. Dr. Hodgkin, a Mr. Greenough, and Mr. Richard King were appointed a sub-committee, with power to add to their number, to take into consideration the bye-laws and regulations necessary to be adopted, and to report thereon at an future meeting. The objects of the society would be to collect, register, and digest, and to print for the use of the members, and the public at large, in a cheap form, and at certain intervals, such new, interesting, and useful facts as the society may from time to time acquire; to accumulate gradually a museum illustrative of the varieties of mankind, and of the arts of uncivilised life; a library of the best books on ethnology, also, voyages and travels, as well as all such documents and materials as may convey the best information to persons intending to visit foreign countries—it being of the greatest utility to those who are about to travel to be aware of what has been already done, and what is still wanting in the countries they may intend to visit;—to render pecuniary assistance, when the funds will permit, to such travellers as may require it, in order to facilitate this particular branch of their research; and to correspond with similar societies that may be established in different parts of the world, with foreigners engaged in ethnological pursuits, and with the most intelligent British residents in the various remote settlements of the empire. The admission fee is proposed to be £3, and the annual subscription, £2, or both may be compounded for by one payment of £15; but the first 200 members are to be exempt from the payment of the admission fee, and their composition will be consequently reduced to £12. When 200 gentlemen have announced their intention of becoming members, a meeting will be called for the purpose of electing the officers of the society, and then, but not before, will the subscriptions become due. In the meantime, those who are already enrolled as members are at work reading papers, publishing transactions, and collecting materials for a museum.

Medical Reform.—In the House of Commons, on Tuesday evening, February 7, Mr F. Maule wished to ask the Right Honourable Baronet whether it was his intention to bring forward at an early period of the present session any measure of Medical Reform? Sir J Graham said the honourable gentleman who had asked him the question must be aware of the extreme difficulty of the subject; he might, however, say that he had given every attention to it. But a preliminary step, as it appeared to him, to every measure of Medical Reform was—and he had stated the same last session—a new adjustment of the charters of incorporation of the two Colleges of Surgeons and Physicians. The Government had for some time been in communication with the principals of those Colleges, and had proposed certain alterations for their consideration, which alterations had been discussed; and he hoped in a very short time to be in a condition to submit to Parliament a measure affecting the charters of incorporations of the two Colleges in London, to which he had referred; and, together with that measure, it was his intention to bring in another Bill affecting the medical profession generally throughout the United Kingdom. (The Home Secretary seems to be growing less confident as he gets longer acquainted with the task he has undertaken, and it is, even now, very, *very* possible that this Session will see the wreck of another Medical Statesman without anything more being done for our profession. The truth is, that Sir James is too careful of the vested interests: his weak fearfulness of their opposition threatens to make his Bill unworthy of a Statesman, and worthless of the profession's acceptance. In his position he has the power of doing what Messrs. Hawes and Warburton had not, of making Colleges bend to right principles, not right principles to the Colleges. Has he greatness enough to exercise it?)

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, Feb. 3, 1843:—

R. D. Edgecombe, G. Beddow, J. Morrison, E. J. Shearmaw, G. Johnson, J. Vincent, T. W. Smith, C. A. Aikin, M. Macnamara, D. Ross.

A GENTLEMAN, M. R. C. S. L., and late House Surgeon to two of the London Hospitals, is desirous of offering his services for a few months gratuitously to some medical gentleman in the country, who, through illness or otherwise, might feel disposed to vacate, or only partially to superintend his practice.—Apply by letter to A. Z., at Mr. Mellonish's, No. 9, Bedford Street, Bedford Row, London.

JEREMIE'S SEDATIVE SOLUTION OF OPIUM,

First prepared at Patna, in Bengal.

THE great merit of this Preparation is its peculiar freedom from the noxious properties of Opium, and has, therefore, been found available in cases where other forms have been inadmissible, from its not disturbing the nervous system. The rest procured through its instrumentality is divested of the heaviness and stupor usually the effect of Opium, and the patient, though taking it continuously, is left in free possession of his faculties. It has for several years been supplied to the H. C. Dispensary, by order of the Medical Board of Bengal, from its being found to meet Cholera in India beyond any remedy that had been applied to that fatal disease. Cap. sin Jeremie, from whose formula it is prepared, is well known to scientific persons as the talented improver of the Patna Opium. It will be found not to constipate the bowels, and to keep any time in any climate. It is exceedingly powerful in Cough, especially Consumptive Cough, wherein it may have found it a great blessing, in Influenza, Gout, Tic Douloureux, Cholera, and Bowel Complaints, Rheumatism, and Cancers, in Accouchement, and all cases where Opium may be desirable. The exceedingly innocuous properties of the preparation have been proved by infants of a few weeks old having taken it without any cerebral disturbance. The testimonials of many talented Gentlemen of the Profession are on the envelope of the bottles, a few only of the names are given here of those who have approved, viz.:

Medical Board of Bengal.
Sir Phillip Crampton.
Sir David Dixon, Physician to the Royal Naval Hospital, Plymouth.
Dr. Cookworthy, Physician to Plymouth Dispensary.
Dr. Watson, Physician to Middlesex Hospital, London.
J. G. Perry, Surgeon, Foundling Hospital, London.
Dr. Rae, Royal Hospital, Chatham.
J. R. Martin, Esq. (late of Calcutta) Grosvenor Street, London.
Dr. Jackson, late Apothecary-General, Bengal.
Dr. Graves, Meath Hospital, Dublin.
Dr. Hannay, Professor of Physic, Glasgow, and Physician to the Royal Infirmary.
Dr. Yonge, } South Devon Hospital.
Dr. Hingston, }

Prepared only by Francis Lean, 27, George Street, Plymouth, whose signature is WRITTEN in red ink, on the pound and half-pound bottles put up for dispensing, as well as on the envelopes of the bottles sold at 2s. 9d., 4s. 6d., and 11s., accompanied by the stamp of Barclay and Sons, Farringdon-street, London, Wholesale Agents. Agents abroad, Scott, Thompson, and Co., Calcutta; Binney and Co., Madras; Treacher and Co., Bombay; Menzies and Co., Jamaica; W. Blake, Montreal, for the Canadas. Sold also by all respectable Druggists.

RHEUMATISM.—Lieutenant-Colonel Stisted, of the Third Regiment of Light Dragoons, informs those who have Rheumatism, that he has worn Coles's Medicated Bands four months, that they have relieved him from a state of suffering scarcely to be described. The Colonel, to evince his gratitude to Mr. Coles, has authorised him to make use of his name in any way he thinks proper.

No. 4, Craven Street, Strand, April 22, 1837.

There are about fifty generals, admirals, and noblemen, who wear these Medicated Bands with equal satisfaction.

RUPTURES.

Colonel Francklin informs those who have Ruptures, that he has been wearing trusses 30 years, and he never met with but one individual who was master of the complaint. He has likewise an elder brother, a Colonel in the Hon. East India Company's service, who has worn a similar kind of Truss for many years, who can testify the same. Mr. Coles, of Charing Cross, is the individual alluded to.—Blackheath, July 10, 1832.

Two Generals assert that they have sent Mr. Coles upwards of 300 ruptured persons for trusses.

"Mr. Coles has worn Trusses twenty-five years, and during twenty months he has worn his Truss night and day. Read 'Coles on Rupture.'" Manufactory, 3, Charing-cross. Read "Coles on Rheumatism."

INVALIDS REMOVED WITH EASE AND EXPEDITION. HARMAN'S PATENT BED CARRIAGE is so peculiarly constructed that Invalids, however severely afflicted, may be removed from their beds without change of position, or increase of suffering, and conveyed, together with attendants, to any distance, without fatigue. May be seen, and hired for any journey, at S. Willoughby's, Coachmaker, 1, John Street, Oxford Street.

CLENDON ON THE EXTRACTION OF TEETH.

Just Published, with Plates. Price 3s. 6d. Cloth,

OBSERVATIONS on the Extraction of Teeth, by I. Chitty Clendon, Surgeon-Dentist.
S. Highley, Fleet Street.

BRIGHT'S NUTRITIOUS FARINA.—This new VEGETABLE Preparation is strongly recommended by the highest medical testimony, and by ROYAL and NOBLE patronage as the best DIET for INVALIDS, INFANTS and persons of impaired digestive powers. No article ever yet offered to the public contains the same amount of nourishment, is so economical, so easily prepared, or so peculiarly adapted to the delicate and dyspeptic. Sold in canisters by every respectable druggist, where also may be obtained,

BRIGHT'S UNIVERSAL SANATIVE BREAKFAST BEVERAGE,

held in the highest esteem for its refreshing and invigorating qualities. Either are prepared in two minutes, and require no boiling.

Sold in canisters,—the Farina at 1s. 6d., 3s., and 6s. each; the Breakfast Beverage at 1s. 2d., and 1s. each. Manufactory, 5, Holland-street, North Brixton. Wholesale of Messrs. Barclay, Farringdon-street; Sanger, 150, Oxford Street; White, 24, and Johnston, 64, Cornhill; Messrs. Hall and Co. Bell Horse, Bishopsgate-street; Messrs. Raimes and Co., Edinburgh; Newsom and Son, Cork; Anderson, Calcutta; White Stork Bar, York; at the Western Depot, corner of Church-street, Frith-street, Soho, and retail of every respectable druggist in the kingdom.

For the use of charitable Individuals and District Visiting Societies, both articles are put up in small packets—the Farina at 6d., and the Breakfast Beverage at 2s. per dozen.

N.B.—A specimen packet of either, with testimonials, &c., will be forwarded (post free) to any address on an order, enclosing six Post-office stamps (post free) to the Manufactory, 5, Holland street, North Brixton.

None is genuine unless signed by the Proprietor, JOHN BRIGHT

ROYAL COLLEGE OF SURGEONS' AND APOTHECARIES' HALL.

DR. STEGGALL continues his Lectures and Examinations for the College and Hall, and all other Medical Boards. Dr. S. has removed from No. 47, Bloomsbury-square, and his Lecture and Class Room will be in future at his private residence, No. 2, Southampton-street, Bloomsbury-square.

WILLIAM GRAY,

19, DAVIES STREET, BERKELEY SQUARE,
LONDON,

(Under the Immediate Patronage of the most Eminent Surgeons.)
Manufactures

THE MARQUIS OF ANGLESEY'S IMPROVED ARTIFICIAL LEG.

Improved Artificial Arms
Improved Instruments for Division of Tendon
Extending Machines for Contraction of Knee and Arm
Crutches of all kinds
Trusses of every description
Weak Leg Instrument
Exercising Swings, Reclining Planes, &c., for Distorted Spine
Invisible Spinal Machines
Boots for Weak Ankles and Contracted Legs
Elastic Lacing Stockings for Enlarged Veins, &c.
Elastic Knee Caps for Weak and Rheumatic Affections
Bandages, Belts and Suspenders
Elastic Ankle Socks for sprained or Weak Ankles

Directions for Measuring, &c., will be forwarded to any part of the country by applying as above.

SOLUT. MAGNES. BICARB.—Dr. WILKINSON, of Bath, whose well-known familiarity with Practical Chemistry entitles his opinion to respect, says,—

"A bottle of the Fluid Magnesia of Sir James Murray's sent to me for Analysation by a Chemist in this Town, gave me Seven Grains of Magnesia and *Three of Sulphate of Soda* to the ounce, whilst yours yielded Seventeen Grains of PURE MAGNESIA to the ounce. I conscientiously bear testimony to the correctness of the above results,

(Signed) "C. H. WILKINSON, M.D."

"Dated October 23d, 1840."

To Mr. C. DINNEFORD, Bond street, London.

The above conclusive testimony is further corroborated by PROFESSOR BRANDE, of the Royal Institution.

Dr. PARIS, author of the Pharmacologia, and Mr. Morgan, of Dublin, who also examined and reported on Sir James Murray's COMPOUND.

It has also received the sanction of SIR HENRY HALFORD, Bart., President of the Royal College of Physicians, and the most distinguished Members of every branch of the Medical Profession.

Sold in Jars (for Dispensing only) containing 5lb., at 5s. 6d. each by the usual respectable Wholesale Houses, or direct from the Proprietor.

INVALID CARRIAGE.

THE Public are respectfully informed, that this valuable invention is now brought to perfection, on a very large scale. Its advantages to Invalids are too numerous to detail and explain in an advertisement, but on an inspection it will at once convince the most sceptical of its astonishing conveniences. In cases of accident it is invaluable, and should be kept by the proper authorities at every police-station. It has been inspected by numerous scientific persons, and all are delighted with it. To all persons afflicted in any way whatever, the carriage present immense advantages. Although a deal of money has been expended in bringing this invention to maturity, the cost will be very moderate.

For further particulars, please address (prepaid) to Mr. Walter Smith, 11, John street, Hammersmith, who will forward drawings, together with the price, which is regulated according to the manner in which it is fitted up.

DISEASED AND HEALTHY LIVES ASSURED.

MEDICAL, INVALID, & GENERAL LIFE OFFICE, 25, PALL MALL, LONDON.

CAPITAL, £500,000.

PRESIDENTS.

DEPARTMENT OF MEDICAL STATISTICS.

William Farr, Esq., General Register Office

ACTUARY.

F. G. P. Neilson, Esq.

This Office is provided with very accurately constructed Tables, by which it can Assure UNSOUND Lives on Equitable Terms. The Extra Premium discontinued on restoration of the Assured to permanent health. A portion of the extra premium may remain as a Debt on the Policy. Survivorship Assurances where the life in expectation suffers from disease, effected at cheaper rates than at any other office.

Similar tables enable the Society to grant Increased Annuities on Unsound Lives, the amount varying with the particular disease. Members of Consumptive Families assured at Equitable Rates. Healthy lives are Assured on lower terms than at most other Offices. Application for Agencies to be made to the Actuary.

PATENT BELT-BAND SPRING DRAWERS, for Hunting or Riding, on an improved principle, for supporting the loins and abdomen, in riding or other exercise, preventing rupture, checking increase of corpulency, and giving remarkable comfort in general wear, both to thin as well as stout persons. Made by the inventor, S. K. SALAMAN, tailor and breeches-maker, 19, Charing-cross, two doors from Craig's-court. Riding trousers cut upon an improved plan, which renders them extremely pleasant with or without braces. The new light waterproof cape and coat, adapted to all tempers, seasons, and constitutions.

FRESH IMPORTATION of GENUINE ARROW-ROOT from the South Sea Islands, forwarded by Mr. Williams, son of the late lamented missionary, and consigned direct to A. S. PLUMBE, 3, ALIE-PLACE, GREAT ALIE STREET, WHITECHAPEL. This Arrow-root has been tested by the most eminent Physicians and Surgeons in London, and found to be greatly superior to any other. The jelly formed by it is stronger, thicker, and more transparent, and remains much longer in a coagulated state than any other Arrow-root. It may be used for puddings, custard, blancmange, &c., recipes for which are printed on the wrappers. It is also an excellent astringent, and should be taken plentifully in cases of diarrhœa.

Sold by Stationers, Grocers, Druggists, &c., in one pound packets, considerable profit allowed to persons to vend the article. Particulars may be obtained of A. S. P., 3, Alie place, Great Alie-street, Whitechapel.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, begs to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plan and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

COALS.—SAMSON and Co., Essex Wharf Strand, and JARROW, South Shields, Coal-merchants, Importers, &c., assure their Friends that they have unusual facilities for supplying them with COALS, as they are now freighting, direct from the Collieries, and would advise early orders previous to the approaching rise in prices. Very best screened, 25s. 6d.; seconds, 24s.; Anthracite, for Arnott's Stoves, 29s., within four miles, cash. Founders' and Gas Coke, equally cheap.

IMPORTANT TO SURGEONS.

THEIR especial attention is invited to the following extracts of letters received by W. BERDOE.

"I can say of the coat I purchased of you, that I never had any thing so pleasant to wear, or so efficient as a Waterproof, and therefore, in EVERY respect superior to a 'Mackintosh,' it is a very pleasant garment for lightness and moderate warmth, when the weather is dry; as a Medical man and having much daily riding, I have fully proved what is above stated, and you are welcome to use this as the testimony of one much and constantly exposed to the weather, as it may be useful to yourself and others.

"Cirencester, "THOMAS WARNER,
"January 4th, 1843. "Surgeon."

I got a Waterproof Coat from you about two years since, and I never had such comfort and satisfaction from any other description of manufacture whatever. PIERCE NAGLES.
Dublin.

From a Clergyman in Wales.

Enclosed is the amount for the Ventilating Waterproof Frock I ordered of you, I am much pleased with it—it is Waterproof certainly, as a five mile ride on horseback in a very hard rain satisfactorily proved, while the perspiration was not confined. It is decidedly the best rainy weather garment I ever wore.

Lahaness, Landell's Fawr, HENRY R. LLOYD.

The above were sent to W. B. entirely unsolicited by him, and came from parties he has never seen.

The garment referred to is warm, light, portable, durable, economical, thoroughly respectable, free from singularity of appearance, and warranted (WITHOUT CONFINING PERSPIRATION) to exclude any description or quantity of rain whatever. It is already extensively adopted among the Medical Profession, many of the most eminent Physicians and Surgeons having long worn it. Made only by

WALTER BERDOE, Tailor, Waterproofer, &c.
69, CORNHILL, (Eight doors from Bishopsgate Street.)

SILVER SUPERSEDED, and those corrosive and injurious metals, called Nickel and German Silver, supplanted by the introduction of a new, and perfectly matchless ALBATA PLATE. C. WATSON, (late Alderman,) 41 and 42, BARBICAN, and 16, NORTON FOLGATE, aided by a person of Science in the amalgamation of Metals, has succeeded in bringing to public notice the most beautiful Article ever yet offered; possessing all the richness of Silver in appearance—with all its durability and hardness—with its perfect sweetness in use—undergoing, as it does, a Chemical Process, by which all that is nauseous in mixed Metals is entirely extracted—resisting all Acids—may be cleaned as Silver, and is Manufactured into every Article for the Table and Sideboard.

Table Spoons and Forks	per doz.	16	6
Dessert Ditto	ditto	12	0
Soup Ladles		6	0
Sauce Ladles		1	0
Tea Spoons	per doz.		
Gravy Spoons		3	0

C. WATSON begs the Public will understand, that this Metal is peculiarly his own, and that Silver is not more different from Gold, than his Metal is from all others; the Public will, therefore, have no difficulty in discovering the animus which directs the virulent attacks made against him by a party who is daily suffering from the unparalleled success which has marked the progress of his New Plate since its introduction. C. W., unlike this party, courts comparison, feeling confident that the result will establish its pre-eminence. Entire Services of Plate Purchased. 41 & 42, Barbican, and at 16, Norton Folgate.

PAPER TEA TRAYS, 42s.—a full-sized set of three, Gothic Pattern, and an infinite variety of others, up to 10 guineas a set; a set of three convex japan trays, 10s.; very best London made tea urns, in every variety, from 33s. to 105s.; a dozen ivory knives, 14s.; a dozen dessert ditto, 10s. 8d.; carvers, 4s. 6d. per pair, fenders, from 6s. to 60s.; fire irons, from 3s. 3d. to 25s.; American ovens, to bake before the fire, 4s.; copper kettle, 7s. 6d.; copper coal scoop, 11s. 6d.; iron saucepans, enamel inside, 1s. 6d. upwards; and every article in furnishing ironmongery unusually low. Quality is here the primary consideration,—hence its uninterrupted success for 50 years; and its present celebrity as one of the best and most extensive furnishing Warehouses in London.

CLERICAL, MEDICAL, AND GENERAL LIFE ASSURANCE SOCIETY.

INSTITUTED 1824.

A THIRD QUINQUENNIAL DIVISION OF PROFITS was made in JANUARY, 1842, and the BONUS then DIVIDED *amounted, on an average, to*

£28 PER CENT. ON THE PREMIUMS PAID.

AGENTS ARE REQUIRED WHERE NONE HAVE BEEN APPOINTED.

MANY MEMBERS OF THE MEDICAL PROFESSION ACT AS AGENTS TO THIS SOCIETY, TO WHOM THE USUAL COMMISSION IS ALLOWED.

Further particulars can be obtained of

GEO. H. PINCKARD, Actuary,
No. 78, GREAT RUSSELL STREET, BLOOMSBURY, LONDON.

*** THE INCOME OF THIS SOCIETY, WHICH IS STEADILY INCREASING, NOW EXCEEDS £97,900 PER ANNUM.

Published by Longman and Co. London, and sold by all Booksellers. In 1 vol. price 16s.

METHODUS MEDENDI; or, the Description and Treatment of the principal Diseases incident to the Human Frame. By HENRY M'CORMAC, M.D.

"A very valuable practice of medicine, containing a vast quantity of useful information, the result of practical observation and great research."—Dublin Medical Press.

Now ready, 8vo. cloth lettered, with 315 Wood cuts, price 18s. The first volume of

TURNING and MECHANICAL MANIPULATION. By C. HOLTZAPFFEL, Associate of the Institution of Civil Engineers. The work, which will be completed in 5 vols., is intended as a work of General Reference and Practical Instruction on the Lathe and the various Mechanical pursuits followed by Amateurs.

Each volume may be purchased separately, and will form a distinct treatise on the branch to which it is appropriated. Vol. I. treats of Materials from the Vegetable, Animal, and Mineral Kingdoms; their uses in the Mechanical Arts; modes of severally preparing, working, and joining the Materials; with the practical description of a variety of Processes, which do not generally require the use of tools with cutting edges. Vol. II. (to be published in April, 1843,) will treat of Cutting Tools and Abrasive Processes.—Vol. III. The Complete Practice of Hand or Simple Turning.—Vol. IV. Practice of Ornamental, or Complex Turning. Vol. V. Practice of Amateur Engineering.

Published by Holtzapffel and Co., Engine, Lathe, and Manufacturers, No. 64, Charing Cross, and No. 127, Long Acre, and to be had of all Booksellers.

Just Published.

VIEWS upon the STATICS of the HUMAN CHEST, Animal Heat, and Determinations of Blood to the Head, &c., with an Appendix, examining certain Views of Professor Liebig. By JULIUS JEFFREYS, F.R.S., formerly in the India Medical Staff, Staff Surgeon of Cawnpore, &c.

Longman and Co., Paternoster row; S. Highley, Fleet street; J. Churchill, Princes street, Soho.

CURTIS ON DEAFNESS, &c.

Just published, with plates, Third Edition, price 1s.

THE PRESENT STATE OF AURAL SURGERY, with the most successful and approved modes of treatment as employed at the principal hospitals of France and Germany, and at the Royal Dispensary for Diseases of the Ear. By JOHN HARRISON CURTIS, Esq., Director and Surgeon to the Institution. London: John Churchill, Princes street, Soho.

Of whom may be had, by the same Author, 4th Edition, price 2s. 6d.

THE PRESERVATION OF HEALTH.

With Remarks on Air, Exercise, Diet, and Clothing, &c. Causes and Prevention of Disease. Suggested Improvements in the Metropolis as to sewerage, supply of pure water, purification of the atmosphere, erection of fountains and additional pumps, recreation in the open air, and the establishment of casinos in the parks.

"Full of judicious and sensible observations."—Literary Gaz.

"The best manual of health that has ever appeared."—Standard.

"The advice to the sedentary and the studious is deserving of attention."—Morning Chronicle.

"Curtis is clever, and his little book is alike amusing and well informed."—New Monthly Magazine.

"The work will do much to open the eyes of the public on this subject."—Metropolitan Magazine.

"In this useful treatise we find well conceived observations on the subject of labour and exercise."—Chambers' Edinburgh Journal.

"This is a plain, sensible unpretending little treatise."—Tait's Edin. Magazine.

"Extremely well worthy a careful perusal."—John Bull.

CRONIN ON TRACTION IN CONSUMPTION AND ASTHMA, WITH CASES.

Will be published immediately,

AN ESSAY on the SUCCESSFUL TREATMENT of ASTHMA and CONSUMPTION by TRACTION, the new remedy successfully introduced into practice, by Mr. CRONIN, late Surgeon to the Dispensary for the Diseases of the Lungs and Heart, Liverpool, and Surgeon to the Free Dispensary, 91, St. Martin's Lane.

VAN BUTCHELL on FISTULA, &c.—The Sixth Edition.—Just published, in 8vo., cloth boards, price 7s. 6d. (enlarged).

FACTS and OBSERVATIONS relative to a Successful Mode of TREATING PILES, Fistula, Hemorrhoidal Excrescences, Tumours, and Strictures, WITHOUT CUTTING or CONFINEMENT; illustrated with numerous Cases. Being a familiar Exposition of the Practice of S. J. VAN BUTCHELL, Surgeon-Accoucheur.

"It is very rarely our practice to advert to books on professional subjects; but the 'Facts and Observations' appear, by their practical and unpretending character, to indicate so easy and prompt a relief from a large class of most painful and distressing diseases, that we believe this word of commendation from us, which we give with much sincerity, will not be thought misplaced or without its use."—Examiner.

Published by H. RENSHAW, Medical Bookseller, Strand; sold also by the Author, at his residence, 27, Baker street, Portman-square.

A MADEIRA HOUSE, 36, BEDFORD SQUARE.—For the benefit of persons in delicate health, or labouring under old or variable disorders of the internal organs or of the joints. A complete and liberal family establishment has been formed, in which an uniformly high temperature, with airiness and the indispensable comforts of an invalid in retirement has been carefully considered. Professionally directed by a gentleman who has had peculiar opportunities of observing the advantages of a warm climate, as well as the methods required to render it safe and available. Applications for particulars must be by letter addressed to Mr. R. NUTH. One or two domestics in declining health, and of superior character, may find an advantageous engagement.

TO MEDICAL PRACTITIONERS.—To meet the convenience of those Medical Practitioners, who (owing to their connection with the Poor Law Unions, or other services) are desirous of expeditiously refreshing their Anatomical Knowledge, with the view of obtaining the Diploma of the Royal College of Surgeons, also for the accommodation of Senior Pupils, Mr. DERMOTT receives Gentlemen into his House by the Month; an arrangement vastly advantageous to those who cannot absent themselves long from their Practices. And in reference to the many inquiries of candidates with respect to the extent of indulgence on the part of the College, Mr. D. inserts their own official announcement:

The Court of Examiners have resolved

"That gentlemen who were practising surgery prior to 1815, be admitted to examination on producing proofs of such anatomical and surgical education as may be deemed sufficient by the Court of Examiners.

"That other candidates be admitted to examination upon the production of the several certificates required by the regulations, and also, when they began their professional education by apprenticeship, or by attendance on lectures or hospital practice."

Apply to Mr. DERMOTT, Charlotte Street School of Medicine, 15, Charlotte Street, Bloomsbury.

Dissections, Private Instruction and Surgical Lectures continued during the Summer.

*** Private Courses of Operative Surgery.

DR. RAMADGE ON CONSUMPTION.

[illegible] Edition, Illustrated by Coloured Plates.

CONSUMPTION CURABLE, and the manner in which Nature as well as Remedial Art operates in effecting a healing Process in Cases of Consumption, explained and illustrated by numerous remarkable and interesting Cases. By FRANCIS H. RAMADGE, M.D., Fellow of the College of Physicians, &c.

"The author's treatment is so simple, so accordant with physiological and pathological laws, so free from charlatanism and imaginative dreams, that I not only feel a high predilection for it, but think it worthy to be recommended to the impartial and careful examination of my Professional Brethren."—Preface to the German Translation, by Dr. HOHNBAUM.

"My own experience has proved to me that the work of Dr. Ramadge abounds in interest, and especially deserves the attention of Practitioners."—Preface to the French Translation, by M. LEBEAU, Physician to the King of the Belgians, and Principal Physician to the Military Hospital at Brussels.

London: Longman and Co.

MESSRS. J. C. & S. STEVENS beg to announce that on Saturday, Feb. 18th, at 12 o'clock, they will sell by Auction at their Great Room, 38, King Street, Covent Garden, a large Collection of Specimens in Comparative Anatomy, Skeletons of Birds and Animals from South and North America and Australia, including Monkeys, Kangaroos, Boa Constrictors, &c., in fine preservation. Reptiles preserved in spirits from Africa and India, &c. &c., on view the day prior, and Catalogues had at the Room.

No. 178. Vol. VII. LONDON, SATURDAY, FEBRUARY 18, 1843. PRICE FOURPENCE, Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times' Office, (late Lancet Office), London

SUMMARY.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

By C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

I have now to notice an important phenomenon resulting from percussion that I did not mention yesterday, and that is, sound proceeding from the deep-seated parts. I have mentioned that sounds on percussion may be elicited either from the superficial parts or the dilated parts in some degree, and I mentioned the different sounds that arise, and that may be thus elicited, by deep seated percussion in the upper parts of the chest. But in the upper parts of the chest, you will observe there are constituents of sounds that I have not adverted to,—the large tubes themselves.

Now it appears that a certain amount of tubular sound is given in a state of health, by forcible percussion, if it is not mixed up with an unusual pulmonary sound, which tends to give a great resonance to those parts of the chest. If the pulmonary tissue is of such depth and thickness as to be adapted to transmit the stroke to the interior of the tubes, you will not, if you listen, find a tubular sound on percussion. But if you come to the trachea, and make the percussion there, you will get a tubular sound. This sound varies according to the length of the tubes. It happens in some cases of disease in the upper parts of the lungs, especially towards the roots, that they do transmit the sound to the tubes, and under these circumstances, you find a tubular sound on percussion. This completes the whole history of the percussion sounds of the chest. The tubular stroke sound is produced in cases of disease, where the pulmonary tissue is so far condensed as to transmit that stroke from the exterior to the tubes, or where the tubes are pushed into closer contact with the walls of the chest, or when the tubes themselves become expanded by irritation or by dilatation, or by the formation of cavities communicating within them; where this is the case, the sounds are more or less of a tubular character, and what is called the *crack-pot* sound is produced by the percussion in the tubes or cavity communicating with the tubes. The percussion in that case gives not only the sound of the tube, but likewise a little tinkling or quivering sound, which resembles not only a pot or a jar sound when struck, but a crack pot sound, with the addition of a certain jar or tinnitus, or bubbling through it.

We now proceed to the next class of sounds, those produced by the passage of the air to and fro, or expiration and inspiration. I shall not be too minute in explanation of these signs and the varieties of auscultation, because I have detailed them fully in the works I have written on this subject in the last edition of the "Pathology and diagnosis of diseases of the chest." I shall only here refer to those points which require observation in reply to some able writers who have treated of this subject.

Now you will find that I have given a certain definition of the sounds produced by the passage of the air, that is motion resisted. Motion alone does not constitute sound, but there must be resistance. And so with regard to the motion of the heart; the motion of the air to and fro, gives sound in proportion to the amount and the velocity of the air, and the amount of resistance given to it. Accordingly, in the sound produced by inspiration, the air being received into the mouth in the act of inspiration, passes with considerable force through the tracheal cavity, enters the larynx, goes down to the trachea, and passes down to the ultimate divisions of the bronchi. Now the air meets with a certain degree of resistance from the sides and angles of the tubes and various prominences which it meets with in its course. If the motion of the air is forcible, the passage of the air produces sounds. Accordingly, we have sounds characteristic of the parts through or over which the air passes. We have sounds produced by the passage of the air in the nostrils, and in the upper part of the head. There is the palatal sound, from the passage of the air against a sort of palate, evident in the snorting of persons during sleep. There is likewise the laringeal sound, quite distinct, and highly characteristic; you hear it by applying your ear to the stethoscope over the larynx. Then the air passes down with considerable force, and carries sound with it through the air tubes, and therefore there are various sounds produced at the upper part of the air passages. They are heard likewise in inspiration as the air passes down the trachea over the larger bronchi. The sounds become more tubular over the smaller bronchi, and when the air gets into the smaller ramifications of the bronchi, the sound produced give the idea of concentrated air in motion with considerable force. It is more concentrated in one body than when it becomes expanded over a range, because the tubes and their divisions are enlarged in area, and hence there is a greater velocity in the passage of the air through the trachea, than the larger divisions of the bronchi. This is the reason why the sound is louder and more intense in this situation than it is over the surface of the lung. But where the tubes plunge and divide into the tissue of the lung, there the resistance met with is still somewhat deadened, though there is enough to produce sound. When the air becomes diffused over a greater extent, and enters into the vesicular texture, it gives rise to a diffused dull sound, of a more agreeable character, which is called vesicular or respiratory. The sound in this case is somewhat like the passage of a breeze through the leaves of trees, and its peculiar character is that it has not the sharpness or harshness of the concentrated tubular sound. For a more correct description and better understanding of these sounds, I must refer you to the direct impression of the senses, which will give you a far better idea than words can express. In fact, words do not properly convey any representation of the senses.

We now consider the air passing out. In this case there is a little modification in the sound; it is not of the same kind as it is in the air passing in. After the lungs are expanded by air, there is a passive state, and the motion commences in a reverse direction. But the motion commencing has but little force; it is a thing beginning to move. It has little impulse or momentum, and clearly has not the elements of sound, or the element of sound and motion is wanting. Resistance is the first effort, and this is created by the air passing through the minute vessels into the tubes. The tubes are funnel shaped, and there is no angle to oppose them whatever. Hence when you listen to the chest in the act of expiration there is a little faint sound, but it is trifling to the full and equal sound in inspiration. It is different when the air gets into the tubes. It acquires in that case greater momentum or continuence of this motion, and acquires greater velocity also; but as I have mentioned the area of the tubes is considerably smaller than the area of the vesicles; and the area of the large tubes is considerably smaller than the area of the small tubes. There is a progressive increase of velocity as the area passes from one to the other, and with the increase of motion there is an increase of sound. A certain degree of reverberation is produced by the passage of the air along the sides of any tube, and more or less motion will be produced.

Now there is one principle we have not yet clearly seen. You hear the sound on inspiration fully all over the lung, because the sound is produced all over the lung, not only in the tubes, but in the vesicular texture itself. But we hear the sound of expiration very indistinctly over the lung, and it is only produced in particular parts—internal parts. How is it that we do not hear the sound of the tubes through the vesicular texture? For this reason—that it is an exceedingly bad conductor of sound. The texture of the lungs consists of a succession of bodies, differing very much in density from each other; and differing so as to impede the transmission of sound, there will be a certain amount of equality of tension given to them to transmit the sound just as soft bodies are dampers of sound.

Now where sound is produced, its propagation is owing more to the yielding of the texture, than to the transmitting of the vibrations. This is the reason why the sound of inspiration is purely vesicular over the greater part of the lung, as also why in expiration there is but a slight sound over the greater part of the vesicular texture. The sound transmitted to the tubes is not transmitted to the interior. When you come to the bronchi near the axilla, you have the air in the tubes so intense as to pass across the vesicular texture, and you hear the sound of tubular inspiration. It is louder and more concentrated, because there is no intervening texture to cut off the sound.

Now all these principles are applicable to disease. Suppose a particular texture is consolidated or is compressed by liquid effusion, the result will be more sound than is given by the vesicular texture. This very compression of texture renders the lung a good conductor of sound. It was before a bad conductor on account of the porosity of its substance, which is very membranous and very flaccid, giving a dead sound. But now the sound is more concentrated from the medium of the sound being more uniform, and being in a condition capable of transmitting sound. In expiration you will have not only the sound of the tubes in the region examined, but you may have the sound transmitted to the other regions by the concentrated texture. It is transmitted from the interior to the exterior.

Now let us consider a few things in respect to unhealthy sound. Loudness depends on velocity, and the amount of resistance. Accordingly, quick breathing and rapid breathing give the greatest amount of sound. On the other hand, low or long breathing gives little sound, and where you have difficulty in hearing the sound on inspiration, you may render it more audible by desiring the patient to take a quick breath. A cough does the same thing. In children the respiration is naturally both more forcible and more energetic or rapid, like most other movements of children, and this is one reason why respiration is naturally louder in children. The texture of the lung is more dense. There is a greater proportion of solid contents in the texture of the lungs of young subjects than in old persons, and the superficial parts of the lung are in fact denser. And this is the reason why the sounds there are transmitted, and the sound is so much more of a tubular character. There is a greater sharpness in it and in the neighbourhood of the tubes, and it is more-

[illegible] tinct. The tubular phenomena are altogether more developed in children than in adults.

Now disease sometimes produces a somewhat similar effect at one part of the lung. We find in children that if anything incapacitates a large portion of the lung, it will acquire increased exertion and increased rapidity. Thus it is when one lung, or a large portion of one lung, is diseased; there is caused supplementary respiration, a term given to it by Dr. Andrew. Morbid varieties, consisting of different degrees of loudness and intensity in the character of the respiration are induced in different parts of the chest. There may be many varieties of the respiratory murmur or breath sound all over the chest, without there being any [illegible], and therefore with regard to the first sound, or with regard to the stroke on percussion, the chief standard is that of comparison of the one side with the other. Then there are varieties in the degree of the respiration. For instance, the sound of inspiration is impaired by those diseases that obstruct the tubes, preventing the access of the air through the texture. It is likewise impaired by compression of the texture, as in liquid effusion. Then there is unusual rigidity of the texture, a want of elasticity, a want of obedience to the motions of the chest, which prevents the passage of the air in and out, to and fro, regularly, as in the ordinary act of respiration. Again, this differs not only in degree but in kind, and thus you may have varieties of sharp and soft respiration, the sharp sound somewhat approaching to the tubular character, or a soft and diffused sound which is naturally deep.

The varieties of tubular respiration may be transmitted to the exterior, and give rise to different signs. There is a cavernous variety arising from the communication of the air with a cavity, instead of dividing in the usual way. We find this taking place near the apex of the lung in phthisis. There are sounds depending on the size of the cavity, sometimes by the passage of the air in and out of the cavity, and sometimes across the mouth of the cavity. Great varieties may be presented by the condition of the lung when diseased. Under these circumstances, when there is cavernous respiration or tubular respiration, you [illegible] that the sound is produced not only in inspiration, but more or less in expiration. This is [illegible] a constant phenomenon. Now, just [illegible] the reason why you have not always the [illegible] constant phenomena in cavernous respiration and in bronchial respiration. The sound [illegible] by the passage of the air into a [illegible] from a resonance taking place [illegible]. The sound in this case is [illegible] blowing into a decanter of water. On the other hand, there may be a cavity, across the [illegible] of which the air blows. It often takes [illegible] that a cavity is formed in the neighbourhood [illegible] and the air merely blows across [illegible] it passes downwards. Every [illegible] is produced, and the sounds [illegible] may be produced by the [illegible] mouth of a cavity in [illegible] and accordingly in [illegible] of the air resounding [illegible].

[illegible] are varieties in the respiration [illegible] may be prolonged [illegible] the other; or it may [illegible] side, while it is [illegible]. The inspiratory sound lasts [illegible] the motion of inspiration. But in some [illegible] you find on listening to the chest that the [illegible] is stopped short, instead of going to the full [illegible] respiration. It is stopped short, as if [illegible] it from going to its full [illegible] arises from various causes of disease. [illegible] instance, when the bronchi are very [illegible] with mucus; [illegible] is, however, [illegible] the result of compression of the [illegible] effusion. Sometimes it arises from [illegible]. The irregular prolongation [illegible] of the air tubes, as in [illegible], where the air cells [illegible] however other they do [illegible] with freedom. This [illegible] respiration. In inspiration [illegible] in bronchitis and

in expiration most remarkably in emphysema. Sometimes it has other things added to it. Not merely are the sounds of respiration modified, but new sounds are added, sometimes of a totally new character. Their principal character generally is dependent upon an unnaturally increased resistance to the passage of the air through the tubes and into the vesicular structure. Increased resistance to the passage of the air will produce new vibrations, which are rendered in some degree universal: it is soniferous, and altogether a peculiar sound.

This peculiar new sound is referable to various causes. For instance, it may be produced by a swelling on the trachea, by a tumour pressing on it, so as to leave the passage very narrow. This even will cause an increased resistance, and that increased resistance, when increased to a considerable degree, causes new sounds. There is not only a blowing sound where the passage of the air is free, but there is a musical sound. There are variations of sound produced by different rhonchi—the mucous rhonchi. There may be a clot of mucus across the angle of the tube, and as the air passes, it receives a jerk, and is driven into a sonorous vibration. There are the sonorous rhonchi, the snorting, or dry mucous rhonchi. There are other varieties that are produced by the passage of the air through a liquid; the air passing through with considerable rapidity produces bubbles, the breaking of which bubbles causes a new sound, a crepitation, or a bubbling sound, more of a crackling character in the smaller tubes, and a bubbling in the larger ones. There is the whistling, which is one of the dry rhonchi. This takes place chiefly in the small tubes. Also in the large tubes, where the passage is narrow. This whistling implies a very narrow orifice. There is a condition, again, that is indicative of serious disease; that is, where the loud sonorous rhonchus is hardly heard. This depends on a tumour external to and compressing the tube, as in obstruction from mucus or a thickening of the passage; and where it remains permanent, it may imply something serious.

There are other signs of disease independently of these, to which we should direct our attention. For instance, compression on the aorta by one of the large bronchi, and a great enlargement of the bronchial gland. The rhonchi are very often unnatural and vesicular, for this very obvious reason; inasmuch as there is a bronchial tumour, there will be a certain degree of obstruction to the passage of the air, and consequently the act of vesicular respiration will be very much impaired. Again, some of the varieties of rhonchi owe their presence and their character to their being in the finer bronchi instead of the larger and middle-sized ones. Not in the vesicular texture entirely, but in the tubes leading to them. This depends on the amount of the liquid. Where it is [illegible], and it does not amount to a crackling, it is subcrepitant; and where it is crackling, it is crepitant. The cavernous sound consists of some other sound being associated with the blowing sound in respiration, and it depends on the character of liquid in the seat of the respiration. Very often there is musical sound and the mucous crepitant together. This is a very common kind of mucous rhonchus. The dry mucous, the crepitant and the subcrepitant, is sometimes produced; it varies very much, and has been called the muco-crepitant rhonchus.

Now the bubbling rhonchi are rather more important. The moist rhonchi are more important than the sonorous, for this reason that the presence of the liquid in the texture or in the tubes will more interfere with respiration than the obstruction producing the sonorous rhonchus. In fact, it may arise from a partial obstruction, whereas the mucous and the other rhonchi, imply a bubbling in a great many tubes; and accordingly you may judge that the bubbling rhonchi are important in proportion to their extent, and to the amount of infringement on the respiratory function.

Now a few words as to the subject of the voice. Sounds of the voice are transmitted through the chest. As the air passing along produces sounds in the vesicular texture and then traverses the tubes, so the sound of the voice is produced in the tubes in various ways. Let us start from the loud and open voice. If you apply your ear you will hear the voice in its greatest character; the whole of the trachea is occupied in a strong degree, and the larger tubes especially. You have in this case natural bronchophony, like to the voice in the interior, in the region of the larynx and the trachea, over the sub-divisions of the large tubes. When we come to the texture of the lung, you have a condition greatly different. The tubes divide and subdivide, and diffuse an amount of resonance by that subdivision which extends all over the texture of the lung. The lung, as I said before, is a bad conductor of sound, and not only is it so, but it is a stifler of sound, a sound damper. This is a principle natural philosophers have lost sight of in a great degree, that a body may not only be a bad conductor of sound, but may actually intercept sound, so that it is not only not transmitted, but damped and cut off. In some parts there are particular notes of the voice. The sounds may be transmitted over the chest. Take the tubular sound. There is the natural sound of the voice or tracheophony, which is heard also in the back of the neck, and is transmitted pretty strongly. When it is transmitted into the texture of the lung, and is transmitted over the larger tubes, you hear natural bronchophony. You hear it in the axilla, and also in the intercostal regions, and then there is a resemblance between the sounds of the two sides. You hear the sound of natural bronchophony more on the right side than on the left. Besides these sounds there is pectoral fremitus. The sound in this case is diffused more forcibly over the whole chest, arising from the air being so strong as to overcome any difficulty offered by the vesicular texture. When the sound is very strong and cannot be muffled, it is transmitted into the interior, and is heard in the form of diffused resonance. It may be both heard and felt, and you find that the sound causes the interior to vibrate with your ear.

Now with respect to the explanations that have been adduced, I have given those of Laennec. Dr. Schomel asserts that the morbid sounds produced in the tubes, and the natural sounds of the bronchial voice arise from what he calls consonance. It is very well known to musicians that when stringed instruments are tuned to a certain key, and you strike a corresponding cord in another instrument, that will vibrate and give a respondent note, according to the capacity of the body to vibrate. Hence Dr. Schomel says that the reason why you do not hear bronchophony in all cases is, because there is no consonance. If this were the case, we should hear certain sounds given in diseased bronchophony, and certain sounds given with regard to natural bronchophony. I shall take up the other varieties of these sounds tomorrow.

Cure of Epilepsy.—Dr. De Losch, of Brussels, records a case of great interest. The patient was a young lady, 11 years of age, and of a nervous and very excitable temperament, in whom epileptic fits became frequent, after an accident she had met with. Antiphlogistics, anthelmintics, sedatives of all kinds, change of air and scene, emetics, oxide of zinc, cyanuret of iron, assafœtida, indigo, nitrate of silver, &c., had been tried without success, when the Doctor tried ammoniacal sulphate of copper, of which he ordered one-sixth of a grain three times a-day, to be followed by a glass of old Malaga wine. Three days now elapsed without a fit, but, on the fourth, one of much violence occurred. The dose of the remedy was now increased to one-fourth of a grain, and no subsequent fits took place. Some vertigo was experienced for a time, but this disappeared gradually, and the young lady has enjoyed perfect health for the last two years. The renal secretion was somewhat augmented, and the urine exhaled an ammoniacal odour while the patient was under the influence of the ammonio-sulphate, but no other function underwent the least disturbance.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

(LECTURE VII., Delivered December 16, 1849.)

Gentlemen, I propose to begin this lecture by referring to the subject of congestion of the brain, and its symptoms,—apoplexy; in order that I may mention one or two facts to you which are full of interest. In the first place, I may venture to say that the purest case of apoplexy, arising from congestion within the brain, is that which follows a violent attack of epilepsy, and I do this, that we may have a fair view of what congestion will produce. For in epilepsy, in the majority of cases, you may be perfectly sure that congestion is quite pure if it is accompanied by anything like effusion.

The first remark I have to make is, that congestion may go so far as for a moment to affect the excito-motor system, so as to produce a little difficulty in swallowing. I want, in the first place, to mention a very interesting fact. I was called a short time ago (three or four years) to see a patient labouring under that violent degree of apoplexy following epilepsy, to which I am now alluding. After examining the case, I adopted these measures:—I took some of the coldest water I could get, and dashed that cold water in the face of the patient. The object of this was to excite the muscles of respiration. I then placed the patient perfectly upright, and took blood until a little impression was made on the whole system. I repeated the experiment of dashing the cold water on the face, but all that we could do had not the least effect. This is, therefore, an interesting case, as giving you a diagnostic of the violence of the disease; and the conclusion to which we come is this, that in the most violent cases of apoplexy from congestion of the brain,—those cases in which the respiration is affected, and the swallowing is affected, if you dash cold water on the face, it is most probable you will produce no effect whatever, and it may pass in your mind for a very severe case. Here you have a measure of the case, and it is only necessary throughout our lecture to determine what cases are so very formidable with regard to the prognosis, and the violence of the affection.

Another fact I want to mention is this, that I believe, in many cases of pure congestion of the brain, the patient dies because the respiration is imperfect. You observe in these violent cases the respiration is stertorous; and when it is so, you may be sure that it is more or less imperfect. In a violent attack of epilepsy, the respiration is first of all stertorous, because the excito-motor system has been involved in the disease. The next thing that follows, is the affection of what may be called the ganglionic system; and the way in which I would describe this, will be by a reference to the experiment of an animal with the pneumo-gastric nerve divided; and even the lungs become suffused with mucus, so that there is an obstruction in the respiratory function as well as stertorous breathing.

Now in these cases there is first a question, whether you will use any kind of relief beyond what is most common? Suppose you have such a case, and it is distinctly (from the absence of all paralysis)—distinctly a case of congestion of that kind which follows epilepsy. Some of these cases are treated entirely on the principle of congestion of the brain, where even impediment is offered to the respiration by the counter pressure of the congested brain on the medulla oblongata itself. Suppose you bleed, and adopt every measure to relieve the patient, and yet the patient remains in a condition very likely to prove fatal. There is, you will recollect, the subsequent state of sinking. The question is, whether you may do anything more?

Now I beg to mention one of the most interesting cases, I think, on surgical record. The case was treated by Mr. Sampson, of Salisbury. The patient was brought to the hospital attacked with epilepsy. Every means were adopted to relieve him, but still he remained comatose, and affected with stertorous breathing. "At this period," says Mr. Sampson, "it occurred to me, that the comatose state in which he lay might not arise from apoplexy, but from that state of the brain arising from that organ being supplied with blood not duly oxygenated; the breathing had a shrill tone, and it took place with extreme difficulty, and there was an extreme state of collapse, and this fact would account for the paralysed state of the eighth pair of nerves. I appealed to my colleagues, and strongly urged a trial of the operation of tracheotomy; for I could not but conceive, that if this mechanical operation was carried on for a time, the blood might regain its proper stimulant quality, and restore the energy of the brain and the nervous system. On their consent being given, the operation was performed. The obstruction of the veins about the head and neck caused an obstruction to the flow of blood." Here you observe a very important thing, that obstruction raised up an antagonistic power against any remedies you might apply to subdue the state of congestion of the brain, therefore the case was not one of mere defective respiration, but one in which there was an impediment to the reflux of the blood from the brain. He goes on to say that the violent condition of the respiratory efforts ceased, and in about half an hour from the performance of the operation the circulation of the blood was completely established. I believe that man would infallibly have died of congestion of the brain; at any rate, from that comatose condition which impeded the respiration, and that impeded the reflux of the blood from the head, but for this kind of operation performed by Mr. Sampson. Tracheotomy was performed, and the respiration became comparatively easy, and the reflux of blood from the brain comparatively free, and the patient recovered.

I do not suggest this in doubtful cases of apoplexy. I do think that patients ought to recover from apoplexy following epilepsy, without having recourse to tracheotomy. I have seen many cases of apoplexy following epilepsy, accompanied by a more than usual congested state of the brain, followed by violent convulsions. Here, therefore, I have made up my mind not to let a patient die without performing this operation of Mr. Sampson's. I would do the best I could in that manner, by relieving the congestion of the brain, and by causing a free flow of blood and air to the lung. That is the second remark I have to make on this subject, and which I give to supply the several defects left at my last lecture.

Now I am going to mention another fact which I think will be exceedingly interesting to you. I need hardly have recourse again to that state of apoplexy or congestion of the brain resulting from the violent struggles of epilepsy. In such a case, the larynx is closed, whilst the violent efforts of respiration, and of the whole muscles of the body, drive the blood to the head, and produce a temporary congested state of the brain, and temporary apoplexy. It is just possible that rupture may take place within the brain, and therefore, though I regard such a case as pure apoplexy, there may be an exception to such a rule as this. The reason I conclude that there may be rupture of the vessel within the brain is this, that sometimes there is actually a rupture and an escape of blood from the vessels in the skin on the face itself. I have a little sketch of a case which is remarkable for the spots upon the whole surface of the face. These spots are slightly ecchymatose, and come on under three circumstances. One is violent epilepsy; another, the violent efforts of parturition; and the third, violent efforts of vomiting. My object is to show what takes place in epilepsy. You will observe very minute ecchymatose spots which do not disappear under the pressure of the finger. I some time ago, was called to see a person of high rank who had an attack of some kind or other; he lived in St. James's-square. The question came to be, whether it was an attack of apoplexy in the usual acceptation of that term, or whether the patient had a fit of epilepsy? In the first place, before I saw him, he had entirely recovered from the state of coma in which he had been carried home. When I came to examine him, there was not the slightest paralysis. Here are two circumstances which led to the idea, not so much that there was apoplexy after rupture, but that there was something else. I observed his peculiar habit, and that his forehead was affected with ecchymatose spots of blood which would not disappear under the pressure of the finger, and I concluded that there had been a violent convulsion. I knew that violent convulsion did not accompany apoplexy, especially such a case as that which must have soon subsided. I gave it as my opinion that there was epilepsy, and so it proved, for there were subsequent attacks of epilepsy. These are the three points to which I wanted to draw your attention, and to supply the defects of my last lecture.

There is another point I mentioned at that lecture, but which I did not illustrate by any plate, or by any drawing. It is the case of a clot between the cerebrum and the medulla oblongata. You will recollect the case was one in which a person died in an instant from an attack of hemiplegia. In a case of this kind apoplexy is general, and paralysis is general; and all the functions cease in a moment. Well, that is one of the cases in which we may absolutely have sudden death. When anything interrupts the circulation of the blood and produces death, it may be called sudden and instantaneous.

Now the next subject I wish to bring before you, is the subject of local and partial diseases of the brain, and for the most part tumour at the base of the brain, and you will have here various disorders of this kind. In the first place, there is the influence of a tuberculous tumour at the base of the brain, or tumours variously situated; and these tumours produce their effect by irritating or compressing the brain. Now these diseases are characterised by pain, more or less. You have irritation of the brain attended with a derangement of the cerebral system. You have compression of the brain attended with coma, but more frequently a state of things different from this, which is characterised by compression of some of those nerves passing along the base of the brain.

I may here mention to you the case of Dr. Wollaston. He died of such a tumour as this, situated at the base of the brain. He lost part of the sphere of vision, and he lost more or less of the motions of the eye. Like a philosopher, just as the disease pursued its progress, so did he say—"now this part has been compressed, and now that." He was attended by Sir Benjamin Brodie. For further details of the case, you may refer to Dr. Holland's recent classical work—Medical Notes—the second edition, under the head of "The brain is a double organ." This case is merely an illustration of tumours at the base of the brain, which show themselves by pressing on the organs that lead to the senses, and that, more or less, impede the functions of the senses.

If there is a tumour in a certain locality, you can easily imagine that it will press on the optic nerve, or in another locality on the olfactory nerve, and that if in a lateral situation, it may affect the sense of hearing, and, if that situation is further back, it induces some of those sudden cases of hemiplegia that are produced by compression on the medulla oblongata. Some of those cases are attended with spasmodic affections, but I want particularly at this moment just to allude to a case in which you have what has been supposed to be hemiplegia arising from a state of ossification of some of the membranes of the brain. I have seen a portion of ossified matter at the pharynx, and I have seen it at various parts of the membranes of the brain which have been affected by hemiplegia, and which have been supposed to be the cause of hemiplegia by irritating the substance of the brain itself. But how, gentlemen, shall we reconcile this idea with the fact that no irritation of the substance of the brain will produce spasmodic action? In fact, there are many facts which seem literally to contradict any such opinion as this; in the first place, see how the ossified portion of matter is situated, and then see if it is situated between the layers of the thick membranes in such a manner that there is any possibility of any point irritating the substance of the brain. Now when you irritate the substance of the brain you [illegible]

I have said that there will be no spasmodic affection, and therefore none of that affection which you see in hemiplegia. What then is the probable reason, if it be true that this is a case of hemiplegia, what is the probable manner in which such a portion of ossified matter will produce hemiplegia?

I am now going to read a small paragraph of a late paper of my own in the Medico-Chirurgical Transactions, the twenty-fourth volume, in which I have endeavoured to explain this fact of spasmodic affection arising from an irritation of the membranes of the brain. "In an important experiment which I purpose to lay before the society in the next session, I found that although every kind of irritation, puncture, or laceration of the cerebellum was entirely inoperative, yet that laceration or pinching of the dura mater, immediately induced peculiar spasmodic movements of the eyeball, the eyelids, the head, &c. These effects are probably induced through branches of the trifacial nerve, which, as the recurrent of Arnold, is well known to impart branches to the dura mater, and which may do so to the other membranes within the cranium. The whole subject is in need of investigation. Our way must be pointed out first by experiment. This must be followed by observation. The membranes within the cranium and spinal canal, the other *serous* membranes, and the *internal* textures in general, must be submitted to a similar examination." Here, therefore, I have placed before you the best idea I can form of the result, in the form of hemiplegia, induced by that kind of ossified body found very frequently in the lining of the dura mater and also attached to one of the membranes within the brain.

Now with regard to the nerves: I need not go over every nerve in succession, as you can easily imagine a tumour situated in any part of the cranium; and you can very easily imagine what are the symptoms. Accordingly, if you have the optic nerve compressed, you will have more or less of blindness; if the olfactory, more or less affection in the organ of smell, and so on. But there are two or three points I want to draw your attention to, because they are so exceedingly important, with regard to the diagnosis. Now suppose a case in which there is a loss of sensation in the face. I want to make a remark or two here; how is it that there is loss of sensation of the mouth, so as almost to have paralysis arising from cerebral causes? There is an imperfection in the organ of speaking—a loss of sensation—a paralysis of sensation—a paralysis of muscular motion arising from cerebral causes. The loss of sensation is the cause of hemiplegia. That is one reason why the eyelid will close. It causes a paralysis of the face from cerebral disease. Where it cannot close at all, there is paralysis of the same side of the face, from a pressure on the sympathetic nerve; on the other hand, whenever a loss of sensation comes on from disease of that nerve, it is, generally speaking, a state of things that arises from an utter abolition of the function of the nerve; and, therefore, the loss of sensation, or loss of motion, is, generally speaking, perfect. Suppose you are called to a case in which you perceive loss of sensation. The question comes to be, is this a case of cerebral affection, or is this a case of affection of the nerve? If it is imperfect, I should, generally speaking, be led from that fact alone to infer that it is cerebral; but if it is perfect, I should conclude it is not cerebral, but disease of the nerve itself. You see how important this fact is.

Then with a view to the diagnosis I have another remark to make; that whenever a nerve is affected, it is almost invariably attended with other affections, with a loss of sensation, and a loss of muscular power. Suppose the fifth pair of nerves is affected, what is the effect? In the first place, you will have a loss of sensation at the corresponding part of the face. In the second place, a loss of the power of closing the eyes, which never occurs in cerebral paralysis. Therefore this is an indication of some disease of the nerve in the cranium. There is another fact, and that is the loss of nutrition to the eyeballs. Now, whenever you have perfect loss of power of the muscles that move the eyeball on one side, whenever you have a degree of atrophy of the eyeball, you may be perfectly certain that there is nothing but disease of the fifth pair of nerves. If it is not cerebral, it is more important to make this distinction, because cerebral paralysis may have done this first, but it will do no more. The patient may live in this case, but when there is disease of the seventh pair of nerves in the brain, I believe it is invariably the case that the patient sinks rapidly, and it proves fatal.

I once had an interesting case of paralysis of the seventh pair of nerves, one of the most interesting cases I have ever witnessed. It was totally impossible to trace that paralysis to any disease externally; there was no tumour on either side on the external part of the eye, there was no disease on the external part of the nerve, yet the paralysis was quite complete, and the patient could not close the eyelid. I soon found out the fact, that it arose from cerebral paralysis. Are there any other facts that lead to the idea of paralysis of the nerves of the brain? Yes, I had a very interesting case, one in which with this paralysis of the eyelid, there was deafness. Now considering this case what must have happened! The same thing must have happened as in the other cases in which there was a loss of sensation, and a loss of power of the muscles to close the eyelid. Now it is possible that you may have one or the other of these affections independently of any disease of the brain, but it is morally impossible for you to have both. Therefore when the cerebral system is perfect, when there are no cerebral symptoms, and you have perfect paralysis, you may be almost sure that there is injury of the nerve itself. You have sometimes added to this another symptom, that is, paralysis of the muscles of the eye and loss of hearing, and you are sure that this arises from compression of those nerves at their source in the cranium.

Now we come to a very important diagnosis in internal syphilitic diseases, between that which is a mere affection of the cerebrum, and that which is a tumour or disease of the substance of the brain. I wish, now, to draw your attention to another sort of diagnosis, also, I think, a very interesting one. You have doubtless heard of what is called a blight. I mean the effect produced by a draught of wind falling on the face. It sometimes happens that a person is exposed, for instance in church, (I know of such a case,) and comes home with a face distorted—drawn to one side. Now what I want to mention to you in the first instance is, that in the course of this disease, the face may be in the first instance drawn to one side, and in the second instance may be distorted to the other side, in the very same case. This is a case I have never seen described anywhere, but it is a case in which Sir Charles Bell has said there is, in the first instance, perfect paralysis of the seventh pair on the one side, and in the second instance, paralysis of the same pair on the other side. This is not always the case. Now you are aware that if the hands are exposed to the cold, the first thing that takes place is numbness, and the second thing is reaction or undue sensibility. I remember the case of a patient, who came home after having been in a violent storm of sleet and snow, with one side of the face utterly benumbed, and nothing would restore the sensation of the face. The next morning there was excruciating pain. You have numbness, then, in the first instance, and undue sensibility in the second. It may perhaps be that the cerebral nerve relates naturally to the motor nerves. In one instance the face is drawn to one side, and then you may have a spasmodic affection of the other side, and the face is drawn back again. Now the diagnosis here is important. If you come to the conclusion that there is first of all paralysis on one side, and then on the other side, you come to a false conclusion. It must be that there is some disease in the cranium. The true conclusion must be, that where you have paralysis on one side of the face, causing it to be drawn to the opposite side, in the first instance there has been a spasmodic affection; the nerve has become benumbed and is unduly sensitive, and you have first of all over action, and then undue action. The first impression of cold is to paralyze the nerve. The second state is a state of inflammation, and then you have numbness and undue sensibility. In the other case you have spasmodic action and over sensibility.

Now I believe I must leave this subject of partial paralysis of the face, and pass on to the subject of injuries of the nerves. You will all have observed how rapidly I have given you these sketches. You are aware the number of lectures allotted to me is only ten, whereas I could easily fill three times the number. I must be limited to that number, and therefore my object is to give as much practical and as much diagnostic information in a small number of lectures as is in my power. This is the reason I have been very brief on some points, especially on mere pathology; I have other reasons, but the chief one is this, that you will have the greater advantage of hearing all that relates to the pathology of the nervous system from one whom I have long deemed one of the ablest physiologists of the present day, as well as, I may add, one of the most generous of men. You will, I hope, remember that any advantage you may derive from any remarks I can make, you owe entirely to one whose name I am bound to mention, Dr. Hodgkin.

I will now bring before you the subject of diseases of the nerves very briefly, as I see our hour is very nearly expended. In the first place then, you may have injury of a nerve, and it may entirely subside. In the second place, you may have injury of a nerve, and it may produce certain effects. Now I wish you all to remember these effects, because they are most important in practice, and the diagnosis of diseases. You may have pure tic, that is to say, you may have the symptoms of tic, and they may be confined to the nerve. You may have, after that, what I believe I must call a reflected sensation. For observe, you may have injury of a nerve in one finger, and pain in another finger and the thumb. I do not know what name to give to this, but that of reflected sensation. In one case you may have epileptic pain, that is to say, pain reflected into the thumb and the other finger. Instead of this pain, this reflected pain, you may have what is much more violent and severe, you may have complete tetanus, and instead of that you may have all kinds of partial tetanus. Now I do think I have set before you one of the most interesting arrangements of the effects of injured nerves you can possibly imagine. Remember how an injured nerve may be manifested. It may be attended with an excruciating pain in the part injured, but instead of the pain being confined to that part it may be, in some inscrutable way or other, reflected to other parts, from one finger to the other. If then you have an injury of a nerve, and it is not of a sensitive character, you may have violent tetanus. But instead of that you may have what is called local tetanus: this is the fourth form of it. There was a case I mentioned to the Medical Society a short time ago in which I believe the nerve had been injured by blood-letting. There was immediately a partial sort of tetanus produced, and the hands drawn as in paralysis. I believe it totally impossible for the fingers to have been so drawn by any act of the will, or of any other kind of action. I have not time to go further into the subject, but you will just remember the remarks I have laid before you, that in the first instance, you have pain in the part injured; and in the second place, reflected pain from that part to the adjacent parts; and that from another point you may have complete tetanus, and from a fourth point you may have partial tetanus.

I shall conclude this lecture by alluding to another subject, one of the utmost interest. The question came to be, whether, from an injury of a nerve you may have injury of the brain? Now you remember one instance—you remember a case I quoted, that of a ligature applied to the principal nerve, of the *axillary* plexus. You remember the result of that, was inflammation and suppuration of the opposite hemisphere of the brain, the posterior lobe. That fact leads to this idea, that inflammation may run along a nerve, or it may run along a vein, and produce its effect in the central organ, namely the brain.

In the beginning of this lecture I alluded to the case of a lady who returned from church and when

she got home, every body observed her face perfectly paralytic on one side. That went off, and the next thing observed was, that the face, which had been drawn to the left side, was now drawn to the right side. Now the dreadful result was, that this patient was prematurely confined, and she had a convulsion after her confinement, which terminated fatally. Now the question came to be, did the inflammation that affected the nerves on one side of the face, run along those nerves and affect the spinal centre of those nerves, and so lead to that fatal convulsion that came on after confinement? We had no means of determining this point. But the gentleman who attended that lady had no doubt it was so, and he was criticised by those who had written previous works, and who had only taken the superficial affections of the nerves. I leave the case with you, and the whole subject, advising those who wish to pursue the matter, to take up this point—whether inflammation may run along the nerve to the cerebral and the spinal system, just as it may run along other tissues, especially those of the nervous system?

I will conclude this lecture by just adverting to the fact, that after amputation you have what I have described here. Tubercles are formed on the extremity of a nerve, those tubercles being the source of excruciating pain after the amputation, and it very often happens that a second amputation is made, and a third amputation at the shoulder joint, and then you begin to understand why the amputation here proved successful. One thing I forgot to mention, and that is what is called a subcutaneous tumour. It sometimes happens that a very minute tumour is formed along the course of a nerve, which leads to dangerous symptoms. I have now done my best to give a general idea of the cerebral system and its diseases, and for the next three lectures I must beg your attention to another class of diseases—a totally different kind of disease, belonging to the excito-motor system; having their seat or their centre in the spinal marrow.

CURABILITY OF CONSUMPTION.

(Continued from page 296.)

(To the Editor of the 'Medical Times.')

SIR,—All attempts to place the treatment of consumption on a satisfactory *medicinal* basis have signally failed. The animal, vegetable, and mineral kingdoms, have been laid under contributions to supply prophylactics and curatives Demulcents, expectorants, emetics, sudorifics, narcotics, tonics, astringents, balsamics, &c., &c., have been combined in formulæ of endless variety, congruous, or incongruous, scientific or empirical, and as yet without effect. If the subject were not too grave, the perusal of Dr. Young's History of Treatment, is sufficient *risum movere* in no moderate degree; it reminds me forcibly of Ovid's description of Chaos;—

> "*Obstabatque aliis aliud, quia corpore in uno,*
> *Frigida pugnabant calidis, humentia siccis,*
> *Mollia cum duris, sine pondere habentia pondus.*"

The multifarious details show that in the attempts at cure there has been no want of industry, perseverance, or boldness approaching even to temerity. But what a miserable, ludicrous exhibition of the impotence of ill-directed efforts the whole presents! In his laborious compilation, though the Doctor must have been not a little relieved by the amusing conceits and vagaries of his predecessors and cotemporaries, yet it is not a matter of wonder, that after parading them all in grand review, he should have joined the forlorn hope at last.

It is, however, to be regretted that he had not turned his researches to more practical account than recording the absurdities of the profession. His labours remind me forcibly of those of Sisyphus in the condemned regions of Orcus, who figures as an example of barren toil, rolling a huge stone up an ascent which he is conscious he can never win. The employment of this famous character was quite as useful as that of Dr. Young.

Laennec commences his chapter on the treatment of consumption, by remarking on the numerous remedies proposed for its cure; the employment of every known medicament, however different or opposite in effect; the proposal of new remedies every day, or the revival of old ones, after having been long consigned to deserved neglect, and the inconstancy of every plan but that of giving palliatives, or fulfilling symptomatic indications. On such grounds, he proceeds to say, have acids and alkalis been alternately recommended; spare diet, and rich animal diet; dry air, and moist air; pure air, and fœtid air; oxygen, hydrogen, and carbonic acid; exercise and quiet; emollients and tonics; heat and cold; paregorics and other anodynes, and stimulants not only of the aromatic and antiscorbutic kind, but the most irritating preparations of mercury; the sulphate of copper, arsenic, and others. His own views of treatment are, however, equally dark and empirical with those of his predecessors, and wind up with the very unsatisfactory conclusion, that in the present state of our knowledge, we have no better means of opposing the disease than a sea voyage, or a residence on the sea coast in a mild climate. This impression was so strong on his mind, that for the purpose of establishing an artificial marine atmosphere, he actually introduced sea-weed into a ward of the clinical hospital to which he was attached. Could anything previously tried have been more empirical than the use of offensive *fucus verrucosus?* Oh! most lame and impotent conclusion!

In the records of the treatment of this disease, approximation to juster views discovers itself here and there, in the high value attached to exercise, particularly such as bears more immediately on the lungs. The principle, however, of its beneficial operation appears not to have been appreciated, viz., its giving expansion to the pulmonary tissue. In his work on consumption, Dr. Ramadge very truly observes, "neither perfect recovery, nor indeed exemption from the danger of a relapse into a consumptive state is found to occur, except in very rare instances, unless the pulmonary organs become naturally or artificially voluminous." By medicine alone this effect is impossible, and so long as we confine ourselves to it, disappointment will track our course; there is no alternative left; the lungs must be expanded by some means, and those are obviously at our command in the process of artificial respiration, mechanically regulated by the construction of the respiratory tube.

Diminution of the pulmonary volume and contraction of the chest are always found together, and have a reaction on each other. The moment the chest begins to contract from inadequacy of power in the respiratory muscles,—the result of debility, no matter how superinduced,—that moment also the lungs begin to contract, and *vice versa.* The area of the great air passage remaining the same, while the capacity of the lungs is diminished, subverts the normal relationship between the inspiratory and expiratory powers—renders the expiration too easy. The consequence of this contraction, diminished activity, and disturbed balance, is the deposition of tubercles primarily in those parts of these organs, which, from their locality, possess least expansive power. Auscultation and autopsy concur in this conclusion. The evil once commenced, multiplies itself; the dissemination of tubercles at the summits of the lungs propagates irritation to the adjacent pleura costalis, and leads to adhesions. The deposit in this site is very common; in the majority of adult *post-mortem* dissections, we find either tubercles or black stains, or dark oval indurations of the pulmonary tissue remaining after absorption: unless some stop be put to the progression of pulmonary contraction, a second crop succeeds to the first, and the morbid deposit goes on if not cut short by dissolution, till at length the lower lobes are implicated. This increasing monopoly of the lungs by tubercles proportionally diminishes their expansibility. Even in health, owing to the various motions and positions of the body, the entire capacity of the air cells is seldom fully dilated; how much more must this be the case under tuberculous dissemination?

The altered form of the chest as it gradually departs from the healthy standard is a faithful index of the morbid changes going forward internally. In phthisis there is generally a wide intercostal space; the convexity of the ribs looks more downwards than in health, and the lateral defences of the chest appear greatly lengthened; the sternum is either perpendicular, or drawn downwards and backwards, increasing the usual elongated appearance of the neck; the chest losing its arched contour, becomes flat; from the sinking of the ribs, a marked depression is seen both above and below the collar bones, and the shoulders advance forward, giving to the scapulæ behind a wing-like form; all combining to contract the chest round the collapsing lungs. Now, in asthma we have the same coincidence exemplified by contrast. The lungs being preternaturally expanded, the chest also becomes so; some of the muscles of the neck are hypertrophied and unusually firm; a hollowness is seen above the sternum from the retraction of the trachea and advancement of the larynx; the shoulders are raised, the patient stoops, and unless there have been previous pleuritic adhesions or contractions from tuberculous disease at the summits of the lungs, there is no depression above or below the clavicles; the sternum advances forward in its entire extent; the arches of the ribs tend upwards, so as to give the chest a rounded, full form, adapting the capacity of the thorax to the voluminous state of the lungs. By regulating the respiration, we bring both the chest and the lungs to the normal state, which lies in the middle between these two extremes. I have seen very many instances of this both in phthisis and asthma. Even so early as a month from the commencement of the use of the respiring tube in young consumptive patients, it becomes occasionally necessary to let out the clothes round the waist. The following case will give some idea of its power over the structure of the chest.

The Rev. Mr. Howe, late chaplain of the City Hospital, New York, employed the tube under Dr. Ramadge's directions for the cure of true consumption, which had reduced him to a state of almost hopeless prostration. In connexion with medical treatment adapted to the alleviation of symptoms, his health was restored by its use, and according to a communication lately received, still continues in a very satisfactory state. His own account of the changes in the form of the chest appears in an American publication, dated 1839.—He says, "the shape of my chest is astonishingly improved and enlarged. About six years since, the measurement of my chest close under the arms was thirty-two inches; but for five years following there was a gradual diminution, so that for three years previous to my getting the tube, my measurement was thirty inches, making a decrease of two inches; since getting the tube, I have increased in size two and a half inches, making my measurement now thirty-two and a half inches. But the alteration in the conformation of my chest is truly wonderful. The collar bones were very prominent, and the chest so drawn together, that I was afraid to see myself in the glass. Now my chest has recovered a round and plumper appearance, and my neck is filled out so that the conformation is better than it had been for years."

This individual had consulted some of the most eminent physicians of France, and also in London, without deriving any benefit from their advice; immediately before resorting to the use of the respiring tube, he had been under the care of Dr. T. Davies, whose treatment failed to give any relief. He then applied to Dr. Ramadge, who found him in a state of great despondency and prostration, but by the agency of mechanical respiration and subsidiary medical treatment, he recovered under his care. In a publication, he mentions the names of several clerical and other friends, who made use of the tube by his recommendation, for relief from catarrhal asthma or phthisis. In some of the former, the disease had gone so far as to deprive the ribs of mobility; and in the latter, the chest had undergone various degrees of contraction. The mechanical respiration steadily persevered in, had the effect of restoring free motion in the asthmatic, and expansion of the chest in the phthisical cases, some of them to a much more considerable extent than in his own case.

I have now before me a letter from another American gentleman, in which he states that he placed himself under Dr. Ramadge's care, last

autumn for consumption, his chest then being contracted, and his flesh much wasted: since that time, under the use of the tube, he has gained forty-one pounds in weight, and some inches in the size of his chest. He had been recommended to go to Madeira, but in deference to the advice of the above-named physician, remained in London, and has found his account in doing so, as indeed have many others also with whom I am acquainted, who had been ordered abroad, but have remained at home and recovered under this treatment. I select this opportunity to state that although the use of the respiring tube has, in phthisis, the effect of enlarging the pulmonary volume and the chest, it is not to be inferred that there is any danger of its being carried so far as to bring on a permanently emphysematous or asthmatic state of the lungs.

In the treatise by Dr. Palmedo, of Berlin, alluded to in a former letter, he charges Dr. Ramadge with having asserted "that an asthmatic state of the lungs was produced, as well in cases where nature cures the phthisical disease, as in those where his method of cure is resorted to." I do not wonder at his want of success in the trial of this treatment, when he took so little trouble to comprehend Dr. Ramadge's meaning as to fall into the above-quoted error. This author, in many parts of his work, very distinctly asserts that the practice of tubular respiration never superinduces asthma or emphysema properly so called, but on the contrary, that it possesses an equal power over asthma as over phthisis. I have seen many cases of asthma at the infirmary, and also in private practice, in which it has been employed with the most decided advantage, restoring the lungs and air passages to their healthy state, and the thorax to its normal proportions;—of this I shall say more in another place.

Our theory will uniformly apply even to facts, which at first may appear to oppose it. We may be asked why is consumption so prevalent among musicians who perform on wind instruments? Because they make several successive expirations to one inspiration. This is in direct opposition to the natural process of respiration, and also to the mechanical, as regulated by the respiratory tube, and therefore produces effects directly the reverse, contracting the chest and diminishing the pulmonary volume. On one occasion, Dr. Ramadge was consulted by the leader of a band on behalf of himself and fellow musicians, as to the best method of counteracting the effects of this irregular breathing, and recommended that they should all take a long and quick run immediately after the close of their performances, or provide themselves with a tubular walking stick, constructed on his principle, and respire through it at proper intervals. This was followed by the best effects. Thus we find an objection as apparently against our theory constituting really a marked exemplification of its truth.

Again, how many instances of consumption occur among females who habituate themselves to the use of very tight stays, corsets, &c.; an injurious practice against which medical men have long lifted up their warning voice to no purpose. The confinement and stooping attitudes of counting-houses, manufactories, and various mechanical branches of trade, send thousands prematurely to the grave, and sow the seeds of death to be reaped by future generations. All these bad effects may be resolved into the simple principle I have laid down,—contraction of the chest, and want of due pulmonary exercise.

The North American Indian, in the humid atmosphere of his boundless forests, exposed with very imperfect coverings to the rigours of variable and inclement winters, almost uniformly exhibits symmetry of the chest, and a sound state of the lungs. It is only by coming in contact with the habits of civilised nations he learns the practical history of the malady, that desolates the enlightened regions we inhabit, and under which so many myriads pine as if

——"Enamoured of decay,
Cling to their couch, and sicken years away."

His life from youth to age is one of vigilance and exertion, amidst the toils of the chase, or the alarms of war, and leaves no opportunity of sinking into a state of habitual inactivity. The child of nature, he inhales her own balmy breath, and expatiates freely amidst her woods and waters, happily a stranger to the pernicious restraints we submit to, in obedience to the tyrannic caprices of fashion and prejudice, or in the pursuit of pleasure, wealth, and power.

DISCIPULUS.

ANNUAL REPORT OF THE REGISTRAR-GENERAL, 1843.

This vastly-important volume, just issued, is now before us. We propose to make from it a few of the more interesting extracts:—

VARIATIONS OF ANNUAL MORTALITY.

More Deaths were registered in the year ending the 30th of June, 1841, than in any preceding year; the number registered (355,622) having exceeded the deaths in the three previous years by 5,521, and 14,615, and 19,666 respectively. To judge accurately of the rate of mortality, the increase of the population must be taken into account; and we then find that the mortality, last year, slightly exceeded the mortality of the preceding year, and was nearly 6 per cent. (5·7) above that of the year 1838-39.* The relative annual mortality per cent. as shown by the mortality of females, was 2·055 and 2·157, and 2·171; if a correction be made for the deaths not registered in the first year (1837-38) the mortality in that year will be found little less than that which prevailed, in 1840-1.

With reference to the increase or decrease of mortality in the several divisions of the kingdom, the mortality attained its maximum in 1839-40, throughout the North Western, York, and North-Midland divisions; whilst it increased slightly, but progressively, from 1838-39 to 1840-41, in the Western, South-Midland, Northern, Welsh, South Eastern and South Western divisions. The mortality was lowest in Essex, Suffolk and Norfolk, and in the metropolis, when it was highest in Cheshire and Lancashire (1839-40.) The mortality, I may remark, in that year was excessively high in the North-Western Division; but I have the satisfaction of stating, on the authority of the Quarterly Returns, that the decline observable in 1840-1, continued in 1842. The diseases causing the mortality will be stated in the Appendix. It may be mentioned here that scarlatina was epidemic in 1840, and committed great ravages in Lancashire. The same disease has since been epidemic in the southern parts of the island.

A glance at the table will show that the mortality in different parts of the country has differed to an extent ranging from 1799 to 2670 annual deaths out of the same number (100,000) living. The mortality was above the average of England (2143) in the North-Western, Metropolitan, York, and North-Midland divisions; and below the average of England in the seven remaining divisions. The Metropolitan Division, with its dense city population, which is recruited partly by immigration, can scarcely be compared with the other ten divisions; the mortality is necessarily higher than it would be among the same population, scattered over a wider space, if equal precautions were taken to remove as well as to dilute the effluvial poisons generated around human habitations. The density of population in Lancashire, though much greater than in the rest of the kingdom, is incomparably less than the density of the population in the metropolis; yet the mean mortality was higher in that county than the mortality of the metropolis during the three last years. The mortality was nearly half as high again in the North-Western Division, as it was in the South-Western Division. It may make the fact more striking to those who are unaccustomed to calculations of this kind, to state, that, if the mortality had been everywhere as high as in the North-Western Division, instead of 355,622 deaths, 440,363 would have occurred last year; and that only 302,800 deaths would have been registered, if the mortality of the entire population had been as low as that observed in the south-western counties.

* We have no means of knowing what the average mortality absolutely was before the present system of Registration was introduced; but according to one of the best estimates (by Mr. Edmonds) the annual mortality of females was 2·05 per cent. during the 18 years 1813-30.

PUBLIC HEALTH IN THE YEAR, 1840.

A comparison of the number of deaths registered in the four quarters of the corresponding years is exceedingly instructive.

Quarters ending	March 31,	June 30.	Sept. 30.	Dec. 31
	—	—	—	—
1838	98,114	90,810	72,791	80,816
1839	98,739	87,965	76,280	84,995
1840	93,813	90 339	80,820	89,630

The increase bore principally on the summer and autumn months.

It will be observed that in 1840 the supposed causes of 351,757 deaths were stated; leaving 7,804 deaths, of which the causes were not assigned. It has been assumed, in calculating the mortality by each cause, that the causes of the 7,804 deaths, in which the causes were not stated, were the same as those of the 351,757 deaths in which the causes were specified.

The mortality by all causes was higher in 1840 than in 1838, and considerably higher than in 1839. Out of 1,000,000 living in 1839, only 21,856 died; while in 1840, out of the same number living, 21,856—and 1,022 more—perished. Upon referring to the deaths by different classes of causes, it will be perceived that 626 of the excess (1,022) arose in the epidemic class of diseases; the remaining excess being distributed over all the classes, except that of the violent deaths, which diminished somewhat in each of the two last years.

The deaths from small-pox fell from 16,268 in 1838, to 9,131 in 1839, and 10,434 in 1840, the deaths from typhus fell from 18,775 to 15,666 and 17,177. From both diseases the mortality was less in 1840 than in 1838, but greater than in 1839. Hooping cough progressively declined from 9,107 deaths to 8,165 and to 6,132.

Scarlatina was the reigning epidemic of the year 1840. According to the theory of Sydenham, it would communicate its character to the acute diseases and constitute the medical constitution of the year.

The deaths from this severe epidemic were in the three years:—1838, 5,802; 1839, 10,325; 1840, 19,816.

And the deaths by scarlatina, out of 1,000,000 living, were in the same years 393,683, 1,289. The epidemic was most destructive in the North-Western, North-Midland, York, Welsh, and Northern Divisions. In the North-Western Division (Lancashire, Cheshire), the annual mortality by scarlatina was 2·5 in 1,000; so that the mortality of children, who are the principal sufferers, must have been excessively high. The epidemic had not terminated, and we shall have in the next Report to trace its destructive course through another year, and in other parts.

The deaths by diarrhœa, cholera, influenza, and ague, increased to a considerable extent: though not so as to assume the epidemic form, or to present anything very remarkable.

The deaths from hydrophobia in the three years were 21, 15, 12; and, therefore, not half so numerous in 1840 as in 1838.

The mortality by the diseases of the Nervous System was nearly the same in the three years, viz.; ·003365, and ·003255, and ·003302. The mortality by cephalitis and paralysis was slightly higher in 1840, than in the two preceding years.

The mortality by the diseases of the Respiratory Organs was, 6 in 1,000; or in each of the three years ·006149, ·005989, and ·006043. The deaths ascribed to Consumption in each of the three years were 59,025, 59,559, and 59,923; and the mortality was ·003996, ·003939, and ·003897. The mortality from this disease declined very slightly. About 4 in 1,000 persons died annually of Con-

sumption, and about one-fifth or one-sixth of the total deaths were by this disease.

The mortality of diseases of the Digestive Organ was ·001307, ·001373, and ·001465. The increase was chiefly in Enteritis.

The mortality by diseases of the Urinary Organs was ·000112, ·000101, and ·000110 in the three years. The deaths by Stone (and Gravel) were 320, 299, and 303; the mortality ·000022, ·000020, and ·000020. About 1 in 50,000 persons die of stone annually. It will be interesting to see whether the mortality be reduced in future years by the discoveries of surgery. The mortality by Diabetes is to that by Stone nearly as two to three.

The deaths in Childbed were 2,811, 2,915, and 2,989 in the three years. The mortality increased from ·000190 to ·000193, and ·000195. To about 187 children born alive, *one mother died.* The proportion of mothers who perish at this important period is unquestionably excessive; and must suggest to every humane person the inquiry whether the education of the nurses who attend the poor in labour, may not be improved?

The number of deaths ascribed to Rheumatism and to diseases of the joints was 962, and 1,170 in 1840.

If we except "Debility" under which head are included "premature births"—"Dropsy" was the most fatal of the diseases of "*uncertain or variable seat.*" The deaths ascribed to dropsy were 12,312, 12,251, and 13,261 in the three years; the annual rate of mortality ·000836, ·000810, and ·000683. It is scarcely necessary to add, that according to the present views of pathologists, Heart Disease, or Nephritis, would, in the majority of cases, be considered the primary affections. So difficult, nevertheless, appears to be the diagnosis practically, that nearly as many cases of simple "Dropsy" are registered in the London Hospitals as out of doors in private practice.

EXTRACTS FROM FOREIGN JOURNALS.

From the Berlin Medicinische Zeitung, for the "Medical Times."

GERMANY.—*Chronic Case of Glander, transferred to the Human Subject.*—(*By* DR. KRIEG.)—The more evidence we have afforded, that the glanders, to which the horse and ass are subject, was long known to the Greeks as a dangerous, and even incurable disease; so much the more striking must be the fact, that in modern times only, men first turned their attention to the transference of the malady to the human subject, for human disease through glandered animals was in no period wanting. We can, although under other names, find more than one case described in the Ephemerides of the old physicians, which, although then treated as scorbutic, were, in fact, nothing else than glanders. The five cases observed, nearly together, in the Prussian Regt. of Gens-d'Armes, described by Henckel, belonged indubitably to this disease. Few physicians would have been so candid as was the brave and conscientious Henckel. "All these cases," he says, "disquiet me, and make me desirous to know how I shall properly denominate them, wherein I should place their cause, and what more should be practised in their treatment, to prevent death, if it be in any way possible." He pictured the disease as a Febris Irregularis, and, among other symptoms, perceived its malignity in the fetid transpiration and those "wonderful matastases, so suddenly arising; even within one hour, fluctuation was speedily perceived in those places, &c." He also adds, he has not remarked that "this malignant essence became contagious," for in that quarter no one else became diseased. Bernhard Ritter has lately, in an excellent tract upon this subject, noticed the elder Osiander, as the first who made public (in 1803) a case of infection in a man, from glanders. Since then, however, similar observations have accumulated from all sides, so that now, notwithstanding the repeated doubts raised, the not rare occurrence of its transference stands certain.

Where infection is caused through the inspiration of poisoned air from glandered animals, symptoms of pathognomonic value are ever disclosed in the course of the disease. And certainly the circumstance ought not to be overlooked, that it produces cases in which the disease can be prolonged for many months, without the phenomenon of reaction of the human system, raising itself to the form of that entirely peculiar typho-septic process, which hitherto has always put an end, at the same time, to the disease and to life. In my Inaugural Dissertation (Berlin, 1829), I have distinguished it by the name of "Typhus Maliodes." That this received name, following Bartels, now suits, not the entire disease, but only the last stage, is understood of itself. On the contrary, the including terms, "Morbus Mallearis," "Passio Maliodes" will answer for the entire form of the disease, much the same, whether their individual periods end within longer or shorter intervals, and whether the essential symptoms appear more drawn out from each other here, or there crowded together in shorter stadia. Bartels, however, is the only one, until now, who has assigned to Glanders its destined position in the Nosologic system, as a peculiar disease, not to be confounded with any other; whilst, e.g., Mason Good, and his famed commentator, Samuel Cooper, have not at all mentioned this disease, although they have near enough included it under "Erythema Anatomicum" in described cases of constitutional disease.

One case of long-continuing glander disease has been communicated by Wiggins. He had under his treatment the son of a butcher, æt. 12, who was ten months ill of this disease, and died under the usual symptoms of this affection. A second case has occurred, only lately, to myself. I was requested to visit the postillion, Walter, who lay ill in D——, about a mile from this place. I proceeded thither in company with Herr Department Veterinary Surgeon Korber, whom other business called there. I found Walter in agony. After proper examination, I pronounced to my companion, with great confidence, that the patient was dying from infection by the poison of the glanders. The right side of the neck was taken up by an enormous, dark, erysipelatous, hard swelling, upon which had arisen numerous pustules and bladders, of irregular forms, from the size of a pea, to that of a small walnut; the lesser, yellow and pale red; the larger, bluish green, all filled with a thin humour. (Jauche.) Similar swellings covered the left shoulder, the hips, the leg and thigh, the right ham, and upon all these had those bladders elevated themselves in numerous grades of development. The nostrils were dry; they had, nevertheless, before, poured out a profuse thin secretion. The tongue dry, incrusted with slime. Pulse and respiration shewed already-commenced paralysis; the hands and feet were cool; the skin clammy; the exhalation from the patient not strikingly penetrating. Although he had been ill more than six months, yet only in the last ten days had he become so weak, that he could no more leave his bed, and, since then, his condition had visibly deteriorated. From the commencement of the disease, until three weeks before, he had been treated by Surgeon Durbeck; since then, as his wife asserted, he had been without medical assistance. The man died on the following night, and by accurate investigation, I was convinced that, previously to his first sickness, he had repeatedly groomed glandered horses. Surgeon D., at my request, informed me of the course of the disease as observed by him, substantially as follows: Six months previously, he had first seen the patient; for many weeks he had complained of great weakness, and drawing pains in the limbs; he had, notwithstanding, performed his duties, till at length he was quite unable, from pain and debility. He was now at times obliged to keep his bed; he had light fever, with gastric attacks; profuse morning sweats; and violent pains in the extremities, especially on the right side. Soon, rose-coloured and very sensible swellings arose on all his limbs, great and small, in which fluctuation greatly shewed itself. The abscesses were successively opened, evacuating a thick, not ill-smelling, pus; and were then generally well healed again in the course of some weeks. At the same time the condition of the patient, who had become very weak and emaciated, appeared in general to have bettered itself: his strength had markedly increased. Nevertheless, gouty-like pains continued, with intermitting violence, in all his limbs; the morning sweats also remained; and soon the at first rosy inflamed boils quickly elevated themselves in different places, yet, in a great measure, again discussed themselves. In the fifth month, the apparent amendment had completely ceased. The hitherto tolerable pains became manifestly more violent; the patient had strong fever, stitches in the breast, anxiety, and cough, and at length began to expectorate great quantities of matter. (Most probably, the peculiar suppuration of the disease had destroyed even the tissue of the lungs.) Later, when the difficult breathing had abated, the pus expectoration had nearly ceased, and his condition had acquired a more mild appearance. As the last act of his long sufferings, typhus fever, with gangrenous boils, suddenly developed itself under quick augmentation of the old pains in the extremities, in the neck, and shoulders. Unfortunately, various causes prevented my making the section: the results would have been,—although in essentials not different from those known in such cases,—so far worthy of remark, as here the disease had had sufficient time to engrave its destroying traces in every organ, and in the organic system. Even in the case communicated by Wiggins, the section did not take place. One circumstance well deserves to be mentioned here. From the tranference of a poison from one species of animal, where it is in condition to develop itself, not barely through infection, but even spontaneously, to another which never spontaneously generates this poison,—the glanders is, in man, as it were, a bastard production. As such this appears, like other hybrid diseases, to possess only a limited generation of the power of infection. So indeed even the vaccine will be transferred from man to man only by inoculation. So even is it more than probable that the accidental inoculation of the contagion of glanders, perhaps by a wound in the section of a man dying from this disease, would call forth a similar disease in a predisposed individual.* But no case is known to me that persons who have attended such patients, have become ill through infection. In the above case, many members of the family had, in their turns, slept near the patient; even his wife lay in the same bed with him, during the whole of the last deadly stage, without apparent prejudice to her health.

* A case of this kind absolutely did take place at Paris, under the care of M. Bouillaud. We gave the case in a previous number.

TO CORRESPONDENTS.

A case of personation has been placed under our notice. On the 24th January, Dr. Jonathan Green, of Marlborough Street, had his attention called by a post letter, ill-written, and on shabby paper, to "the interesting notice" of his book inserted in the last number of a minor contemporary. The doctor thus kindly informed of what otherwise could never have reached his knowledge—being a denizen of good society—was induced to purchase, or at all events to consult, a copy, when much to his surprise, he discovered that the interesting critique was a low personal attack. In the sale of the journal, or attraction to it of notice, the plain object of the note-writer was evidently answered; but will our readers believe that to gain this petty end, our name as Editor of the "Medical Times" was assumed, *coupled with a request (to give that assumption countenance) of a copy of Dr. J. Green's work. The note is in our possession, and if the Mr. Burgess who, as writer on skin diseases, is interested in using the attenuated journal with which he is connected, in decrying a gentleman who has the largest practice in skin diseases of any medical man in London—be not the author of the despicable personation, nor in any way connected with the attack that gave it birth, he will do us a favour in enabling us authoritatively to say so. Once for all we never have, never do, and never shall write to any author or publisher in respect of books for review.*

Mr. Houghton.—*The necessary expences for horses and vehicles only used for professional purposes are deducted in returns as to the property tax. Common justice and the words of the act equally provide this.*

I. N. A.—*We shall be glad to receive the paper named.*

Mr. Watts is informed that it is well understood that our Periscope of the week consists of condensations or extracts from other journals, a circumstance duly announced to all our readers. Where we use matter of any great importance we give it as a separate article, with the names of the different sources, but in our Periscope (made up of short facts) we should lose as much space in publishing the history of an article's successive lodging place in various foreign and English journals as the article itself often contained. We shall probably pay our monthly and quarterly contemporaries more notice both critical and extractive than we have hitherto done, and the Chemist among others.

A Student.—*We should recommend Dr. Walshe's recent work.*

M. N.—Devotus—Gnyeusis—" All Hail"—Constant Reader, *Bath*—Mercator—*declined.*

Our Lectures by Dr. Sceffern on Chemistry, and Professor Serres on Organogeny, with the case of Spina Bifida by Dr. Kinns in our next number.

THE MEDICAL TIMES.

SATURDAY, FEBRUARY 18, 1843.

Good laws make good subjects.—OLD SAW.

THE Bill introduced by Mr. French, for the regulation and support of Irish Medical Charities, which received its second reading on Monday evening, now lies before us. Antecedent to any expression of our opinion on its merits, we shall present our readers with a faithful abstract of its contents.

The first clause repeals that portion of the Irish Poor-Law Bill which authorizes the Poor-Law Commissioners to scrutinize and partially direct the administration of hospitals or infirmaries supported, in part, by Grand Jury presentments, or Parliamentary grants. In the second, the Lord Lieutenant is authorized to appoint, *during pleasure*, a certain number of persons, being not less than [*five*],* of whom a certain number are to be "physicians or surgeons residing in Ireland, *and who shall have practised as such*, not less than ten years previously," to whom shall be added the two Presidents of the Irish Medical and Surgical Colleges, and the Governor of the Dublin Apothecaries' Hall, who, collectively, are to form the Medical Charities' Board, and are to "act under such regulations as the Lord Lieutenant *shall from time to time think fit to prescribe*." These new Commissioners are to have no salary, nor other kind of remuneration.

The next clause refers to the formation of an office, appointment of secretary, clerks, &c.—enacting, further, that the meetings of Commissioners shall be fixed by the Lord Lieutenant, and that four members shall form a quorum. The Commissioners are then authorized and required to demand accurate statements from all persons in whom any State Charity may be vested, on every point concerning it, and to "issue any order they may think proper, for enforcing obedience to the statutes, charters, &c., governing any such Charity." By Clause 5, the Commissioners are empowered to enquire into all charities founded on bequests, to examine into breach of trust and mal-administration in such cases, and they are required to present the results to her Majesty, with such suggestions as they may think most serviceable for the restitution of misapplied funds, or the prevention of further misapplication.

The next clause requires public officers to give copies of public records, or extracts, gratis, on the order of one Commissioner; and, by the following, the Commissioners are instructed to send in to the Lord Lieutenant, as early as possible, a report upon the state of disease, and the conditions and circumstances of every medical eleemosynary institution in Ireland; and to furnish, half-yearly, the statistics of the inmates. The treasurer, also, of each institution is to send to the Board a yearly statement of its funds, and mode of application. By the 9th Clause, the Commissioners are empowered, with consent of the Lord Lieutenant, to make, alter, or revoke, at pleasure, orders for the medical economy and management of dispensaries and fever-hospitals. The consent of the Lord Lieutenant is to be attested by warrant under his hand, transmitted by his chief or under secretary to the Commissioners. The Lord Lieutenant, however, can revoke or suspend all such orders at pleasure. [11] The Commissioners are,* *ipso facto*, to be members of the "General Board of Health for Ireland," and [12] are to have the same powers, in respect to discharge of their duties, as "the Commissioners for auditing the Public Accounts." They are, however, like the Lord Lieutenant, [13] to have no power to interfere in individual cases of medical relief. [14] The orders of the Commissioners are to be sealed with the special seal of the Board, which seal is to prove itself. All the orders published [15] are to be laid before Parliament within the first week of its sitting.

By Clause 16, the Lord Lieutenant is empowered to appoint, during pleasure, any number of persons not exceeding [*four*], being physicians or surgeons, practising as such at least seven years, as "Inspectors of Medical Charities," to act under the direction of the Commissioners; and these [17] are in no way to be connected with any public medical institution, or school, or prison—or to sell drugs—or to practice—or to be inspectors of anatomy—or to derive, in any way, any emolument from their special duties, as Inspectors of Charities, save their regular salary. (This salary is said to be "*hereinbefore* provided," but is "hereinbefore" altogether omitted, even in name.) The Inspectors [18] are to use the office, and be assisted by the clerks of the Commissioners; and [19] are to examine into the state of every medical charitable institution at least once a-year, and to prepare exact reports for the Commissioners. The 20th Clause compels treasurers, &c., of infirmaries, to pay fivepence in every pound received, to the Commissioners, to pay for the working of the present Act, which fund can only be paid out on orders signed by three Commissioners, and counter-signed by the Secretary. The Inspectors [22] are to have [£600] per annum, with their travelling expenses; but the whole expense for working the Act is not to exceed [£1,600] per annum. The Commissioners, by the next clause [33], are ordered, when so required by [*twelve*] or more payers to grand-jury cess, to inquire into the extent of medical relief in any district, and to give a report thereon to the Lord Lieutenant, who is then [24 and 25] empowered to create a dispensary or fever-hospital district, of the extent suggested as required. The grand-jury is required to present off the said district the sum of money necessary towards the support of such dispensary or fever-hospital. If the district, however, lie in two counties, or more, the respective grand-juries are to present the proportionate portion fixed by the Commissioners, to the secretary of each grand-jury, [ ] days previous to each assizes. Of all such institutions, so appointed, [27] all unpaid justices of the peace, with the principal minister of each religious denomination in the district, are to be ex-officio Governors, to whom, [28] if not amounting to ——— shall be added as many of the *highest* cess payers in the district as will supply the deficiency. [29 and 30] Donors of [£20] whether resident or not resident, as, also, annual subscribers of £2 and upwards, are to be Governors—without votes, however, in the election of officers, unless after 12 months' Governorship. By Clause 31, the Governors are made bodies-corporate, subject to the Lord Lieutenant; and, as such, property will vest in them, &c. Clause 32 refers to the times of meeting, and the number of Governors required to form a quorum—points unfixed, except [33] that no one Governor can do anything in management, &c., except at a meeting of Governors. [34] The Governor's non-quali-

* The words in italics, and brackets, are to be decided on specially in committee.

fications are not to vitiate proceedings in which other Governors have concurred. [35] *No medical officer is to be elected, save under the warrant of the Lord Lieutenant; and the Commissioners are to define the several duties of such officers—their "places and limits,"—and regulate their amount of salaries, and mode and time of payment.* [36] The physician must be a member or licentiate of King and Queen's College of Physicians, Ireland, or of some other College or *University* in Great Britain and Ireland, duly authorized to grant licenses, &c. [37] The surgeon is to be a member of the English, Irish, or Scotch College of Surgeons; or have a surgical degree or diploma from some College, University, or *body* in Great Britain and Ireland, duly authorized by charter or statute. [38] The apothecary must be a licentiate of the Dublin or London Apothecaries' Society; and all medical candidates [39] must have their *legal* (?) qualifications first attested by the Commissioners, before being eligible. [40] The Lord Lieutenant may, however, require in *each* candidate the *double* or *triplicate* qualification, including a certificate for midwifery. [41] The mode of election of non-medical officers, and their qualifications, are similarly arranged. [42] Where the Governors do not elect within a month of the *conge d'elire*, the Lord Lieutenant may appoint an officer.

By Clause 43, the Lord Lieutenant is empowered to remove any medical officer on the Commissioners' application, or upon application of [*four*] or more Governors, supported by whatever investigation the Lord Lieutenant may think proper.

[44] The Governors have power themselves to remove any officer not medical. [45] Register Books are to be kept by the medical officer, and [46] half yearly returns of accounts are to be sent to the Commissioners by the grand-juries. [47] Paid officers furnishing to inmates for profit, medicines, furniture, &c., or concerned in any contract relating thereto, are to forfeit [£20] with full cost of suit to any party sueing, or if caught [48] embezzling to pay [£10] for the offence, and to restore treble the amount of embezzlement. [49] Disobedience to the Lord Lieutenant's orders entails a [40s.] penalty for the first offence, and of [£5] for the second offence, and all penalties [50 and 51] are to be recovered summarily on an oral hearing, and conviction before one or more magistrates, the forfeiture being at once levied by distress if necessary, or in default of goods by imprisonment. The remaining clauses refer but to appeals, payment of costs, and latitude of interpretation.

We proceed to conclude our description of the state of our profession in Germany, by brief statements of the Medical Governments of Wurtemburg and Baden.

In Wurtemburg, there are two *grades*, and five *divisions*, of medical men: that is, we have, first, Doctors of Medicine only, with Doctors in Medicine and Surgery; and, secondly, three classes of Surgeons, known as first, second, and third. The Doctors' studies are commenced with proving paternal permission, and preliminary education; they extend through three years, one of which must be spent at the Tubingen University. The candidate follows whatever studies he pleases, and as he pleases—and the half-yearly examinations are matters of mere choice. A verbal examination, called "rigorous,"—and which is twice sustained, if the diploma is for the double qualification—is followed by a thesis, the positions in which are maintained by the candidate against the objections of the Professors. The Doctorship is now conferred, but the liberty of using it in practice is only purchased by shewing certificates of having attended, for a twelvemonth, clinical studies in some hospital of importance, or the practice of some distinguished practitioner, as assistant—and undergoing the State examination, which is long, and extremely searching, requiring practical proof of high capabilities in every part of the domain of Medicine. Doctors of Medicine are inhibited, under severe penalties, cases of Surgery and Midwifery.

The *Surgeons* of the first class write no thesis, and undergo but the State examination. In other respects, their studies are followed in the same way as the Doctors'. Their medical education, however, costs but about 72 florins. The lower divisions need no further description.

In Baden, we have, first, Physicians, who are examined during eight days, both orally and in writing, and who have their characters attested as highly moral; 2dly, Surgeons, who prove preliminary education, and are examined during 5 days as to their competency; 3dly, Accoucheurs, being Physicians or Surgeons who have studied Midwifery especially, during six months; 4thly, Assistant-Surgeons, whose principal requisitions are, four years' practice with a master, and the composition of an article before his examiners, as a proof of his ability to write.

Cure of Hoarseness.—The hoarseness proceeding from laryngeal and tracheal inflammation, as well as that of an idiopathic kind caused by long speaking or singing, or that which supervenes during fevers of a typhoid type, has been treated successfully by the external application of croton oil. Dr. Trusen, of Posen, employs friction with from five to ten drops of the oil over the larynx, but over only a small area, as the pustular eruption it causes has a great tendency to spread, particularly in persons with an irritable spine, for whom it ought to be used mixed with olive oil.

Cements for China, &c.—Mr. Rowland recommends the following:—℞. Pulv. Mastic.—Acaciæ, aa. ℥j.—Cretæ. ppt. ℈ij. Misce. This should be kept in powder for use, and when required, it should be made into a stiff paste with a little water. This is a very hard cement, and well adapted for china, glass, &c. India Rubber and Shellac, equal quantities of each, dissolved in naphtha, form a cement, insoluble in boiling water, and on this account invaluable for many purposes.

STATE REPORT UPON THE TREATMENT OF CHRONIC DISEASES BY COLD WATER.

By Dr. GIBERT, of the Hospital St. Louis, Paris.
(Extracted from the Gazette des Hospitaux.)

In consequence of the numerous abuses which had crept into the treatment of the diseases of women, I had for several years directed my attention towards the employment of sedative astringent applications, and especially cold water with a cooling regimen, in the treatment of those nervous affections which are often combined with leucorrheal discharge, and congestion of the neck of the womb. I published an especial article upon these affections, founded principally upon the observations which I had collected at the *Hopital de Lourcine*, and I prevailed upon the management to provide an apparatus for the administration of the cold water *douche*. In 1840, on reviewing a work by Dr. Bigel, on the treatment of diseases by the cold water system, I penned the following observations. "This is a little book containing neither detailed observations on disease, nor accurate diagnostic remarks, which does not disclose the result of post-mortem examinations, nor of arithmetical deduction nor anything, in a word, which constitutes the body and substance of most modern works. But still this is a book containing more good and sound medicine than it is possible to collect in most of the large works published at Paris during the last twenty years. At Graeffenberg, on the summit of a high mountain, guided by the aid alone of experience and of good sense, a peasant of Austrian Silesia, Priessnitz, performs cures which have aroused the attention of all Europe. Cold water, either as drink, or external applications, is the only medicine employed by Priessnitz; such is the simple means by which he succeeds in curing a host of diseases which have resisted the ordinary remedies. "I leave behind me," said a celebrated man when dying, "two grand physicians, diet and water." Priessnitz has availed himself of this heritage. In the same year, when appointed to St. Louis, I resumed the course of instruction so successfully commenced in this hospital by Professor Alibert, and I then took the opportunity of applying the cold water treatment publicly to diseases of the skin. This method rests, as we know, upon two essential points:—1st. The use of cold water either in drink, in the form of *douches*, and in general or partial baths, as lavements, injections, &c. 2nd. The natural transpiration obtained and provoked by means of swathing the body in a covering of wool. Sometimes this covering is applied naked upon the skin; at other times, the body is previously enveloped with a sheet soaked in water. During the whole time that the swathing continues, we give the patient cold water to drink in repeated doses, to allay the thirst, moderate the heat, favour perspiration, and replace the liquid exhaled from the body. In patients, affected principally with dry cutaneous affections, as *psoriasis* and *icthyosa*, when subjected to this operation, it was some time before perspiration showed itself; two, three, four, and even five hours elapsing before this result took place. After allowing them to perspire for a variable time, from half an hour to an hour or more, according to the case, they were carried into the bath. They were then unswathed, and frictions or washings of cold water applied to the body; a cold *douche* was likewise showered upon them from an elevated place, or they were plunged into a cold bath. These experiments were not continued from beyond two to five minutes; after which the patient

dried himself, dressed, and took a little exercise. Several subjects attacked with *lepra inveterata*, and two little girls affected with congenital *icthyosa*, have been subjected to this kind of treatment. All have experienced from it a remarkable amelioration; some have appeared completely cured. This result is so much more remarkable, as it concerns affections usually rebellious to all our modes of treatment. If the hydropathic method does not appear applicable to all cases nor to all subjects, if even it may cause great inconveniences when it is not employed with due prudence; if lastly, and above all, our experiments are still too few and too incomplete to enable us to deduce any rigorous conclusions; we may, at least, affirm at the present moment that no other treatment appears so proper to restore to the skin that state of smoothness, of softness, and of permeability, which is their natural condition, and the re-establishment of which is so difficult to be obtained by our usual methods in subjects affected with diseases of the skin.

Among the obstacles to this method, the most powerful has been the want of co-operation of Dr. Wertheim, who after having studied the method at Graeffenberg, had proposed its adoption at the hospital St. Louis, and had, for several months, zealously superintended its application. Discouraged by the difficulties which he had to encounter, Dr. Wertheim joined myself in demanding from the administration of the hospital, certain ameliorations. While waiting for these improvements, we have thought it our duty to suspend our experiments. I am, therefore, still unable to give an absolute opinion upon the method of Priessnitz. With respect to the statistics requested by the council, I am able to give precise data upon seven patients only, of whom two (*prurigo* and *psoriasis*) have been completely cured; two others (*icthyosa*) have appeared cured, but had a relapse at the end of a few months; two more (*psoriasis*) have experienced a most remarkable improvement, without arriving at a perfect cure; lastly, the seventh was obliged to renounce the treatment which appeared to have an injurious influence upon the state of the chest. Excepting this last case, in all the patients whom we thus treated, (about twelve in number) besides the effects produced on the skin, a most marked improvement was brought about in the general health.

The following are the conclusions at which I have arrived on this subject.—1st. That the treatment of chronic diseases by cold water and a cooling regimen, (following more or less implicitly the practices employed at Graeffenberg,) has produced advantageous results. 2nd. That when it is directed with suitable care, and attended by favourable conditions, it may, without presenting any danger to the patient, produce therapeutic effects, which have not been obtained from the ordinary methods. 3rd. Lastly, that in diseases of the skin, in particular, it may alone induce a cure, or at least concur in rendering it more perfect, when this treatment is used as an auxiliary to the other curative methods.

Rupture of Trachea. In a child, fifteen months of age, labouring under an attack of bronchitis, after a few efforts to cough, an emphysematous tumour suddenly appeared in front of the neck and upper part of the chest. A small incision was made and gave exit to air. The child died on the second day; and on examining the body it was found that the trachea was lacerated to the extent of half an inch, just above the first ring.

ROYAL MEDICO-BOTANICAL SOCIETY.

EARL STANHOPE, PRESIDENT, IN THE CHAIR.

Dr. Hedson read a Paper on the Artemisia Absinthium, and its Preparations, of which the following is an Abstract:—

The Artemisia Absinthium, or common wormwood, has been held in estimation as a medicinal plant, from the earliest period of medico-botanical history; but at the present time it is very little employed in the regular medical practice of this country, although it is extensively used on the continent. All writers agree in ascribing to it tonic properties; but some object to it on account of its unpleasant flavour, and say that, in practice, the more agreeable bitters should be preferred. It is said to render the milk of nurses, who take it, so bitter, that the child is affected by it. Numerous medicinal virtues have been attributed to it, the chief of which are, antiseptic, anthelmintic, deobstruent, tonic and stomachic. It has been employed with success in jaundice, dropsy, gout, worms, dyspepsia, intermittent fevers, and various kinds of cachectic diseases,—in the forms of powder, extract, conserve, tincture, wine, distilled water, essential oil, &c. The doses mentioned by writers on materia medica seem too large, and likely to be offensive to the stomach. The following infusion and tincture have been employed by the author of this paper, with satisfaction:—Infusion of Wormwood. Take of the dried herb, free from the stalk, half a drachm, boiling water, ten ounces; macerate for an hour, and strain. The dose, an ounce and a half three times a-day.—Tincture of Wormwood. Take of the dried herb, free from the stalk, two ounces; rectified spirits, sixteen ounces. Macerate for twelve days, and strain. Dose, from ten to fifteen minims, in an ounce and a half of water, three times a-day. This tincture has a beautiful green colour, and possesses the full aroma of the plant, as well as its bitter flavour. This tincture is the most pleasant preparation of the plant, and is an elegant and excellent stomachic.

Some Remarks on the Sweet Acorns of Portugal, by William Lukin, Esq., were then read:—

The sweet acorns are the fruit of the Dynheiras, the Quercus Ilex of Linnæus. It is a tall forest tree, very frequent in the forests south of the Tagus, but rarely found north of that river. It is extensively planted in the oak-woods of the Alemtego, for the hogs, which are driven in large herds into the woods, to fatten on the fruit.

There are two other trees, quite distinct in character, which produce sweet acorns, and are found in the same woods, but are not frequent.—1. Quercus Rotundifolia, of Lamarck.—2. Quercus Bulleta, of Desfontaines. Broteia, in his Flora Lusitania, considers both these as varieties of the former. They are smaller trees; all three are evergreen; and the acorns so similar, that it is difficult to distinguish between them without seeing the leaves. These acorns, roasted like chesnuts, are served up with the dessert, in Spain and Portugal: they are much eaten by the peasants, who eat them roasted. That the custom of eating these acorns is of some antiquity, may be seen by referring to a very humorous letter in "Don Quixote," in which Cervantes represents Theresa Panza as sending a peck of ballotas to the Duchess, in acknowledgment of the hospitable reception her husband, Sancho, had met with at the castle.

Among the presents announced during the meeting, were some very fine specimens of the the new salts of iron, from Mr. Bullock, of Conduit-street.

CASE OF HYDROPHOBIA.

By William Henry Booth, M.R.C.S., West Bar, Sheffield.

The subject of the following remarks, is a case of hydrophobia, with which I became acquainted on the night of Thursday, January 26th, 1843. The patient was a boy, of the name of Jabez Robinson, aged seven years and a half. As he was returning from school on the morning of the 10th of December, 1842, crossing a field leading to his home, a small terrier dog, belonging to a neighbour, attacked him, and bit him in several parts of his body, viz., the arms, legs, and face. The boy attempted to take refuge in some water, which was near, into which the dog followed him. The animal there continued its attack, until a man, who was working by and saw the dog have the boy down upon the sand-bank, near the water, immediately approached the spot, with a stick in one hand and a stone in the other. The dog immediately ran off, recrossing the water. The boy was bleeding very profusely from the wounds inflicted. He was immediately conveyed to the Sheffield General Infirmary, where, I understand from Mr. Law, house surgeon to the establishment, the actual cautery was applied to the parts bitten. He remained a patient, under the care of Wilson Overend, Esq., and Mr. Law, until Friday, January 20th, 1843, when he was made an out patient. After he got home he complained of sickness, and appeared very listless and poorly. On Thursday morning, January 26th, the father applied to Mr. Law, at the Infirmary, stating that his son was very poorly, when Mr. Law prescribed two powders considering him to be suffering from fever, the effect of cold. On the night of Thursday, January 26th, the father came to me, and desired that I would go to Slack Work, near Owlerton, to see his son, who he stated was affected in a very curious manner. He also stated that his boy had been bitten six weeks and five days, previously, by a dog, and that he had shortness of breathing and sobbing. I immediately went, along with a professional friend, and found him suffering from all the symptoms of that dreaded malady hydrophobia, for he evinced a dread of fluids, and great difficulty in swallowing the same. He was very much excited by currents of air, he complained severely as if suffering a sense of suffocation, when any person was moving quickly about him, and when the door was open, all which tended to the disturbing of the functions of respiration; his pulse was from 110 to 112, quick and full. Tongue dry and furred. Complained of great thirst. These symptoms, up to the time of his death, which was at half-past seven on the following morning, Friday January 27th, increased, and he became very violent. He did not sleep from early on Thursday morning up to his death, although I prescribed opiates in full doses. All the time of his suffering, he appeared much disturbed by strangers, yet complained of no pain in any organ except the front part of the head, and that only occasionally. He was not able to put out his tongue, it was drawn to the left side of the mouth. He was frequently sick, and occasionally vomited saliva. He was sensible up to a short time before his death, but appeared to die in a paroxysm.

Inspection of the body 30 hours after death.—There was considerable evidence of the boy having been stout and healthy previous to the fatal disaster. Decomposition had not taken place on any part of the body. The number of cicatrices amounted from fourteen to sixteen, the largest being upon the calf of the left leg and right arm.

Cerebrum.—Upon removing the calvarium, there was a considerable discharge of dark-

...ated blood, which I suppose must have ...ned from some lacerated veins. The ... mater, as well as the other mem...es of the brain was very vascular, and ... congested with dark blood. The surface ...e brain was very vascular. There were ...numerous deposits of lymph. Upon slic... into the substance of the brain, there was ...mmense number of bloody points. Ventri... contained no fluid. Choroid plexus na...

...rebellum.—The cerebellum, medulla ob...ata, and about one and a half inch of the ...lla spinalis, were removed, and appeared ... very vascular, and much congested, but ... more so than the cerebrum. The pons ...ii was very vascular, the structure of the ...bellum rather softened.

...arynx.—Larynx removed together with the ...ynx. The lining membrane of the larynx ...pharynx were much congested, or inflamed, ... there appeared some constriction about ...lottis.

...horax.—Heart natural. Lung presented a ... dark appearance, and when cut into, ap...ed to contain a large quantity of blood.

...bdomen.—Liver rather paler than natural. ...-bladder distended with bile. Stomach ...œsophagus of a natural appearance, the ...er being quite empty. Intestines natural ...ppearance. Kidneys healthy. Bladder ...racted.

...S.—This is the second case which has fallen ...r my care within a very few weeks.

LONDON HOSPITAL.

...EMARKABLE CASE OF CONSTIPATION.

... B. aged 10, was a patient of Dr. Cobb.

...story.—He had always been a weak ...y child, and had been from infancy pecu... liable to a torpid condition of the bowels, ...y having an evacuation without the use of ...atives or enemata.

... year ago the constipation lasted for 9 ...s, but finally yielded to the sulphate of ...esia in ounce doses.

...evious to his admission into the hospital, ...eeks had elapsed without his having a ...e evacuation. His abdomen was very ...l, and resonant on percussion along the ...e of the colon. His constitutional symp... were by no means so severe as might ... been anticipated.

...emata of soap and water, combined occa...lly with turpentine, were ordered; the ... matter within reach being first removed ...eans of a director: it was as hard as a ... The injections were readily returned, ...ing with them occasionally scybalæ of ...t an inch in diameter.

... ... one or two places the peritoneum had actually given way, such was the degree of distension it had been subjected to.

On being emptied of their contents, 13 quarts of dark, soft, feculent matter were collected in pails. All the other viscera were healthy.

HYDROCELE.

James Robinson, aged 65, was admitted under Mr. Andrews in September, 1842, with a contused leg. He was also found to have an enormous hydrocele, reaching half-way to his knees; he says he has had it for 10 years, but finding little inconvenience from it, has never had anything done for it. He now consents to have the fluid evacuated. Mr. Wildash, dresser, performed the operation; 52 ounces of a clear yellowish fluid were collected.

Some months ago, I saw Mr. Luke tap a hydrocele for a young man, æt. 20; thirty-two ounces of fluid were collected!

I mention these cases, only, because the amount of fluid evacuated in both appears to me unusually large.

HUNTERIAN ORATION.

Delivered at the Royal College of Surgeons, Feb. 14
by J. M. ARNOTT, Esq. &c.

THE pleasant duty which has devolved upon me is not unmingled with sorrow. If it is instructive to dwell upon the merits of that great name which has to-day assembled us together—if it is agreeable to trace the steps of genius, forcing its way from utter oblivion into the meridian blaze of fame, until it has become impossible to discuss the science of surgery without pronouncing the name of John Hunter—it is with regret that we must recount the losses we have recently sustained—the gaps not easily filled up—which death has made in our ranks.

At our last anniversary we had to deplore the loss of Sir Astley Cooper, a man for whom scarcely any panegyric can be too strong, since his fame as a practical surgeon was limited only by the boundaries of the civilised world. This year we have to lament the decease of one whose merits were equally great, but in a different domain of knowledge—Sir Charles Bell, whose transcendant reputation as a physiologist has, with the mass at least, eclipsed his eminent deserts as a surgeon. Sir Charles Bell, though not a pupil, revered the memory of his great predecessor, for if the phrase *damnant quod non intelligunt* aptly describes the judgment of the multitude, it is equally true that it requires high, and, perhaps, kindred talent, to estimate genius at its full worth.

Sir Charles Bell was born in 1775, and after studying some years at the High School of Edinburgh, he began the study of anatomy under his brother John. That brother, twelve years older than himself, was already in high repute both as a surgeon and as a lecturer. The instructions of such a teacher would rarely have been without profit by an ordinary pupil, and their effect on Charles Bell was the publication in his 22d year of the first volume of the system of Dissections, a work marked by his characteristic originality. At an early age he was appointed surgeon to the Royal Infirmary; but the feuds which at that time distracted the profession in Edinburgh as well as in other places, induced him to try his chance in the metropolis of the world, and Mr. Bell came to London in 1806. The rest of his career is well known to you—at any rate it is unnecessary to dwell on all the professorships which he held, or the other marks of public distinction which were heaped upon him. I will content myself with touching upon a few of the more prominent parts of his genius and character.

As a surgeon, Sir C. Bell ranks high, if not the first, in the very first line. His letters on the diseases of the urethra, his surgical observations, and other works, show how deeply he had studied, and how diligently he had practised the art which he professed. His dexterity, and his coolness as an operator, were remarkable, yet he went to operations with the reluctance of one who has to face an unavoidable evil, in this respect resembling Hunter, and many other first-rate surgeons. Like Cheselden, who is said always to have turned pale when about to cut for the stone, Bell's cheek was often seen to blanch as he was proceeding to operations performed with the utmost self possession and skill. As the fruits of the zeal with which Mr. Bell cultivated surgery, I may instance his hurrying to Haslar after the Battle of Corunna, and to Waterloo after that of the 18th of June, in order to study gun-shot wounds. Still more eminent was he as a teacher of anatomy, and in the lecture room he shone almost without a rival; his views were nearly all solid, and always ingenious, while his manner enchained the attention of his audience. Dull, indeed, must have been the pupil who could have slumbered when Sir Charles Bell was in the professional chair. In his hands dry bones lived again, his imagination clothing them with the texture which had once invested them. A muscle was no longer a mere bundle of fibres, rising here and inserted there; it was a guide to the surgeon's knife in some important operation, or kindling with his own fire, betrayed by the anatomy of its expression the emotion that was enclosed within. The flaccid artery on the table spirted forth its crimson stream, and demanded the arresting hand of the skilful surgeon. He made descriptive anatomy at once interesting and instructive to his pupils, and taught them to rest more surely upon it as a guide to the healing art, and though his impressive tones, which gave such effect to his teachings, have passed from amongst us, yet his fame will still live in the affections of his contemporaries, and he will be remembered by posterity as the discoverer of the varied functions of the nervous system.

Let me now be permitted to make an observation or two on the opinions of physiologists that have been given out on this subject, both before and since the publication of Sir Charles Bell's works. It is, now, generally admitted that the anterior nerves possess the power of controlling motion, while the posterior have the power of governing sensation. It had formerly been thought that each spinal nerve possessed in common the power of ruling both motion and sensation, and in some cases additional functions were attributed to it. This may be called the popular theory. Yet occasional glimpses of the truth were in a manner forced upon reflective physiologists. For the ordinary theory was obviously insufficient to explain why sensation remains in a paralytic limb when the power of motion is lost, and why, on the other hand, motion survives feeling in cases of another kind.

But although it had been supposed by some that the nerves of motion were distinct from those of sensation, no progress had been made in pointing out the principle in the anatomy on which it depends that one nerve communicate sensation, another motion; and the singularly original remarks of John Hunter, in his paper on the nerves of the organs of smell had fallen unproductive—they had not met with a congenial soil.

At an early period the intricacy, multiplicity of arrangement, and distribution of the nerves, had engaged the eager attention of Sir Charles Bell, and I have it from one who so far back as the year 1806, had repeatedly seen him rise from the contemplation of the subject with the exclamation,—"I must make something out of these nerves;" and already, in 1807, he had got a glimpse of the principles of his subsequent researches, as the extracts which I am about to read will shew. They are from letters addressed by Sir Charles Bell to his brother George Joseph Bell, then at the Scotch bar, and now Professor of Law in the University of Edinburgh. Fortunately these letters were written before the use of envelopes, and the first letter from which I quote, bears the Edinburgh and London post mark of December, 1807. Mr. Arnott here read the letter. In another, post mark also, March 1809, Sir Charles, then Mr. Bell, says, "that he has some idea of having a room five or six miles from town, and there prosecute his enquiries on the nervous system—that which is to make me, I am convinced." This may be called the second sight of genius.

At length in an essay entitled Idea of a New

Anatomy of the Brain, printed in 1811, Sir Charles Bell developed some of the principles which were destined to exercise so great an influence on the theory of the nervous system.

Having called attention to the prevailing doctrine of the anatomical school, that the whole brain is a common reservoir, and that the mind, by the same nerve which conveys sensations, sends out the mandates of the will to the moving power; we proceed to state in our opinion that the parts of the cerebrum have different functions, and that the nerves which we trace in the body are not single nerves possessing various powers, but bundles of different nerves, whose filaments are united for the convenience of distribution, but which are as distinct in office as they are in origin from the brain. He re-called attention to the fact of the spinal marrow being divided into an anterior and posterior fasciculus. We proceed to relate how he was led thereby to make experiments, of which he describes the results on the anterior and posterior columns of the spinal marrow, and on the anterior and posterior roots of the spinal nerves, and how he came to the conclusions, that every part possessing a double function, obtained that by having a double root.

Adhering to the important principle thus clearly laid down, Bell next directed his inquiries to the facial nerves, and aided by his indefatigable pupil and coadjutor, Mr. John Shaw, instituted experiments to assist him in determining their functions, more especially those of the portio dura of the 7th, and of the 5th pair. And happily he did so, for without the fortunate circumstance, that in certain parts of the body, especially on the face, the nerves of sensation and motion are distinct throughout their whole course, his great discovery could never have been clearly established.

The results were communicated to the Royal Society in a paper read before that body in 1821, and afterwards succeeded by others. Notwithstanding the novel and important matter which it contained, the "idea of a new anatomy of the brain" failed to attract attention. Not so the first paper, which appeared in the philosophical transactions. His views and opinions were now questioned, doubted, denied; then a certain amount of truth allowed to them—and, ultimately the real and substantial credit of a patient, laborious, and original enquiry was attempted to be wrested from him and attributed to others whose single merit in the part, at least of physiology, consisted in their adoption of that key which Bell had invented, fashioned, and shewn how to use—a key without which the secrets of the nervous system, so far as they are now known, had probably yet remained concealed.

In estimating Bell's claims as a physiologist, we are not called upon to regard these memoirs on the nervous system as complete and perfect. Along with all that is distinct and precise, we may allow that there are some allegations not quite specific; allegations which a mind more severely disciplined might not have hazarded. We may grant that the function of the posterior roots of the spinal nerves were therein suggested, rather than positively stated. We may acknowledge, as he himself did acknowledge, that he misinterpreted an experiment in his first attempt at proving that which he afterwards did prove through Mr. John Shaw, that the fifth nerve is a nerve of motion, as well as sensation; and we may agree in receiving with doubt, or at least, without conviction, as not yet proved, his views with respect to certain nerves being superadded in the higher class of a vertebrate animal with a distinct tract or column in the brain and spinal marrow, for the purpose of respiration.

But after all these acknowledgements, there remains to him, clearly and unequivocally, the merit of having first shewn and established, that, in investigating the functions of the nervous system, we must direct our attention to the roots, and not to the trunk, of the nerve.

That the nervous trunk, conveying motion and sensation, consists of two distinct sets of filaments in the same sheath.

That the filaments for motion form a distinct root from those for sensation,—and that the anterior roots of the spinal nerves are for motion, leaving it to be inferred that the posterior were for sensation.

That the *portio dura* was a nerve of motion; and the fifth, a nerve both of sensation and motion.

And, lastly, of having been the first who, dissatisfied with the observation and study of the mere form of the various parts of the nervous system, applied the method of experiment to aid him in determining their functions.

In a word, there belongs to Bell the great discovery—the greatest in the physiology of the nervous system for twenty centuries—that distinct portions of that system are appropriated to the exercise of different functions.

Very valuable practical precepts were immediately drawn and applied by Sir C. Bell and Mr. J. Shaw, from these discoveries. Perhaps, the most important was, the distinction of a local nervous affection from that which depends on disease of the brain. I will not detain you with the recital of the cases of this kind, which, since the introduction of this new principle in the recognition and diagnosis of nervous diseases, have been accumulated of late years in the records of medicine. This doctrine, however, and the consequences which ignorance of it leads to, is illustrated by a remarkable anecdote, in a work where we do not usually look for physiological instruction; and, as the story is little known, I will take the liberty of narrating it.

A physician in Paris, on visiting a case, found an Abbé playing at cards in the patient's chamber. Struck by the unfavourable aspect of the Abbe's face, he informed him that he had not a moment to lose, but must be carried home immediately. The Abbé, overpowered with terror, was taken to his lodging, where for several days he was bled, cupped, and purged, till he was brought to the brink of the grave; yet his face still bore the appearance which had so much alarmed the physician. The brother of the of patient at length arrived from a distant part of France, (there were no railways in those days) and asked what was the matter with his unfortunate relative. "Don't you see," said the bystanders, "his mouth is all on one side?" "Alas!" he replied, "my poor brother has had his mouth on one side these forty years." Such cases will, in future, present no difficulty, even to the beginner; and we recognize at once, in Charles Bell, the great characteristic of genius, that of giving the clearness of certainty to what before was either utterly unknown, or but obscurely suspected.

Even supposing, however, that this was the sole practical lesson as yet deduced from Sir C. Bell's discoveries, it would be unjust to measure their merit by this alone.

Independently of the direct instruction to be derived from them, they have brought physiologists into the true path; and should the dim veil which nature has thrown over the operations of the nervous system be once drawn up, it will ever be remembered who first constructed the machinery for raising it.

It is agreeable and instructive to remark and to remember that Sir C. Bell did not make very numerous experiments on living animals; but guided by a careful study of the anatomy of the parts, and reflecting on the spontaneous experiments, so to speak, furnished by disease, he was led to form views which supported by a few well considered and well planned experiments, discovered to him the truth, and enabled him to convert the guesses of former observers into admitted facts.

Had Sir C. Bell not been a surgeon or a physiologist, he might have been an artist, so admirable were his drawings, so exquisite his perception of the beautiful. This talent was with him a favourite, and might be cited as an instance of "the ruling passion strong in death;" for he was employed in sketching the gay scenery of Worcestershire but a few hours before his decease.

His love of art led him to Italy in the Summer of 1840, that he might become more intimately acquainted with the master-peices that enrich it.

During this tour he kept a journal, which I have had the gratification of seeing; it consists of three large books of sketches with remarks, illustrated by numerous sketches.

He passed through Paris and Lyons, a[nd en]tered Italy by way of Geneva. Here [he was] struck by the contrast between streets as [...] as "Blackford Wynd" and the gorgeous [archi]tecture of the palaces which flank them. [His] hotel had once been a palace, and as he sa[t on a] velvet cushion in an arm-chair of gold, [while a] fountain played from a marble lion, and [the] vivid light was moderated by orange trees a[nd] curtains, he felt he was in Genoa *la superba*.

He enjoyed what he calls "a day of Rap[hael in] the Vatican," and he was worthy of enjoy[ing it]. His piercing eye detected, as we might [expect], some errors in the anatomy of Raphael's dra[wings]; "but do not think of that," he adds "but [...] fine comprehension of nature, the feeling a[nd un]derstanding of the human family. Man app[ears a] superb creature in the Vatican."

On the last day which he spent in Ro[me he] stood by the Palace of the Cæsars, from wh[ence he] took his sketch of the Colliseum. "It is a [place]" he says, "to raise strange and solemn thou[ghts;] a mountain has been formed there by ruin[s, now] covered with vineyards and cultivated [...] "Pillars and ruined cornices make the w[alls] even, and the acanthus is growing by the [side of] the broken capital on which it is chiselled."

So much inventive genius, and such indefat[igable] industry are rarely united in the same perso[n; and] when we add the warmth of his friendshi[p, and] among his lesser qualities, the exquisite refin[ement] of his taste, the combination is not often to [be pa]ralleled. He had some of the irritability t[hat] often accompanies genius; yet take him [as he] was, he has left a blank not easily to be [filled] up, either in the republic of science or the [circle] of his friends.

I need not apologise, I think, for the len[gth at] which I have discussed the merits of this il[lustri]ous fellow-labourer; for the very conditi[ons of] my office require that I should celebrate the [merits] of those persons recently deceased, whose la[bours] shall have or may have, contributed to th[e im]provement or extension of chirurgical science.

[A pressure of important matter reluc[tantly] compels us to postpone the remainder of thi[s valu]able oration till next week. We may m[ention] that we owe our report to the same shor[t-hand] writer who furnished us with Dr. M. Hall['s lec]tures.]

PERISCOPE OF THE WEEK.

PATHOLOGY OF DEAFNESS.—Dr. Bo[...]leck, of the University of Prague, from a[n analysis] of ten cases, which he describes, conclude[s that] the most common cause of deafness is a[bsence] of one or more of the semicircular cana[ls, or] their imperfect development or destructi[on by] disease. In the third case, indeed, the [semi]circular canals with the exception of th[e] aqueducts (which were wanting), were he[althy;] the deafness seemed to be connected with a [state] of idiotcy. In the fourth case the whole [of the] internal parts of the ear were destroye[d by] disease. It may be worthy of further in[quiry] how far a circumstance noticed by the a[uthor] may exist in cases of congenital deafnes[s. He] observed in five cases that the anastom[otic] branch sent to the facial from the auditory [nerve] near the internal auditory foramen was g[reatly] enlarged at the expense of the auditory [...]

TINEA FAVOSA.—A divison of the Ge[neral] Hospital, Vienna, is set apart for the treat[ment] of chronic diseases of the skin, and the ex[peri]ments there made in the treatment of [tinea] favosa seem to show that the local applic[ation] of caustics (lunar caustic, caustic potass, [...]) is the only mode of treatment followe[d by] beneficial results. Several cases were [cured] within two months by the local use of [sa]turated tincture of iodine.

SCROFULOUS DISEASES OF THE JOIN[TS.—] All who have studied the history of ab[scesses] know that those purulent collections whic[h are] the result of acute inflammation are cur[...]

n more or less quickly, and that scrofulous cesses are seldom cured, until they have be-ne the seat of this acute inflammation — nce, I was led to employ irritant injections cases of scrofulous abscess of the joints, for purpose of exciting that degree of irritation ich is indispensable to their cure.—I shall ide the cases in which this mode of treat-nt was employed into two classes—viz., those iting to children, and those of adults.— Bonnet of Lyons from the fact that scrofu-s abscesses are seldom cured till they be-ne the seat of acute inflammation was lead he use of iodine injection in cases of chil-n, he avoided meddling with such as were accompanied by tumefaction of the cellular ue and signs of thickening of the synovial mbrane, for he felt convinced that the atment was not suited to cases of this kind. vas restricted to scrofulous abscesses of the e-joint, accompanied by swelling of the it, evident symptoms of suppuration, and formation of fungoid or lardaceous tis-s in the synovial membranes and neighbour-parts. The following is one of those cases strative of the effects of this mode of treat-nt:—Mary Notas, seven years of age, of phatic temperament, was admitted into pital on the 7th of March, 1841. This ld never had any scrofulous affection. The is flexed on the thigh; the knee painful, l fluctuation is felt on the inner side of the it. The disease commenced two months viously without any apparent cause.—March The tumour was punctured, and some thin discharged; alcohol at 32 deg. was in-ted; the reaction was very slight.—15. The nour was again punctured and alcohol in-ted as before: the operation was not fol-ed by any unpleasant symptom; the skin the joint was attacked by slight inflamma-1. Gentle pressure was now exercised by ans of a bandage.—On the 6th of May the ient was discharged in the following state: e knee is restored to its normal condition; patella, which previously adhered to the dyles, is now perfectly moveable; no sense luctuation; flexion and extension unattended h pain and freely executed; the patient lks well, but the knee is a little stiff; a ght discharge of serous fluid still takes place m the last puncture.—In this and two other es the only ones in which he employed the itating injections, the injection of pure alcohol of a saturated tincture of iodine produced no ere inflammation. This is easily explained. e surface of abscess is always lined by false mbrane of some thickness; and, on the ier hand, irritants act with little force on sons of scrofulous constitution.—As to e effects of the treatment, the cases shew t even after the injection of stimulating ids the abscesses had a tendency to remain tionary, and it was necessary to repeat them re than once. This treatment, he says, ex-ded over a period of two or three months, l even then a perfect cure was not obtained; t the disease was considerably mitigated, and seems probable that in country air and with e aid of the usual means for improving the neral health, a cure might be obtained within elve months.

Cure of Ectropion by Nitrate of lver.—M. Magne was consulted in the case a child, where the use of the scalpel being erdicted by the parents. Dr. Magne was mpelled to depend for the local treatment lely on caustic. This he applied with great cision to both the palpebral and ocular con-nctiva; and to combat the inflammation ap-ehended from this treatment, ordered frequent ot-baths, and compresses moistened with fresh alder flower-water, to be applied continually to the eye. The process of cauterisation was renewed daily for a fortnight, at the end of which period the granulation had disappeared, leaving only a few whitish eschars on the con-junctiva, and the child was soon afterwards sent away for change of air. Three months after-wards M. Magne again saw his patient, and reports that no trace of previous ectropion re-mained. On drawing forwards the lower eyelid, two new membranous adhesions (brides), similar in appearance to the healthy membrane were seen to have been formed near the ex-ternal angle of the eye, and united the pal-pebral and ocular conjunctivæ maintaining the eyelid in its proper situation, while the motions of the eyeball were not in any way interfered with. M. Magne has since treated other patients successfully by similar means. He states that in such cases, during the employ-ment of the caustic, he finds it good practice to employ cupping between the shoulders, fre-quent warm foot-baths, and the effusion of cold water to the face and forehead, of course to prevent the access of local inflammation as much as possible.

Physiology of Menstruation.—Dr. Ra-ciborski communicates the following conclu-sions. Very intimate relations exist between the catamenia and the graafian vesicles; men-struation begins at the period when these are fully developed and ceases when they are effete (detruits). At each menstrual period one of these vesicles swells and projects from the sur-face of the ovary, from which it escapes by the rupture of its sac, usually about the end of the menstrual flow, without male congress or other sexual excitement. The vesicle which thus escapes has anatomical characters precisely similar to those of the corpus luteum supposed to be formed after conception. Diseases arrest the development of the vesicles, and it is in this arrest that the true cause of amenorrhœa is in many cases to be sought; for the catamenial flow is the result of the sanguineous conges-tion of the internal generative organs, by which the development of the vesicle in its highest degree is accompanied. The state of the ovaries is so intimately connected with the general health of an individual, that the in-ternal appearance of these organs after death is said by Raciborski to be alone adequate to determine whether the patient has sunk under an acute or a chronic disease, or whether she has lately menstruated regularly. Phenomena analogous to those specified above as occurring in the human female at the menstrual period, are noticed also in animals during their rutting season. Among these the ovarian vesicles are found to increase gradually in size during the interval between the rutting epochs; and they ultimately escape altogether at these epochs without congress of the male. The spontaneous detachment of the human ovum at the end of the menstrual epoch naturally renders that period the most favour-able for impregnation, and readily yields a rea-son for the fact that conception is most com-monly referred to that epoch by pregnant women. "Of 15 women (says Dr. R.) who specified acurately the period of their latest menstruation, as well as the dates of the con-nubial act, 5 evidently conceived from coitus taking place from two to four days previous to the period at which the catamenia was due. In 7, conception dated from coitus occurring two or three days after menstruation; in 2, it took place at the actual period of the catamenia; and in one only so long as ten days after the latter had disappeared. —Considered with respect to her generative function, woman holds a place intermediate between rutting animals, which are capable of impregnation only at fixed seasons of the year, and those animals in which a coitus only is re-quired to produce impregnation at any season She, however, approaches much nearer in point of this analogy to the former class, her power of reproduction being infinitely the more active at her menstrual periods to which the rutting time in brutes bears a strict physiolo-gical resemblance.

The Urine.—The essential component parts of the animal matter of bile and of urine are complementary of each other; taken toge-ther they correspond with, or are equal to, the chemical components of the organised tissues, or, which is the same thing, of the blood itself. The cast-off materials of the vital tissues are thus divided between urine on the one hand, and bile on the other. This occurs in the adult; it occurs also in the fœtus; for the animal matter of the allantoid fluid and of meconium or of the urine and meconium, are also, with very slight modifications equivalent to the essential animalised constituents of the blood, and to those of the vital tissues. The nitrogenised constituents of the urine are the products of the oxidation of a part of the mate-rials cast off from the tissues, produced during the incessant change of matter which accom-panies assimilation and growth in the living being; they constitute that part of the hitherto organised molecules which are incapable of any further use in the economy; and they are accordingly first dissolved, and then expelled from the body. The true origin and the final purpose of the secretion of urine, as thus ex-pounded, is substantiated by numerous con-siderations. The quantity of azotised materials which this fluid contains, evacuated at any particular time, bears no proportion to the amount of food ingested during the same period. The man who takes much exercise and little food, secretes more urea than a highly-fed individual who takes no exercise. During rapid emaciation the urine contains more urea than in health. In fever and star-vation, where no food is received into the sys-tem, the formation and excretion of urea con-tinues. An intimate acquaintance with the whole of these phenomena establishes it as a fact, that the quantity of the azotised com-pounds in the urine bears a direct relation to the change of matter in the vital tissues.

Nervous Matter.—It is constituted of a considerable proportion of albumen, and of two fatty acids, distinguished from other fats by the existence of phosphorus or phosphoric acid as a component part. One of these, the cere-bric acid, contains nitrogen, and is combined with soda, other fats being compounds of fatty acids with glycerule, and containing no ni-trogen: it approaches in composition more nearly to the choleic acid of bile than to any-thing else, although the two substances are quite distinct. Liebig remarks, respecting ner-vous matter, that it is, at all events, formed in a manner similar to that in which bile is pro-duced, either by the separation of a highly ni-trogenised compound from the constituents of blood—from fibrin, for instance—or by the combination of an azotised compound proceed-ing from the change of matter in the tissues, with a non-azotised and probably a fatty com-pound. Looking to its composition, the for-mation of nervous matter, in contra-distinction to that of some of the other tissues above cited, pre-supposes some change in the composition and qualities of the constituents of the blood. Liebig deems it highly probable that an accu-rate examination would develop differences in the composition of nerves, brain, and spinal marrow.

CREOSOTE IN PURPURA.—Mr. Whitwell, of Marylebone Infirmary, gives several cases of Purpura, which he states to have cured, by giving creosote in half-minim doses, with sufficient rectified spirits to suspend it in an ounce and a half of mucilaginous mixture, repeated every six hours. He suggests its probable efficacy in sea scurvy.

CONGESTIVE PNEUMONIA, CONSEQUENT UPON OPERATIONS, &c.—Mr. Erichsen read a paper read on this subject, at the Medico-Chirurgical Society. The following is the secretary's abstract:—The object of the author is to show that in the diseases and injuries which usually come under the care of the surgeon, and in operations generally, a form of inflammation of the lungs, characterized by its asthenic nature, and different from that which is dependent on the absorption of pus, is a frequent attendant. The kind of inflammation to which he adverts is distinct from active idiopathic pneumonia, and resembles more nearly that condition of the lungs which is stated by some authors to be frequently found in typhus fever, and other diseases, attended by much debility of the system. While possessing several characters distinct from those of passive congestion produced by mere mechanical causes, "congestive pneumonia," is especially marked by an engorged and condensed condition of an considerable part, and that, most frequently, the inferior and posterior part of these organs. The blood, the author says, under the influence of depressing causes, chiefly attributed by him to confinement in the recumbent position in the impure atmosphere of an hospital or sick-room, and to the irritative fever consequent upon wounds or profuse discharges, stagnates in the lungs; a degree of irritation is consequently set up, and inflammation of a passive type is excited. In the first stage the affected parts are of a livid violet, or purple-mottled colour, heavy, compact, but friable, readily breaking down into a grumous pulp, and scarcely crepitating when pressed upon, but exuding a very considerable quantity of thin, spumous, frothy fluid. In the second stage the tissue of the organ is more dense, but still very friable; it does not crepitate, but sinks in water, and when cut into, the sides of the incision present a smooth, uniform, black aspect, to be attributed to a highly gorged state of the capillary net-work of the lungs compressing the air-cells, which are either empty or contain, at most, a thin serous fluid. In order to establish his proposition, that this kind of pneumonia is prevalent in cases of surgical complaints of the miscellaneous description implied by the title of his paper, he presents a table containing a record of 62 post-mortem examinations of the lungs in patients who had been treated in the surgical wards of the University College Hospital. The list was made without selection, and is composed of a series of diseases, injuries, and operations of the varied nature, as to kind, duration, and fatal character, usually met with together, in an hospital. Burns, which are a special kind of injury, are not included in it, nor are the symptoms of the patients during life, or the morbid appearances found in other organs besides the lungs. He arranges his cases into four classes, and finds, first, that of those in which the presence of a pneumonia was evinced by the diseased condition being confined to one lung, by its having advanced to solidification, or by its being combined with inflammation of the pleura, or bronchial mucous membrane; these are 28 cases, or nearly one-half of the total number. Secondly, that of doubtful cases, in which the lungs presented the characters common to the first stage of pneumonia, and to passive congestion, without there being collateral signs to establish the diagnosis, these are 11. Thirdly, that of cases in which the lungs were diseased, but not inflamed or congested, these are 9. Lastly, that of cases in which the lungs were found perfectly healthy, these are 14. He further states that of the 28 cases included in the first class, the pneumonia had advanced in 17, to the second stage of hepatisation.

MEDICAL NEWS.

PARIS ACADEMY OF SCIENCES, Jan. 30.—An account was given of some experiments by MM. Sandras and Bouchardat, with a view to ascertain the mode of absorption of the different elements of nutrition contained in the principal articles of food used by man or the lower animals. Taking as a basis that soluble aliments are absorbed by the veins, and insoluble aliments by the chyliferous tubes, it remained to be ascertained in what way nature had provided the means of rendering certain aliments soluble, or of separating them to such a degree as to enable them to pass through the chyliferous tubes. MM. Sandras and Bouchardat divided their experiments into two series; one chemical, the other physiological. The chemical experiments showed the action which water slightly acidulated by chloridric acid exercises upon the fibrine, albumine, caseum, gluten, and the gelatinous tissues. All these substances enlarge, and become translucent, and some of them dissolve. It is sufficient, in order to produce most of these phenomena, to add to 10,000 grammes of water, six grammes of hydrochloric acid, but it was found necessary in order completely to dissolve the fibrine to add a few drops of rennet. Hydrochloric acid, therefore, is not the dissolving agent in the gastric juice; the animal matter called pepsine or chymosine, must also be present. This being admitted, it appears probable, from the experiments of Messieurs Sandras and Bouchardat, that neutral azoted animal substances when once dissolved in the stomach pass directly into the veins. This is the case with gluten. Starch and fecula are wholly or partially converted into lactic acid in the stomach, and are absorbed in this form.—Neither starch nor sugar is found in the chyle during a course of feculent alimentation. Greasy substances resist the action of the stomach, and pass into the intestinal canal, where they form a sort of thick cream, and at the same time the chyle, under their influence, develops itself in extraordinary abundance in globules capable of rendering them milky and opaque. According to MM. Sandras and Bouchardat, therefore, greasy substances are the main agents in the production of chyle, so necessary for the process of digestion. A communication was read relative to some experiments on the blood, by MM. Andral and Gavarret. These gentlemen, forcibly struck with the fact that a learned professor had succeeded in precipitating albumine in the form of globules, by adding a sufficient quantity of water to serum neutralised by an acid, repeated M. Leibig's experiment, and were not a little surprised to find that the globulous bodies, which developed themselves in the serum of the blood, were nothing less than the first rudiments of the vegetable of fermentation. Their experiments were repeated on the white of an egg, and on various serosities produced by disease, and the result is that, whatever may be the albuminous liquid, the alkaline property of which is removed by an acid, the same phenomenon presents itself.

THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs.

No. 179. Vol. VII. LONDON, SATURDAY, FEBRUARY 25, 1843. PRICE FOURPENCE. Stamped Edition 5d.

For the convenience of subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to G. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London

SUMMARY.

ANALYSIS OF MORBID PHENOMENA.

NOMENCLATURE.—BY W. FARR, ESQ.

(Extracted from the Registrar General's Annual Report.)

It will be observed that the preceding alphabetical list contains more diseases than the nosology, and the nosology more than the abstracts; to explain this, and to show how the list of the causes of death may be legitimately extended or contracted, it will be useful to inquire how diseases have been named, or upon what principles, morbid phenomena have been grouped and subdivided. I shall therefore pass rapidly in review the elementary phenomena of disease, and consider more particularly how the numerous and, in some instances, apparently arbitrary species have been distinguished by original and systematic writers; for without admitting the assertion, repeated by Cullen, that "species are created by nature; genera by the human mind,"†—as our ideas both of species and genera are creations of external nature and of the percipient mind,—the determination of these primary elements of generalization is unquestionably more important than the subsequent steps in the process, because an error here will be irreparable. The species in the statistical nosology occur in the registers as well as in all the systematic medical works; and my object is not so much to propose anything new either in the names or the species (it being the very nature of an arrangement of the facts observed by all the practitioners of a country, to follow, as the observers themselves follow, the discoveries of pathology), as to point out some of the principles which have guided us in the distinction of species, and in the formation of other divisions of the classification.

The human body consists of atoms of various kinds in certain degrees of proximity—in a polarity—and in relative positions—which probably determine the properties of the organization, considered in reference to its various parts, and to the external world, from which it is constantly receiving, and to which it is incessantly rendering, its elements. The constituent atoms of oxygen, hydrogen, carbon, nitrogen, phosphorus, sulphur, iron, calcium, magnesium, potassium, and sodium, exist in fluid or solid compounds—the result of a long series of metamorphoses—in the earth, atmosphere, plants, and inferior animals. The fluid compounds are blood. The solids, which, according to a recent theory, consist of cells, may be divided into cellular, mucous, fibrous, horny, cartilaginous, osseous, muscular, vascular, nervous tissues; and the blood, apparently a homogeneous liquid, perpetually undergoing transformations, readily separates out of the vessels into a clot of fibrine, entangling globules (cells?), and into serum, containing dissolved albumen, with carbonates, phosphates, muriates, and sulphates of potash and soda in solution. Fibrine and albumen contain the same elements in the same proportions; with a red colouring compound of iron they form the globules. The blood also contains peculiar fatty bodies, and the earth of bone in small quantities. All the *tissues* are formed out of the blood; and they form the parts, organs, and systems of which the aggregate is the organization.

The body in the whole, and in its parts, undergoes innumerable alterations; but these deviations from the normal type may be reduced to certain general heads:—(1.) increase, or diminution of density, weight, volume, cohesion, elasticity, colour, number (of parts),—of which the following present examples—induration, softening, dilatation, contraction, atrophy, hypertrophy, anæmia, plethora, albinism, fracture, hæmorrhage: (2.) displacement,—examples—transposition of viscera, hernia, dislocations, passive congestion, dropsy: (3.) heterologous* products—examples—pus, tubercle, cancer, melanosis: (4.) disorganization,—examples—ulceration, mortification. The secretions—the products of transformations of the blood and tissues—saliva, intestinal juice, pancreatic fluid, bile, (poured into the intestinal canal), milk, urine, (liquor), perspiration, breath (generally in a state of vapour)—may all be excessive (flux), altered in composition (discharge), or deficient (suppression)—examples—diuresis, ischuria diabetes, albuminaria, stone (of uric acid, oxalate of lime, phosphate of lime, the triple phosphates). As the urine, which affords peculiar facilities for chemical investigation, has been found to vary in all its constituents, and to contain either matters derived from the blood, as albumen—or, as in jaundice, secreted by remote organs—or new (heterologous) compounds, such as diabetic sugar, oxalate of lime, free uric acid,—the existence of similar changes may be inferred in the other secretions, and in the blood.

Besides the physical and chemical alterations which may be detected after, as well as before, death, derangements of the dynamic phenomena of life are observed, which may be referred to the heads of heat, refrigeration, spasm, paralysis, pain, coma, mania, amentia; as we see them, for instance, in ague, the exanthemata, typhus, inflammation, cholera, tetanus, epilepsy, palpitation, paraplegia, gastrodynia, apoplexy, insanity.

The elementary phenomena of disease admit of infinite combinations; and none is of more frequent occurrence, or of greater importance, than inflammation; the symptoms of which are "*redness* and *swelling*, with *heat* and *pain*."† The redness and swelling denote an excess of blood in the part; the heat, a chemical reaction of the blood and tissue, the result of which is interruption of the function, and generally the effusion of lymph, the formation of pus, or gangrene. If the hypothesis be adopted, that heat is formed by the combustion of organic matter, and is proportional to the amount of oxygen consumed, we can easily understand how heat is generated, and becomes sensible in inflammation. The heat, accompanied by quick pulse (increased action of the heart), is called inflammatory *fever*; but fever itself is the result of a great variety of morbid processes, in which the disengagement of heat and the waste of flesh is rapid, without any development of muscular or mental force.

If we now inquire how the species of disease have been distinguished, and whence their characters have been derived, it will be found to have been generally from the morbid processes or products, the parts affected, the pain, the perceptibility of phenomena, their duration, their individuality, frequency, and fatality.

The parts affected, and their functions, stand next in importance to the morbid processes, actions, or products. The body is an aggregate of organs, each consisting of a variety of tissues, and performing special offices; the eye for instance, is an organ consisting of a lens, of humours, membranes, blood-vessels, muscles, nerves the optic nerve; its function is vision; and though all the deviations of its apparatus from the normal state are morbid,—interference with vision stamps them with importance, and entitles them to names. The most important organs are the brain, spinal marrow, nerves, and senses, constituting the nervous system: *function*—sensation, volition, motion: the heart, arteries, veins,—the vascular system; *function*—circulation of the blood. The nervous and vascular systems pervade, and their derangement may directly disturb, all the parts of the body. The functions of the absorbent, respiratory, digestive, urinary, generative, locomotive, integumentary, and cellular systems, will be denoted by their [illegible] parts, forming subordinate organs; thus, the hand is an organ of prehension, the mouth of mastication, the pharynx of deglutition. Some parts are more easily observed than others, and will be found to have not perhaps more disease, but a greater number of specified diseases. The influence of function, and of perceptibility on nosological nomenclature, will be seen by comparing in systematic works the diseases of the ear and hand with the long list of diseases of the eye; the diseases of the mucous membranes with the diseases of the skin; the inflammations distinguished by the antients, with the serous, mucous, parenchymatous inflammations of modern pathologists, armed with new instruments of diagnosis, and facilities for examining bodies after death. Where particular parts of organs are liable to attacks, and present characteristic symptoms under the attack, or where the products of pathological processes are distinct; wherever, in fact, important pathological states and phenomena are isolated and can be individualized, they have been made species of disease. Pleurisy, pneumonia, and catarrh (bronchitis,) were distinguished at an early period, and their independent existence has been confirmed by pathological anatomists; they differ in the symptoms, site and fatality; and occurring together, but often alone, are examples of the way in which diseases of different parts of an organ have been divided into species.

In the constitution of species, more attention is now justly paid to structural than to functional changes; the former are often the proximate causes of the latter; but some pathologists, led astray by a principle of classification applicable to natural history,* or pre-occupied by their anatomical

---

* The medical reader who takes any interest in this subject, is requested to refer to the article "Nosology" in the Appendix to the First Report. I say "medical" reader, because it is impossible to discuss a subject so purely technical as Nosology, without assuming a knowledge of facts and principles which can only be familiar to medical men; who it is quite certain will be called upon to exercise all their professional sagacity in returning the "causes of death" with the necessary degree of accuracy.

† A natura vero, species solum datæ sunt; et generum constitutio est mentis humanæ excogitatio.—*Cullen*—Synopsis Nosol. Meth. Even in natural history it would perhaps be more correct to say "individuals" than species.

* Laennec proposed to call tubercle, melanosis, and cancer, which have no analogues in the organization, heterologous products.

† Notæ vero inflammationis sunt quatuor, rubor et tumor cum calore et dolore. *Celsus*, lib. 3, cap. 10.

* Pour que chaque etre puisse *toujours se reconnaitre dans ce catalogue*, il faut qu'il porte son caractere avec lui: on ne peut donc prendre les caracteres dans des proprietes ou dans des habitudes dont l'exercice soit momentaneé mais ils doivent etre tirés de la conformation: *Cuvier*—Regne Animal, tome i. p. 7. The problem in natural history is or *was*.—Given one of many thousands or millions of individuals, what is its name and place in the "catalogue?" As the specimen is often dead, or

studies, and the recent discoveries in morbid anatomy, have denied the existence of dynamic isease; and, by a violent and improbable hypothesis, have assumed that every case, for instance, of insanity, convulsion, or syncope, is the *symptom* of a congestion, inflammation, or some other evident anatomical lesion. It would be as reasonable to assume that the needle of the mariner's compass never loses its magnetic properties but by evident oxidation.

Upon an examination of the registers of the fatal diseases in the first years of registration made, as is evident from the instructions, without any preconceived notions on classification, it was found that, exclusive of epidemic diseases, a majority of the cases had been referred to particular organs, which were named, or unequivocally indicated, by the nature of the lesion. In other cases, such as hæmorrhage, dropsy, abscess, mortification, and cancer, the seat of the disease was seldom mentioned. The first class was arranged in groups, as sporadic diseases of the nervous, circulating, respiratory, digestive, urinary, generative, locomotive, and integumentary systems; the second as diseases of uncertain seat (*de incertis sedibus.*)* This mode of viewing the facts is common in England; it has been adopted in the treatises on the practice of physic, which are most generally in the hands of practitioners; and, what is of more importance, by the authors who have devoted themselves successfully to research, and have naturally contributed most to the formation of the reigning medical opinions. The Library of Practical Medicine has followed this arrangement; and we have the original works of *Abercrombie and Marshall Hall, on Diseases of the Nervous System; Hope, on the Diseases of the Circulating System; Williams, on Diseases of the Chest; Abercrombie, on Diseases of the Stomach and Intestines; Prout and Sir Benjamin Brodie, on the Diseases of the Urinary Organs; Willan and Batemen, on Cutaneous Diseases:* not to mention others, and the treatises on midwifery, or the surgical treatises on the diseases of the joints and bones. Upon the other hand, there are essays and papers by Carswell, Watson, Sir James Clark, Mueller, Carmichael, and Walshe, on hæmorrhage, dropsy, tubercle, cancer, with a subordinate reference to the parts affected. The French writers, Laennec, Andral, Chomel, Rostan, Lallemand, and Louis, from whom we have derived so much, have cast their practical works in the some mould. This mode of grouping and considering the different types of sporadic disease, appears to be practically the best—to involve few errors in carrying it out, to lead to useful results, and to be in conformity with the general principles upon which diseases have been constituted and named.

It will be observed that the different heads in the statistical nosology are numbered and sometimes subdivided; they may be called species, provided the term be not understood in the strict sense it bears in natural history† with the technicalities of which medical science should not be encumbered, as it has principles of its own, and can derive more advantage from the methods of chemistry and natural philosophy.

Sporadic diseases of uncertain or variable seat.

To commence with the diseases of uncertain or variable seat. *Hæmorrhage* (28) is essentially the *loss of blood;* blood may escape from any of the vessels in any part; and the difference and susceptibility of the part has given eight names to the affection. Hæmorrhage is periodical in females, and hereditary in some families; epistaxis is a type of simple hæmorrhage. The extensive loss of blood in phthisis, stone, cancer, ulcer, wounds, &c., is an important and sometimes fatal complication; but the *combination* of lesions may be described ("phthisis, hæmoptysis," &c.) and does not require a name. Hæmorrhage in the brain is one of the causes of apoplexy; in the lungs one of the causes of asphyxia. Dropsy (30), the effusion of serum in the cellular tissue, the brain, chest, pericardium, peritoneum, tunica albuginea, has received distinct names; it is frequently an effect of retarded circulation: is a sequela of scarlatina: is observed in famines, and is the cause, consequence, or concomitant of Bright's disease of the kidneys (nephria). Abscess (31) or purulent deposit, is a secondary disease; *psoas abscess* (almost invariably scrofulous) has been distinguished; ulcer (32) is generally scrofulous, scorbutic, syphilitic, cancerous, or varicose, and is further described by the addition of the part affected. Scrofula, characterised by the deposit of a matter, allied to, if not identical with, the tuberculous matter of phthisis, so frequently affects the lymphatic glands, that their chronic enlargement and inflammation (adenitis) is almost always considered scrofulous; the deposit of tuberculous matter in the mesenteric glands has a name; it is frequent in children. Tubercle may be deposited in every part, and is found in the bodies of those who die of other diseases; it affects the glands and brain chiefly in children, the lungs in adults. Cancer differs from tuberculous matter in its tendency to assume an imperfect form of organization; it presents several varieties; but as it invades many parts, simultaneously or successively, it has not received special names from the organs, notwithstanding the variety of specific symptoms to which it gives rise. It is unnecessary to extend these remarks; they will apply with little variation, to all the diseases in the class. By following all the possible combinations of the few elementary lesions here fixed upon through all the organs, considering each a separate disease, and giving it a name, the number of species would become very great; but the number has been limited by their unfrequency, imperceptibility, indistinctness, or indestructiveness.

If it were agreed to use the prefixes—hæm-a, hydr-o, py-o, helc-o, choir-a, carcin-o, necr-o hyper, par,—to designate the ten principal lesions in the class, by prefixing them to only ten of the principal parts (and they may be prefixed to a hundred), 100 species would be formed. Thus, as we have hydro-cephalus, serum effused in the brain (including its membranes); we should have hæmencephalus, blood effused in the brain; pyencephalus, pus, (abscess) in the brain; helcencephalus, ulceration of the brain; choirencephalus, tubercles in the brain; necrencephalus, ramollissement of the brain; hyperencephalus, hypertrophy of the brain; parencephalus, malformation of the brain; and carcinencephalus, cancer of the brain; carcinocardia, cancer of the heart; carcinopneumon, cancer of the lung; carcinohepar, cancer of the liver; carcinogaster, cancer of the stomach; carcinentera, cancer of the intestines; carcinephrus, cancer of the kidney; carcinocystis, cancer of the bladder; carcinohystera, cancer of the uterus; carcimamma, cancer of the breast. Carcinosteon is designated osteo-sarcoma in surgical works. All these lesions are the source of special phenomena (hæmencephalus, carcinencephalus, and carcimamma, for example, are attended by very different effects); and they have been enumerated because a comparison of these and other possible combinations of lesions and symptoms affords a good illustration of the way in which diseases have been constituted; but the new names have not been introduced into the nosology, because it could have led to uniformity only at the expense of old names,* and because the primary fatal diseases of several in the class are not numerous, and others, as has been already stated, in which there are organized or unorganized deposits, affect several organs before they prove fatal. Hæmencephalus, necrencephalus, hyperencephalus, hypercardia, may, however, be advantageously adopted. In other cases it will be simpler to write, as has been recommended in the nosology, "cancer of the breast, liver, brain, " than three compound names; and more convenient to describe the disease by the addition of the locality affected, as "cancer of the tongue," "of the œsophagus," "of the stomach," "of the colon," &c., than to invent specific names, which are only required in the place of descriptions, when the things or facts have to be frequently considered and mentioned.

Inflammations.—Local Diseases.

Redness, swelling, heat, and pain, are diagnostic symptoms of inflammation, but they cannot be satisfactorily observed except in external parts; the fever is common to all acute inflammation; though the vascular injection, and other traces of inflammation might be found after death, they are rarely observed, as the internal parts are seldom inspected; so that practically the perversion or abolition of function is the most striking phenomenon in the inflammations of the organs, which are considered sufficiently important to form distinct diseases. Hence the names of the parts affected, with the suffix "itis," give names to forty diseases; a subdivision of phenomena which, if it is not always justified, and is unnecessary for statistical purposes, admits of explanation, and throws light upon the principles already advanced. Inflammation may exist wherever there are blood and capillaries: its species are limited by the importance of the parts affected. Inflammation of the membranes and medullary matter of the brain have been designated meningitis, and encephalitis; of the spinal marrow and its membranes myelitis. Besides these inflammations, which sometimes exist apart and can sometimes be distinguished during life, writers have described arachnitis, cerebritis, cerebellitis, &c., from the appearances after death. Cullen designated by the old term phrenitis the inflammations of the brain, spinal marrow, and membranes; and although the chief distinctions of modern pathologists should be attended to where it is practicable, in assigning the causes of death, it would be unwise to carry the division further, or to preserve more than the one head, cephalitis, in the abstracts. Ophthalmia is now subdivided, and minute oculists describe "conjunctivitis, sclerotitis, iritis, choroiditis, retinitis, and hyaloiditis." Auscultation has facilitated the diagnosis of affections of the chest; and the inflammations of the internal and external membranes have been separated from those of the parenchyma of the heart and lungs; besides pleuritis, bronchitis, and pneumonitis, practical writers now treat of pericarditis, endocarditis, carditis. The inflammation of the two surfaces and parenchyma of other organs are generally designated by one word—glossitis, parotitis, hepatitis, pancreatitis, splenitis, nephritis, cystitis, orchitis. If it were of the least utility, the triple subdivision might be extended to these organs; and hepatitis, for example, might be made choledocitis, perihepatitis, hepatitis. Inflammation of the intestinal tract has received several names; stomatitis, tonsillitis, pharyngitis, œsophagitis, gastritis, enteritis, (under which term I include duodenitis, jejunitis, ileitis, cœcitis, colitis, rectitis, proctitis). These terms are held to designate especially inflammation of the mucous and submucous coats of the canal; which is invested after it enters the abdomen by the peritoneum; inflammation of this serous membrane is named peritonitis. A question has arisen whether inflammation of the part of the peritoneum—investing the stomach, small and large intestine, liver, uterus, bladder, &c.—should not be specifically designated gastritis, hepatitis, &c.? It will be much more convenient to designate inflammation of every part of

—as in fossils—has been only partially preserved, the superior importance of characters, derived from the most permanent structures of the organization, is obvious. Recognition is not a main object of any classification of diseases; and the most expert anatomist would, in numberless instances, find it impossible to divine from the after-death appearances, the previous pathological phenomena.

* Celsus.

† La generation etant le seul moyen de connaitre les limites auxquelles les varietes peuvent s'etendre, on doit definir *l'espece, la reunion des individus descendus l'un de l'autre, ou de parents communs*, et de ceux qui leur ressemblent autant qu'ils se ressemblent entre eux.—*Cuvier*, R. A., tome i. p. 17. With this definition before our eyes, we can not confound the species and genera of natural history with those of diseases.

* Helcosteon and chorosteon for caries, psoas abscess, and white-swelling; necrosteon for necrosis, hyperosteon for exostosis and node, choirenteron for tabes mesenterica, hæmentera for melæna, hæmohystera for menorrhagia, hydroperitoneum for ascites, &c.

the peritoneum—peritonitis: but the serous and subserous coats of the peritoneum derive blood from the vessels of the subjacent organs; and, when secondarily involved, their inflammation is necessarily included in our idea of inflammation of those organs. Inflammation of the liver, causing adhesions of the peritoneum, is essentially hepatitis; the inflammation, from perforation of the intestine, of the investing membrane of the liver, and of the other viscera, although their functions are all violently deranged, is essentially peritonitis. Ileus is ascribed to inflammation of the muscular coat of the intestine by Dr. Abercrombie, who considers it "established that a result of inflammation in muscular fibre is gangrene."* Dothinenteritis has been employed to designate inflammation of the mucous follicles.—The inflammations of the respiratory tract, are—coryza (schneideritis?) laryngitis, tracheitis, bronchitis, pneumonitis; of the urinary tract—urethritis, cystitis, ureteritis, pyelitis. The bones ligaments, joints, (synovial membranes) bursæ, tendons, muscles, nerves, veins, arteries, lymphatics and glands, described by anatomists, are very numerous; the bones, for instance, are reckoned at 246, and every one may be the seat of inflammation, similar in its kind, however different in its effects; so as to avoid an endless multiplication of names, which would be rarely or never used, inflammation of the veins (of one or of all) has been called phlebitis, and the inflammations of the other parts have been named in the same way arteritis, adenitis, neuritis, myositis, arthritis (synovitis, erondritis, *syndesmitis*,), ostitis, endostitis, periostitis,) *fasitis*, *tenditis*. In registering this class of cases it will be most convenient to write "Inflammation of ——," the particular part; or "Arthritis (knee)," &c.

Inflammations are *acute* or *chronic*; but the duration may be more accurately expressed by the ordinary measures of time.

Inflammations may be divided into pure inflammations—*idio*-inflammations—or those which supervene in a normal state of the blood and tissue; and inflammations which are developed in cachexies, and in the course of other diseases. The distinction is of such fundamental importance, that it should be explicitly expressed in the names; which might be effected by restricting the use of the termination "itis" to idio-inflammations, and applying the termination "*ia*" to complicated inflammations. Simple inflammation of the lungs would be designated pneumon*itis*: the inflammation of the lungs occurring in small-pox "pneumo*nia*." Upon the same principle opthalm*itis*, and purulent opthalm*ia*, may be distinguished; the visceral inflammations in typhus and remittent fever would not be cephal*itis*, &c., but cephalia, pulmonia, gasteria, enteria, hepatia. The inflammation of the brain in scrofulous children has a specific name—hydrocephalus; and peritonitis, with tubercular deposition, is qualified by "tubercular;" the adoption of the two terminations would be a useful extension of the analogy, with which dysenter*ia* is in strict conformity.

Functional Diseases.

The systems of organs in the body are liable to functional derangements which cannot be ascribed to inflammations. Neither the inflammation nor the dynamic derangement exists independently of the organs; the two series of phenomena often coexist; and it is not clear that they can be advantageously separated in statistical abstracts of the causes of death. They were grouped together under the principal systems in the first abstracts, and the arrangement has been retained. For the organ determines the character of the disease, as the grafted branch determines the quality of the fruit.

Diseases of the Nervous System.

The brain, spinal marrow, and nerves, are the organs of sensation, volition, and (with the muscles), of motion. The muscles are of two kinds: the voluntary muscles, which are attached to the bony levers of the skeleton, and, by contracting at the bidding of the will, produce the various movements which we witness of the whole or a part of the body; and the involuntary muscles of the hollow organs, for the retention, circulation, ingestion, and expulsion of fluids; some of which, such as the heart and intestinal canal, are independant of the will, while others, like the respiratory muscles, are excited by the brain and by the spinal marrow—by the stimulus of volition and of contact—reflected along the nerves. Spasm is in general the excess of irregularity, paralysis the abolition or diminution of muscular action; the voluntary muscles, in spasm, contract spontaneously despite of the will; in paralysis the will has no effect upon them, or does not produce harmonised contractions; the involuntary muscles in the same circumstances contract violently and irregularly, or cease to contract upon the application of the accustomed stimuli. As volition implies consciousness, the muscles which are exclusively excited by volition are inactive (paralyzed?) in sleep, coma, and apoplexy—which in its simple form appears to be a modification of deep sleep. In tetanus, croup, epilepsy, catalepsy, hysterics, convulsions, chorea, tremor, paralysis, apoplexy, the voluntary and partly voluntary motor system is principally deranged, with or without loss of consciousness; but the spasms or paralysis may originate in the muscles, the nerves, or the spinal marrow; and after Dr. Marshall Hall's ingenious hypothesis, supported by many facts and experiments, the true spinal system, in this sense, may be considered the seat of the spasm, which, as well as paralysis, may affect any muscle to which motor nerves are distributed, as pain may be felt in any part from which sentient nerves proceed. Pain accompanies nearly all diseases; when it is the sole or principal phenomenon, it has been designated neuralgia; or cephalalgia, odontalgia, cardialgia, gastralgia, enteralgia, &c., by suffixing algia, from *algos*, pain. Odynia is used precisely in the same sense (as in gastrodynia); and headache, toothache, heartache, bellyache, stomachache, are translations of the Greek compounds. Tic douloureux is a convulsive pain. The spasms and paralysis of parts may be designated in the same manner as their pains by terminations (cardiasm may denote spasm, cardialysis paralysis of the heart): hemiplegia and paraplegia are in general use; trismus, opisthotonos, emprosthotonos, pleurosthotonos, are scarcely required to denote transitory forms of tetanus. The modifications of muscular force, contraction, and rythm, as well as their combinations with pain, loss of consciousness, and functional derangements, are numberless; it will be sufficient to mention a few from the nosologies, as they are either physiological, and not primary independent affections, or seldom shorten life; trembling, shivering, languor, lassitude, hiccup, sobbing, sneezing, coughing, puffing, snoring, yawning, twitching, twinkling, squinting, stammering, (Linnæus, Mason Good, &c.)

The modifications of the sensations, and of their organs, are equally numerous: the names of disorders of the feelings, passions, intellect, abound in the lexicons of all languages. Mania, monomania, and dementia—a termination of mania—may be distinguished in the registers.

When the brain, spinal marrow, and nerves of persons affected with the lesions that have been called dynamic are examined after death, traces of inflammation are often found; congestion, softening, effusion of serum, hæmorrhage, tubercles, tumours, produce paralysis or apoplexy. The connexion between the anatomical lesions and derangements of function requires further investigation; it is not constant.

Diseases of the organs of circulation.

It was necessary to point out the dependence of visceral pains, spasms, and paralysis on the brain and spinal marrow; which, in their various states of excitement, depression or derangements, influence even the involuntary muscles. The heart, for instance, beats violently or intermittingly under various states of mental excitement, and beats heavily and slowly in apoplexy; but as palpitation, spasm, fainting, cardialgia, &c., are frequent symptoms of heart disease, and as their causes in idiopathic cases may be in the heart itself, they have been classed with its inflammations and organic diseases. The same principle has been acted on in dealing with the neuroses of other organs, and with affections of the brain originating in the diseases of the heart and kidneys. The organic diseases of the vascular system—hypertrophy, atrophy, ossification, diseased valves, aneurism—which are now detected by auscultation, can often, but not always, be traced to inflammation.

Diseases of the respiratory organs.

Laryngismus stridulus, and asthma, appear to be the only neuroses of the respiratory system which require a separate head in a classification of fatal diseases. Deposits of tubercle have so frequently their seat in the lungs that the phenomena to which they give rise have been called phthisis pulmonalis; and on this ground, as well as the supposed uncertainty of diagnosis, where auscultation is not used, phthisis was classed with the diseases of the lungs in the first abstracts. It does not, however, appear to be governed by the same laws as the pulmonary diseases, and will probably require, with the progress of registration, to be classed in the abstracts under a separate head, or with the other tuberculous diseases.

Diseases of the digestive organs.

Hernia (strangulated) and intussusception are inflammations of the intestine, caused by pressure; in the former preceded by the escape, in the latter by violent muscular action, of the bowel, and generally terminating in mortification, with the symptoms of ileus. Constipation may be either the effect of inaction (torpor), or of spasmodic constriction (colic) of a portion of the intestinal tube: stricture is a contraction of the submucous coat, either from previous inflammation, ulceration, or heterologous deposits; and the symptoms vary according as the stricture may be situate in the œsophagus, pylorus, ileum, rectum, &c., and may consequently interrupt the ingestion of food or the passage of fæces. As the canals of the organs of the body transmit fluids, obstructions and retentions form an important class of their derangements; thus, besides the stricture of the intestine, there are obstructions of the gall-ducts, of the ureters, urethra, heart-valves, arteries, veins, trachea, all of which may be fatal. The reduction of aliment is the special function of the stomach and intestine; it is inferred that this is imperfectly performed when there is nausea, heartburn, disengagement of gas, or of acrid fluids; hence the designation dyspepsia. Little is known of the diseases and functions of the pancreas and spleen. Liebig has rendered it probable that the bile is absorbed from the intestine; may not disorders of nutrition, therefore, which put a stop to its destruction (combustion) in the blood, lead to its deposit in the cellular tissue, or secretion in the urine? Jaundice is, however, generally connected with the diseases of the liver, and is always referred to the liver as its source. The fatty degeneration of the liver occurs frequently in phthisis; cirrhosis is an atrophy of the liver produced by the pressure of the contractile tissue, developed in the capsule of Glisson.—(*Carswell.*) The compression of the portal vein leads to venous effusion, and almost invariably constitutes the disease which was called by the ancients ascites.

Diseases of the urinary organs.

Ischuria, diuresis, albuminuria, diabetes, stone, are the principal functional diseases of the urinary system; the three first, though often symptoms (as subordinate phenomena are sometimes called) of nephritis and other diseases, appear to have sometimes an independent existence. As the sugar of diabetes is found in the blood and in the stomach, it has been considered essentially a dyspepsia, and been classified with the stomach diseases, as bile in the urine has been referred to the liver; but we have custom, with the unquestionable, invariable existence of sugar in the urinary secretion, on one side, and only a probable hypothesis on the other. A secretion may be modified as well by a change of the fluids, from which it is made directly or indirectly, as by a change in the secretory organ; and the oxalic acid, uric acid, triple phosphate, albumen, as well as sugar in the urine, may often be considered the symptoms of

* Researches on the Diseases of the Stomach, the Intestinal Canal, the Liver, and other Viscera of the Abdomen. By J. Abercrombie, M.D., &c. Third Edition, p. 6.

changes in the chemical processses of remote organs. The same may be said of mismenstruation.

Diseases of the organs of generation.

All the diseases incidental to *childbirth* are connected together by this function, and their seat in the reproductive organs.

Diseases of the organs of locomotion.

Besides inflammation, the osseous system may be the seat of all the diseases of uncertain seat; brittleness and softening appear to depend upon the excess or deficiency of bone-earth in their gelatinous tissue. Skin diseases require no comment here: the innumerable varieties depend apparently as much on the complicated structure of the integumentary system, and its free exposure to the oxygen of the air, as on the specific nature of the morbid processes.

Two or more diseases frequently coexist; pleuripneumonia, paraplexia, and gastro-enteritis, are examples of the compound names by which these combinations have been designated. If two morbid states invariably coexist, or two parts are simultaneously affected, and the one affection imply the other, a single name is sufficient; if the coincidence is rare, a new name will be unnecessary; and as a general rule, it will be better in such cases to write the names of the separate diseases consecutively, whether they arise from the same cause, or stand to each other in the relation of effects and causes.

The phenomena of all the diseases which have hitherto been considered had reference to the nature of the morbid processes, or the systems of functions and organs: two classes remain to be reviewed—the class of epidemic, endemic, contagious diseases, and the class of poisons, asphyxia, or injuries, in which the cause is the fundamental fact around which the phenomena are naturally grouped.

Poisons and Injuries.

One person dies of corrosion of the stomach and hematemesis, another of palsy of the heart, another of tetanic spasms of the respiratory muscles, another of pure narcotism, another of a combination of these phenomena which have in them something peculiar, and differ from the spontaneous diseases with which they have been compared. All the sufferers have been poisoned by oxalic acid, in various degrees of dilution. Verdigris produces a variety of symptoms—vomiting, cutting pains in the bowels, jaundice, violent headache, cramps in the legs, convulsions, palsy, insensibility,—and the poison itself is the predominating fact: the nature of the morbid processes, and the lesion of the parts or functions being of secondary importance, differing according to the dose, the individual, and many accidental circumstances, but possessing altogether, in connexion with each other, order of succession, intensity, and result, a certain individuality of character, which distinguishes poisoning by copper from poisoning by other substances, and from other diseases. The diseases that poisons—such as oxalic acid and the salts of copper or lead—occasion in the body, should evidently be named, now that the diseases have been ably investigated and described, though they are not so well understood as their exciters. The idea of the metal, lead, is represented by the word "lead;" and as this name is required for the purposes of speech, a name for the series of phenomena caused by lead, or the salts of lead, in the human body, appears to be equally indispensable in medical science. It is as necessary to distinguish the effects of a lead poison in the body, from the lead poison itself—as to distinguish a "burn" from the fire by which it is produced; for arsenic, or any substance of the kind, proves a cause of death only when it produces certain changes (diseases) in the organization, and those changes are logically the direct cause of death. A *burn* or *arsenicia* may be the cause of death—but fire and arsenic are only causes of death by producing burns and arsenicia. Catharsis, narcotism, intoxication, salivation, burn (blister, eschar), asphyxia, fracture, contusion, wound, dislocation, are names, that have already been adopted to designate the pathological effects of chemical or mechanical agents. Catharsis is produced by colocynth, scammony, jalap, rhubarb, [illegible] of soda, potash, magnesia, and a hundred other substances; in the effects of which careful observation might detect peculiarities, slight in some cases, but as broad and obvious in others as the differences in the chemical composition of the cathartics. In strict conformity, nevertheless, with the correct principles of nomenclature, catharsis and hypercatharsis serve to express the actions of the greater number of purgatives; yet it must not be forgotten that these actions are of a peculiar nature, sometimes affecting the whole organization, and constituting specific diseases, of which catharsis is a leading symptom. Opium, hyoscyamus, hemlock, hydrocyanic acid, tobacco, belladonna, digitalis, fungi, cause narcotism; and the term narcotism designates sufficiently well the effects of some of the common narcotics; but it would be absurd to confound the diseases excited by opium and hydrocyanic acid, digitalis and poisonous fungi, under a general designation. Catharsis, narcotism, intoxication, and burn, present nearly all the elementary phenomena of poisoning; but the number of combinations of elementary phenomena, and degrees of intensity, like their chemical causes, are innumerable. In the present state of science many may be described by periphrases, but a few require specific names, of which the following are submitted as examples; and if they should not be adopted, they may still be considered an illustration of distinctions which everybody will admit to be important:—

Poison	Disease produced by the Poison.
Silver (*arguros*) its salts - - - -	argyria.
Quicksilver (*udrarguros*), its oxides and salts - - - - - - - -	hydrargyria.
Copper (*kupros*, cuprum), its oxides and salts - - - - - - - -	cypria.
Lead (*molubdos*), its oxides and salts	molybdia.
Antimony (*stibi*), its oxides and salts	stibia.
Arsenic, its oxides and salts - -	arsenicia.
Iodine - - - - - - - - - -	iodia.
Sulphuretted hydrogen - - - -	hydrosulfuria.
Oxalic acid - - - - - - - -	oxalia.
Hydrocyanic acid - - - - - -	hydrocyania.
Alcohol - - - - - - - - -	alcoholia.
Elaterine (elaterium) - - - - -	elaterinia.
Nicotinine (tobacco) - - - - -	nicotinia.
Atropine (belladonna) - - - -	atropinia.
Morphine (opium) - - - - - -	morphinia.
Strychnine (nux vomica, St. Ignatius's bean) - - - - - - -	strychninia.
Fungine (poisonous fungi) - - -	funginia.

The metals and other elementary bodies having little affinity for water, or for the constituents of the organization, seldom, except in composition with oxygen and acids, produce disease. The insoluble compounds are inert, and of soluble compounds the intensity of action is apparently in proportion to the solubility, or to the power of pervading the blood; and to the importance of the matter or organ on which the poisonous affinities are exercised, destroying its normal composition, forming new compounds, which the poison unites with or sets free, and altering the vital actions, in a manner characteristic of the base. Liebig shows how, according to his ingenious theory of respiration—if the iron in the blood globules carry oxygen—the fatal effects of sulphuretted hydrogen and hydrocyanic acid may be explained by their well-known action on the compounds of iron, and thus enables us to conceive, if we cannot demonstrate chemically, the *modus operandi* of the most virulent poisons.

In very minute doses poisons have no visible effect, or have a sanative effect on the organization; in large doses their action is generally violent and local (acute); in moderate, long-continued, repeated doses, characteristic series of effects are produced, such as the mercurial salivation, erythema, and tremor, lead colic, and paralysis. If small doses of substances, poisonous in larger doses, are innocent or remedial, food in excess acts by its quantity like a poison, and gives rise to acute indigestion, or to the trains of symptoms indicated by gout, plethora, bloated obesity. The alimentary liquors, of which alcohol is the basis, intoxicate in large doses; and frequent intoxication induce delirium tremens, cirrhosis, and other pathological phenomena which may be designated *alcoholia*. The privation of the various kinds of fluid and food every day required by the organization, gives rise to acute symptoms (such as occurred, for instance, in the shipwreck of the Medusa), or chronic forms of disease, such as scurvy, and the malady that decimated the Milbank Penitentiary; the body, acted on by oxygen, when it can no longer serve for food, becoming a poison to itself, or falling spontaneously into states of disorganization analogous to the effects of poisoning. The special disease arising from privation might be called *pinia* (*peina*, famine, hunger); from high living, *obsopnia* (*opsoponos*, "elaborately cooking victuals"); from cold, *psychria* (*psuchros*, cold); from heat, *thermia* (*therme*, heat); without discarding the common terms starvation, scurvy, overeating, gout, chilblains, frost-bitten (cold ?), gangrene, coup de soleil, and some tropical diseases, or replacing the names of diseases which owe their origin indirectly to the excess or deficiency of food and warmth.

Many animals secrete venoms of various kinds, and in others, such as muscles, which are used for food, poisons are accidentally generated.

Epidemic, Endemic, and Contagious Diseases.—Zymotic diseases, or zumoses.

"Miasm, properly so called, causes disease without being itself reproduced. * * * Carbonic acid and sulphurretted hydrogen, which are frequently evolved from the earth in cellars, mines, wells, sewers, and other places, are amongst the most pernicious miasms." (*Liebig.*) Miasms produce diseases like ague, without being propagated by contagion; but the poisons—carbonic acid, sulphurreted hydrogen, and other gases, which are given off by organic matter in putrefaction, afford an illustration of their action. The miasm which excites intermittent fever may be designated *pyretine*; and if it were not probable that modifications of the marsh miasm induce, in certain circumstances, remittent and yellow fever, specific names should be found for their principles. Rheumatic fever is apparently caused by a miasm.* Its changes of seat can scarcely be accounted for on the hypothesis that it is a local inflammation of the fibrous tissue.

Certain matters which have not yet been analyzed produce small-pox, glanders, hydrophobia, syphilis, measles, scarlatina, and other diseases; and as it was before proposed to give names to the well-defined diseases produced by poisons, so, for the purposes of reasoning, it will be equally useful to name these specific matters or transformations of matter by which diseases are propagated either by inoculation and contact (contagion), or by inhalation (infection). The following list exhibits the popular and scientific names of diseases in juxta position with the proposed names of their exciters; and it may be assumed hypothetically, that in the blood corresponding bodies exist which are destroyed, and by the transformation of which the exciters are generated or reproduced. The names in the second column terminate in *a*, except a few in *s*. Lyssa, (from *lussa*, rabies), the old Greek term, has been restored by Mason Good; I propose, for the sake of uniformity, to call puerperal fever *metria*; mumps, *parotia*, reserving parotitis for simple inflammation of the parotids; croup, *trachcia*; and the disease from puncture in dissection, *necsia* (*nekus*, the dead body.)

Diseases.		Zymotic Principles.
Small-pox - - - -	variola. -	varioline.
Cow-pox - - - -	vaccinia -	vaccinine.
Glanders - - - -	equinia -	equinine.
Hydrophobia - - -	lyssa - -	lyssine.
Syphilis - - - -	syphilis -	syphiline.
Infection in dissecting	necusia -	necusine.
Erysipelas - - - -	erysipelas -	erysipeline.
Puerperal fever - -	metria -	metrine.
Measles - - - - - -	rubeola. -	rubeoline.

* The exciting cause of intermittent fevers, rheumatism, and [rheumatic] neuralgia, is generally admitted(?) to be *malaria*; and if viewed abstractedly, and with reference to their specific nature, *it is probable that malaria is the only exciting cause of these diseases.*—[illegible] p. 50

Scarlet fever - - -	scarlatina	scarlatinæ.
Hooping cough - -	pertussis -	pertussine.
Dysentery - - -	dysenteria	dysenterine.
Diarrhœa - - - -	diarrhœa	
Cholera - - - - -	cholera -	cholerine
Influenza - - - -	influenza -	influenzine.
Typhus - - - - -	typh*us* -	typhine.
Plague - - - - -	pest*is* - -	pestine.

The existence of gangrenine, ergotine, ophthalmine, tetanine, miliarine, diphtherine, parotine, aphthine, tracheine, may also be admitted. It is maintained by some pathologists, that the same specific poison produces several of these diseases—erysipelas, necusia, and metria, for instance—but while the diseases are described as distinct, it will be most convenient to consider their exciters as distinct, although they may be convertible into each other, and be as nearly related as varioline and vaccinine.

The chemical composition of these principles is at present unknown; but as salts are distinguished from each other by their relations to other bodies, and, though they may have the same appearance in solution, are found to differ by the compounds which they form with other bodies in solution, so the existence is demonstrated by the effect, of the matter here called "*lyssine*," on animals, although it cannot be detected by the rough analysis of artificial chemistry. The smallest quantity imaginable of *lyssine* inserted under the skin of a dog produces hydrophobia; and the bites of the infected dog will throw other dogs, and even human beings, into a state similar to that of the dog from which the charge of lyssine originally came. Varioline in the same manner produces small-pox, if the patient has not previously undergone its influence, or the influence of vaccinine—a modification of varioline. The diseases of this class have been frequently spoken of as fermentations; and Liebig has now opened the way to the explanation of their nature by a reference to the phenomena attending the transformations of organic compounds, excited by the action of other compounds simultaneously undergoing analogous transformations. Thus yeast, which is gluten in a state of transformation, added to wort, which contains gluten and sugar, converts the gluten of the wort into yeast, and at the same time the sugar into alcohol and carbonic acid, the two transformations going on together, and the latter ceasing when the former ends. The yeast reproduces yeast, if gluten, from which it was originally derived, be present; and if the temperature and circumstances be favourable, fermentation may be spontaneous.*

It must be admitted, with respect to all the forms of these diseases, that the body, in the cycle of external circumstances through which it passes, may run into them spontaneously (in this they differ from the class of diseases referred to external causes;) for it is impossible to trace them invariably to infectious sources; it is not *a priori* more improbable that they, than that other diseases should arise spontaneously, and it is impossible to account for their existence in the world upon any other principle than that of spontaneous origin. Still the property of communicating their action, and effecting analogous transformations in other bodies, is as important as it is characteristic in these diseases, which it is proposed therefore to call in this sense zymotic.† A single word, such as *Zymotics*, is required to replace in composition the long periphrasis "epidemic, endemic, and contagious diseases;" with a new name and a definition of the kind of pathological process, which the name is intended to indicate, persons who have not made themselves acquainted with the researches of modern chemistry, can scarcely fall into the gross error of considering this peculiar kind of diseased action, and vinous fermentation absolutely identical; or of considering that others entertain that opinion. Liebig draws a distinction between fermentation and putrefaction: the reasons are more urgent for distinguishing the pathological transformations from fermentation or putrefaction, while it is admitted that they are of a chemical nature, and analogous to fermentation; by which they are moreover to a certain extent explained, although so little is known of the series of chemical changes and products in any single zymotic malady, or of the chemical reactions of the living forces and organs. Small-pox is by hypothesis the transformation of varioline, and certain concomitant chemical changes in the blood; manifesting the important symptoms which fall under direct observation.

Some of the morbific principles are fixed; others are volatile; but the greater part of them are fixed and volatile in different circumstances. Necusine, pestine, syphiline, lyssine, equinine, and vaccinine, are the most frequently fixed; they give rise, when placed on the skin, particularly where the epidermis is removed, to their peculiar diseases; but contagion is not invariably the result of their contact; indeed in several of them it is the exception rather than the rule. Either there is no matter in the organization susceptible of transformation, or the specific transformation is overpowered by the vital energies; for in every case, if the morbific principle (zymine) tends to impart its movement to the organization, the organization, animated by the natural forces, has a tendency to continue its own processes, and to impart its conservative movements to all the organic matters which are brought within its sphere.

Varioline is converted in the cow (as Mr. Ceeley has shown) into vaccinine, and cow-pox affords an interesting illustration of the modifications which diseases undergo, and which may be imparted to them, by changes in their exciters. Vaccinine taken from the cow effects the transformation of the *materies morbi* in man as completely as varioline; but it reproduces vaccinine; and in the process is never fatal, never produces the variolous fever, and its vapour is never infectious like that of varioline. The mild form of small-pox which appears in persons modified by previous vaccination, or which follows small-pox inoculation, is an equally good example of the changes induced in diseases by the actual constitution of the individual, and the mode of infection.

Syphilis, erysipelas, necusia, metria, rubeola, scarlatina, and the other zymotic diseases, also put on different forms; which may be referred to the state of the exciter, the mode of its application, the matter on which the exciter acts, or the vitality of the patient. A modification of cholerine or of dysenterine, probably produces diarrhœa. Louis considers dothinenteria (his *fievre typhoide*) a different disease from the typhus of this country, and points out the ulcerations, particularly of the glands of Peyer, with the correlative phenomena, and the rose-spots disappearing under pressure, as establishing its distinct character*. The differences in certain cases are unquestionable and may be expressed by dothinenteria and typhus; but the two forms of the disease occur in this country; the characters are frequently mixed; and they are not greater than are observed in scarlatina simplex, and scarlatina maligna, with black incrustations, and gangrenous inflammation of the throat; in the erythema and phlegmonous erysipelas of Mr. Lawrence, or in the varieties of other diseases.

The blood which prevades the whole system is the primary seat of zymotic diseases; but this does not diminish the importance of the local phenomena with which they commence, proceed, or terminate; for they affect (as poisons do) particular organs more extensively and frequently than others, give rise to specific pathological formations or secretions, and derive their character from the lesions and affected organs.

The heat disengaged in these diseases suggested the term fever, derived from feveo, as fermentum is from fervimentum.

Some zymotic diseases recur, others happen only once in life, or, if they happen twice, it is the exception; this has been explained on the hypothesis that some but not all kinds of matter (zymin) are reproduced in the organization after they have been destroyed by transformation (zymosis) in attacks of disease.

The tendency of zymotic diseases to increase and decline in activity, is one of their most remarkable properties; and the suddenness of their outbreaks, with the great mortality of which they were the cause, excited at an early period the attention and solicitude of mankind. This tendency is indicated by the terms epidemic, and endemic; the latter serving to designate diseases which are excited by miasmata, and prevail in proportion to the quantity of miasm developed; the former, epidemic, denoting the diseases transmitted by man to man, independently of locality, or only dependent on locality, temperature, and moisture, as adventitious circumstances. For statistical purposes, the epidemic, endemic, and contagious diseases, have been classed under one head, as they may all be excited by organic matter in a state of pathological transformation. Ague is not contagious, and is apt to recur; it therefore apparently approaches the class of toxical diseases; but I feel inclined rather to consider it a zymotic disease, in which, to use the language of Liebig, the exciter is destroyed as soon as it is reproduced; and this view is confirmed by the analogies of remittent fever, or yellow fever, so intimately allied in some respects with ague, in others with plague, and apparently contagious (though this is disputed) in certain circumstances. Scurvy is a transformation induced by the want or inadequate supply of vegetable food. It formerly decimated the English navy, and is now met with in certain prisons. Scabies and porrigo (both contagious diseases) are ascribed to an insect (*acarus scabiei*) and a low form of independent organization. The mode in which zymotic diseases are propagated has afforded the ground of an interesting comparison between their diffusion, blight of vegetables, and the generation of animalcules.

Sydenham referred, in the following passage, to zymotic diseases, which were so rife in London, formerly, as to divert attention from pure inflammations; and, as they approach nearer than other diseases to the definition of species in natural history, justify the comparison which he has instituted:—

"If the humours are retained in the body beyond due time, either (1.) because nature cannot digest and afterwards expel them, or (2.) from their having contracted a morbific taint from a particular constitution of the air, or (3.) lastly, from their being infected with some poison; by these, I say, and the like causes, these humours are worked up into a substantial form, or species, that discovers itself by particular symptoms, agreeable to its peculiar essence; and these symptoms, notwithstanding they may, for want of attention, seem to arise either from the nature of the part in which the humour is lodged, or from the humour itself before it assumed this species, are in reality disorders that proceed from the essence of the species newly raised to this pitch [zym*ine*]; so that every specific disease arises from some specific exhalation, or peculiar quality of some humour [zym*in*] contained in a living body. Under this kind may be comprehended most diseases which have a certain form or appearance; nature, in fact, observing the same uniform method in producing and bringing diseases to a height or crisis, as she does in the production or growth of plants or animals; for as every plant or animal is possessed of peculiar properties, so is it likewise in every exaltation of any humour, after its being come to a species or disease. We have a clear proof of this every day, in those kinds of excrescences that grow on trees and shrubs (occasioned by the ill quality of the nutritious juice, or other

* See Liebig's luminous exposition of the doctrines of fermentation in his Chemistry of Agriculture, Physiology, and Pathology. Two vols.

† From ζυμοω, I ferment; zymosis—fermentation, and zyma—ferment, may also be employed in English, *not in the sense* which they have in Greek, but as general designations of the morbid processes and their exciters. *Zymosis*, and the verb from which it is derived, occur in Hippocrates. See a good note and quotation from Galen, by Fœsius, in the *Œconomia Hippocratis*, appended to the Geneva edition (1662) of the works of Hippocrates. *Coction* appears to have been used by the father of medicine with the same qualification as ebullition and fermentation by Sydenham. See his Treatise on Ancient Medicine, vol. i. Œuvres Complètes d'Hippocrate, par E. Littré, 1839.

* Louis.—Fievre typhoide. Vol. ii. p. 311.

causes), in the form of moss, misletoe, mushrooms, and the like; all which are manifestly different essences or species from the tree or shrub that bears them."—*Sydenham's Works, trans. by G. Wallis.*

Sydenham's methods of treatment were adopted by him, and recommended, as the results of experimental investigation. However, their use might have been suggested, their efficacy was determined by their apparent influence on the recovery of patients; but, in his exposition of therapeutic principles, he keeps constantly in view his theory of "commotion" (*commotio*); "a general term which he chooses in order to prevent all fruitless dispute about words that might arise from the use of fermentation, or ebullition (*fermentatio vel ebullitio*), which, though they may seem harsh and metaphorical to some, are capable of a commodious interpretation."* Thus, in speaking of "continued fever," he says, "with regard to this disease, I judge that the genuine indications are to keep the commotion of the blood [zymosis] within such bounds as suit the design of nature, so as to prevent its rising too high on one side, whence dangerous symptoms might follow; or sinking too low on the other, whereby either the exclusion of the morbific matter might be hindered, or the endeavour of the blood affecting a new state be frustrated."†

The early medical observers have directed attention to the analogies zymotic diseases have with combustion, fermentation, putrefaction, and poisoning. These analogies have been, to a certain extent, confirmed by the researches of modern chemistry; and Liebig has been led by the study of organic transformations,—fermentation, putrefaction, decay,—to develope a theory invented by the greatest practical physicians to explain the phenomena of zymotic diseases.

Liebig observes, "that physicians had referred formerly to fermentation merely by way of illustration:" from which it is evident that he had not had time to consult the English medical classics on this head, or he would have discovered not, indeed, an anticipation of his own admirable generalizations, but a theory very similar to his own,—the basis of their pathology,—founded upon enlarged views, and well calculated to prepare the way for his researches and the researches of other chemists.

Morton, in his Pyretologia, calls the principle which it has been proposed in a previous page to designate generically *zymine*, "*fermentum contagiosum*;" and the following definition is printed in italics in the introduction, and applied in the subsequent chapters of his work to the explanation of all the "*morbi universales acuti*"—

. . . . . "fomitem febriferum (the 'fermentum venatum' of a previous sentence) asseramus esse—Deleterium quid in spirituum systemate delitescens, quod fermenti ad instar eos adoriensatque oestro primum exagitans, deinde humoribus secundo quasi momento, varias mutationes atque qualitates morbosas nobis sensibiles impertit."—This, he adds, is his general hypothesis—"nostram generalem hypothesin."

Here we have the "deleterium quid" communicating its action like a ferment to the latent assumed constituents (spirituum systema‡), and by a secondary impulse, as it were, producing perceptible transformations (*mutationes*) in the blood, tissues, and secretions. The sentence also reveals a principle in physics, which Liebig has quoted in the words of Laplace and Berthollett, and to which he appears to think all chemical transformations may be referred:—"A molecule, set in motion by any power, can impart its own motion to another molecule with which it may be in contact."

The three great contemporaries, Sydenham, Morton, and Willis, lived in London when plague and epidemic diseases prevailed, and much as they differed, or were mistaken, on some points, all announced more or less clearly the zymotic hypothesis. They were not, it must be borne in mind, mere chemiatric theorists; they had studied diseased action as assiduously and with as much sagacity as modern chemists have studied fermentation; Willis was a great anatomist; Sydenham and Morton have left original pathological delineations, which have never been surpassed, and laid down plans of treatment which are still followed.

Liebig, Dumas, and the chemists of this country, will, we sanguinely hope, not rest satisfied with what has been done, but continue to prosecute their labours with ardour and success; and from the study of the series of transformations of nitrogenous compounds, proceed to investigate the transformations of the blood, tissues and secretions which accompany the production of varioline, typhine, and the other zymotic principles.

The differences of cancer, pneumonia, burn, and small-pox are well marked, but there are some points of resemblance between them; and in the groups, of which they may be considered types, many diseases occur, which have undecided claims to a place in the four classes, and may be referred, in the present state of our knowledge, indifferently to either group, so far as statistical purposes are concerned. The diseases of the epidemic character present the greatest difficulties in classification, and have given rise to most discussion. The importance of the question of contagion,—of the mode in which epidemic diseases are propagated,—and the laws by which they are governed—has induced me to reserve it for inquiry when the laws of those epidemic diseases, which the registers enable us to investigate, are under discussion. Upon the present occasion, it will be sufficient to state that no diseases have been placed in the class which have not been propagated by inoculation, been proved to be infectious, or described by good authorities as endemics or epidemics.

* On the continued fever of 1661-4, sect. 1-4. He adds, "But since the terms fermentation and ebullition have prevailed among the modern physicians, I have not scrupled to use them occasionally, meaning only to convey my thoughts more easily thereby."

† *Id.* sect. 5. See also on the regular small-pox, 1667-9, sect. 30-33.

‡ Morton adopted the hypothesis of animal spirits from Fernel, and though it enabled him to explain many phenomena happily, he did not fail to fall into absurdities, (for so we must now call them,) by employing it to explain everything; still such passages as the following admit of a scientific construction, and are another proof that the exploded theories of ingenious men always contain traces of important truths.

Spiritus animales esse *to enoryetikon* seu primum principium activum, et quasi fermentum universale totius corporis, a quo sanguis et humores varie agitantur, et immutantur, non dubito. T. 2, p. 7, 8.

Willis employed the chemical theory and the few chemical facts known in the seventeenth century with still greater rashness in his treatises *de fermentatione* and *de febribus*; yet he has many felicitous anticipations of modern deductions, and Liebig will admit that in the following passages the Oxford professor referred to fermentation for something more than an illustration. He is speaking of small-pox, measles, (and scarlatina.) Convenit enim homini, *omni, soli, et semel variolis aut morbillis* affici, (p. 165.) . . . . ista diathesis, seu naturalis prædispositio, quæ genus humanum ad hunc morbum inclinat, videtur esse labes quædam seu impuritas sanguinis, inter prima fœtus rudimenta in utero concepta. . . . . .

Licet autem *venenata hujus morbi semina utplurimum semel, et unica ægritudine solent dissipari*; quandoque tamen accidit, ut parte miasmatis adhunc relicta, bis, aut ter ægri in hunc affectum inciderint.

. . . . *Causa evidens*, quæ hæc *semina fermentativa* commovet, et sæpissime in actum deducit, triplex assignatur, scilicet, *contagium* aliunde susceptum, *dispositio aeris*, ac *immodica sanguinis et humorum perturbatio*. *Contagio* hunc morbum in alios serpere, lateque grassari, quotidiana experientia manifestum est: scilicet *a corpore infecto continuo decidunt effluvia, quæ ab aliis corporibus suscepta statim, instar veneni cum sanguine fermentescunt, et semina ejusdem affectus latentia, ipsisque longo exsuscitant*, et in hujus morbi ideam disponunt, nec solum contactu, sed ad distans miasma communicatur. . . . . peculiaris aeris dispositio; hinc sæpissime popularis evadit ac per totas regiones, urbes, vicosque passim desævit, p. 166.

He adds that the "immodica sanguinis, et humorum perturbatio" may arise from immoderate exercise or excesses.—*Opera Medica et Physica, Ludg.* 1676.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

THE two simple bodies which have come under our notice, do not unite in any proportions by direct mixtures, a circumstance which seems to indicate that their mutual affinity must necessarily be very slight; however by certain indirect methods to be mentioned to you in this lecture, they may be made to combine in no less than four proportions,—the composition, and the names of which will be indicated by the table here exhibited:—

	Cl		O
Protoxide of Chlorine Synon. Euchlorus (Davy) Hypochlorous Acid (Balard)	1	..	1
Peroxide of Chlorine Chlorous Acid	1	..	4
Chloric Acid	1	..	5
Perchloric Acid	1	..	7

The slightest glance at this table leads us to believe that there are other compounds of chlorine and oxygen as yet unknown. In order to render the gradation perfect, so far as it goes, two compounds of chlorine with oxygen must be discovered, and inserted between the protoxide and peroxide, and one between chloric and perchloric acid.

The protoxide of chlorine was discovered by Sir H. Davy, in 1811, and on account of its peculiar colour, which is a very deep yellow green, he termed it euchlorine. He prepared it by mixing together in a retort two parts of chlorate of potash, with one of water, and one of hydrochloric acid of commerce. To this mixture a gentle heat was applied, and the gas in question came over, necessarily contaminated, however, with a variable portion of chlorine, which circumstance was the cause of a great deal of dispute in regard to the exact composition of this gas. Davy found its specific gravity to vary, which circumstance, as you are aware, must necessarily have added weight to the supposition that the euchlorine of Davy was not an actual chemical compound. Moreover Davy imagined that five volumes of this gas expanded, on the application of heat, into six, which proportions reduced to their lowest terms are in the ratio of $1\frac{1}{4}$ to $1\frac{1}{2}$; since half a volume is regarded as the atomic or combining size of oxygen. Were these data correct, the atomic or combining size of this gas should be $1\frac{1}{4}$ volumes, which would be altogether dissimilar to the combining size of any other gas. Hence until lately, the euchlorine of Davy was thought by many chemists to be merely a mixture of peroxide of chlorine, and pure chlorine, in variable proportions. Soubeiran, I believe, was the first who suggested the probability of these conditions. He passed it over calomel, by which the excess of chlorine was absorbed, and peroxide of chlorine was liberated. Sir H. Davy, too, had observed that water resolved it into the same gases. It remained for M. Balard to clear up the difficulty; this gentleman, during his investigation of the nature of bleaching compounds, succeeded in making the protoxide of chlorine by an entirely different process, and in a state of complete purity. His plan consisted in agitating peroxide of mercury with water and chlorine gas; the latter abstracted from the oxide of mercury, a sufficient quantity of oxygen to form the protoxide of chlorine, which, combining with the water, formed a yellow solution, analogous to the solution of Davy's euchlorine in water. This liquid is now distilled in vacuo, by which means a dilute solution of the protoxide of chlorine is obtained, and from this the gas itself may be developed by the following process. I take an inverted vessel of mercury and throw up into it a little of the fluid; next I insert a few fragments of nitrate of lime,

which absorbs water, and together with it, forms a layer that swims on the surface of the mercury, and protects it from the action of the gas. Protoxide of chlorine, thus obtained, and called by Dumas, hypochlorous acid, is found to be composed of 1 volume or equivalent of chlorine, and half a volume or 1 equivalent of oxygen condensed into 1 volume; a fact demonstrated when the gas is decomposed by means of a heated substance, under which circumstances four volumes expand into six, two of which are oxygen and the remainder chlorine. For all common purposes of illustration, the impure protoxide, or euchlorine of Davy may be employed, inasmuch as there is not present chlorine enough to veil its leading properties. With respect to the decompositions in the processes for making it, they are as follow. When hydrochloric acid, water, and chlorate of potash are heated together, the results are protoxide of chlorine, free chlorine, water, and chloride of potassium; this you are aware was Davy's original process. As to Balard's process, the rationale is that peroxide of mercury yields up oxygen to one portion of chlorine, and another portion unites with the mercury to form a chloride of that metal. If the oxide be in excess (as it always should be,) the chloride and oxide of mercury unite, forming the oxychloride. The properties of this gas, besides those which have been casually mentioned, may be briefly summed up. Its colour is a very deep yellowish green, and it possesses bleaching qualities. Unlike chlorine, it does not support the combustion of copper leaf; water absorbs 100 volumes of it. On plunging a heated wire into this gas it explodes, although not very violently, and expands in the ratio already mentioned. Its specific gravity by theory is 3021-3, its atomic weigh, 44, and its formula Cl. O. This gas, which Balard terms hypochlorous acid, combines with bases forming hypochlorites. These are valuable bleaching agents, and will hereafter be referred to again.

The next compound which we have to investigate, the peroxide of chlorine, called also chlorous acid, and hypochloric acid, is a very dangerous agent, and must be prepared and manipulated with much caution. It was discovered in 1815, by Sir H. Davy, who obtained it by heating gently a mixture of sulphuric acid and chlorate of potash. The decomposition is exceedingly simple; sulphuric acid sets chloric acid free, which immediately breaks up into two new compounds, peroxide of chlorine, and perchloric acid; the latter becomes attached to potash, forming perchlorate of potash, mixed with bisulphate of potash, and peroxide of chlorine escapes. In books, this very dangerous compound is recommended to be prepared in a retort, the source of heat being a water bath carefully maintained below the temperature of 212 deg., and the gas is to be collected over mercury, or by displacement. I will show you the explosive properties of this gas presently, evolved on a much smaller scale. After witnessing these effects, those who like to make peroxide of chlorine in a retort *may* do so. I content myself with preparing it in a tube.

Into a little tube containing a few grains of chlorate of potash, I pour a few drops of sulphuric acid, and now I apply the necessary degree of heat by holding the tube in my hand; the gas is rapidly developed. I shall not transfer it into another tube, but will test it in the same. Its colour you will observe is a very bright yellow, and its smell is narcotic. It is rapidly absorbed by water, and the solution bleaches. So feeble are the mutual attractions of oxygen and chlorine in this compound, that even the slightest causes separate them, and a violent explosion is the consequence; under these circumstances, 100 volumes expand into 150, 100 of which are oxygen; proportions which correspond to 1 equivalent of chlorine, and four of oxygen: its specific gravity (calculated) is 2337.5. In order to demonstrate the explosive properties of this gas, I first immerse into the tube containing it a hot wire, decomposition immediately results, attended with a loud report. Into another tube containing it, I immerse a bit of phosphorus; a violent explosion again is the consequence, and the phosphorus burns brilliantly in the resulting mixture of oxygen and chlorine gas. This experiment is not unattended with danger, but I will show you a modification of it which is quite free from danger, and which is, at the same time, exceedingly pretty. I drop into a deep conical glass containing water, a few crystals of chlorate of potash and phosphorus; on the two latter I now pour a little sulphuric acid, by means of a funnel; peroxide of chlorine is evolved as before, and coming into contact with phosphorus under water, the explosions which result are quite free from danger.

This compound is very justly termed by chemists, chlorous or hypochloric acid. It unites with bases to form a class of salts termed chlorites, or hypochlorates, but not being of much importance we need not enlarge upon them. The next compound in our list is chloric acid, a compound of 5 eq. oxygen, and 1 chlorine. It is prepared by adding to chlorate of baryta, sulphuric acid, a substance which has the property, as every chemical tyro knows, of forming a most insoluble substance with baryta, (sulphate of baryta,) so that chloric acid is liberated and remains combined with the water, from which, like the nitric, it cannot be completely separated. This acid cannot be obtained solid; when a solution containing it is evaporated, it is resolved into chlorine, oxygen, and perchloric acid. It neither bleaches, nor precipitates a solution of nitrate of silver. In its strongest form it possesses the consistence of an oil, and from its facility of giving oxygen, it sets fire to many organic bodies, and is a powerful oxidising agent. This acid forms by uniting with bases, a class of salts termed chlorates, which may be recognised by the following properties. They deflagrate when thrown on charcoal, and paper imbued with them becomes converted into touch paper; any salt having this property must be either a nitrate, a bromate, iodate, or chlorate. By exposing a chlorate to a red heat, it is converted into a chlorite and chloride, the latter is usually the more soluble of the two, and its solution has the property of yielding with nitrate of silver a precipitate which is soluble in a *weak* solution of ammonia, and insoluble in nitric acid. Moreover, chlorates become red on the application of sulphuric acid, which is a perfectly distinctive test. I have mentioned that chloric acid is prepared from chlorate of baryta. I ought, perhaps, also to mention how this chlorate of baryta is obtained, premising that if potash be substituted for baryta and exposed to the action of chlorine, precisely analogous reactions take place. On passing a stream of chlorine gas through a solution of potash, a combination results, the composition of which is very imperfectly known. Its nature will be discussed at a subsequent period of our lectures. I must content myself at present by saying that when boiled, oxygen is given off in great quantity, and the dry material which remains, is a mixture of chlorate of potash and chlorate of potassium,—the former salt crystallizes first and may be separated. If baryta be substituted for potash, analogous results take place.

The next and last compound of oxygen and chlorine, is the perchloric acid, remarkable for the large quantity of oxygen which it contains, and for the very insoluble compound which it forms with potash; consequently it is a very excellent test for this alkali. With respect to the preparation of perchloric acid, I must remind you of the insoluble salt prepared during the evolution of peroxide of chlorine. This is the perchlorate of potash, which, by distilling it with a mixture of equal parts sulphuric acid and water, yields *dilute* perchloric acid, a condition in which it possesses the greater utility. However, it may be obtained in a solid form by using a great excess of sulphuric acid. Dilute perchloric acid is always kept in chemical laboratories as a test for potash, which it precipitates, as also do tartaric, with the hydro-fluo-silicic acids, and chloride of platinum. No substances, however, precipitate soda, hence the two alkalies may thus be distinguished. Although perchloric acid contains such a large quantity of oxygen, yet it is a remarkably stable compound, which is rather extraordinary. It is not decomposed by hydrochloric acid, although as we have observed chloric acid is; by this test, the two may be distinguished.

SPINA BIFIDA.

(To the Editor of the 'Medical Times.')

Sir,—As this disease appears to have attracted the attention of some of your correspondents, the following case may be interesting.

I was sent for some time since, at Maidenhead, to see a male child, which was described in the note as "unnatural." It was a patient of Mr. Bishop, surgeon, at Maidenhead, was ten days old, fed very heartily, and the features were those of a child considerably older. It was an ordinary case of *spina bifida*, but the tumour was situated somewhat higher up than usual. It was agreed by Mr. Bishop and myself, that nothing could be done with any reasonable hopes of success, and the task of communicating this intelligence to the mother fell to my lot. She received the opinion with wonderful equanimity, and requested me to return to Maidenhead again. At the termination of about three weeks I again visited the patient. It was still alive, but sinking fast. Mr. Bishop was again in attendance. The child, as predicted, died the following night, and the tumour was examined by Mr. Bellis, surgeon, the partner of Mr. Bishop. The *post-mortem* examination presented the usual appearances. The only circumstance attending the case which seems worthy of notice, is that the patient lived for a month, otherwise in good health, and even at that early age, knew its nurse and mother.

I agree with your correspondent "Medicus" that "it is much to be regretted that the repositories of medical facts are so little consulted by the young practitioners of the present day, who frequently bring forward as new, observations and operations that have been made or performed over and over again, before." The fact is, that as soon as a young man passes "the Hall" he thinks he has unlocked the stores of medical knowledge, whereas he has barely possessed himself of the *key*.

I am, Sir, your obedient servant,

EDWARD BINNS, M.D.

21, Montague-street, Portman-square.

[It is rather singular that the modest enquiry which led to the smart objurgations last week of "Medicus," and the notice now, of Dr. Binns, came from a gentleman (an M.D. also) who, we have reason for believing, is the senior of both, and whose communications to us show him to be anything but an inconsiderable reader.—Ed.]

Sulphate of Quinine in Rheumatism.—M. Devergie prescribes five grains of sulphate of quinine, either in the form of pill or mixture, to be taken four times a day. This quantity to be increased according to the intensity of the disease and the tolerance of the individual. He has never exceeded a drachm or a drachm and a half in the 24 hours. He advises reserve in the administration of this medicine, and especially, not to commence with such elevated doses, as some have recommended. M. Devergie cites two cases which terminated fatally, in one of the Parisian hospitals, in consequence of the cerebral affections determined by too large doses of this medicine. He gives the particulars of three cases of acute articular rheumatism successfully treated by this plan; but it is important to remark, that none of these cases presented anything beyond simple rheumatic pains, and were unaccompanied by redness, swelling, or acceleration of the pulse. In six cases of chronic rheumatism, the pains ceased in less than three weeks, under the employment of this medicine. Great caution is requisite in applying this treatment to plethoric subjects or those pre-disposed to cerebral congestion.

TO CORRESPONDENTS.

A Constant Reader.—*Our first edition is ready every Thursday evening at five o'clock, and our Correspondent when told that other medical journals are not published until Friday or Saturday, will see that it is not we that sin, but we that are sinned against. As last week we saw the Hunterian given in another journal, we should not be surprised to see our case of Mr. Carlile similarly given in this.*

An Old Practitioner.—*We shall consider the paper.*

X. Y.—*The Communication should be authenticated.*

P. T. *should consult a respectable practitioner.*

P. N.—Mr. Hay—Pater—Mock Coroner—A Constant Reader, Edinburgh—*declined.*

The cases by Mr. Brunel, and Mr. Philip Kean are under consideration.

Mr. James Pearsons, Ancoats-Street, Manchester.—*If this gentleman, who has been on our books a very considerable time without paying a single fraction of his arrears, or even noticing them, do not forthwith settle his account, the publisher will decline sending him any further numbers. A medical journal, however good, is not so much an article of necessity as to justify in any case dishonesty as a means of procuring it.*

THE MEDICAL TIMES.

SATURDAY, FEBRUARY 25, 1843.

Quis, Catilina, tuis natalibus atque Cethegi
Inveniet quicquam *infimius?* Arma tamen vos
Nocturna et flammas domibus templisque parastis
Ut Braccatorum pueri, Senonumque minores
Ausi quod liceat tunica punire molesta.

JUVENAL.

It has been well said, by an erudite friend, that the future Plutarch of our age when recording the biography of its *great men*, will find it of service to divide the life of one of its *purest* (the *tertius a cœlo cecidit Cato* of Lord John Russell)—we mean, of course, Mr. Wakley—into the two periods preceding and following the conflagration of his drug-shop. The great fire of London—he insists—was not a more remarkable, nor that of Moscow a more accidental, circumstance, in the annals of those two cities, than the little fire of "the beggarly account of empty boxes," in Argyle-street, to the honourable member for Finsbury. As London rose, phœnix-like, from the one, so did Mr. Wakley from the other: and what the metropolis has consequently grown among cities, that has the ex-apothecary become among his brethren. Considering this, however, if not a bad, an imperfect distribution of epochs, we would take a somewhat different direction. We should choose to divide the honourable member's important life into the two grand periods—before and after his accession to the dignity of metropolitan coroner. In the first, we should picture him as centralizing every less profitably engaged energy in the work of proving, by words, the uselessness of *non-medical* coroners. In the second, we should paint him similarly absorbed in demonstrating, by facts, the mischievousness of *medical* coroners. If any further division would be required, it would have reference to the crowning period, apparently not far distant, when his efforts in both directions, verbal and active, shall have accomplished the utter cessation of inquests, under either medical or non-medical coroners.

It is said that your truly great men prove the genuineness of their mission by the accomplishment of some one great object. Is this distinction—which is supposed to have characterized Socrates, Aristotle, Alexander, Mahomet, Luther, Bacon, Newton—to be unpossessed by Mr. Wakley? Belonging evidently to their honoured order, it is not to be doubted that a great mission is entrusted to his destiny. If it be not coronatorial destruction, what—(will any kind reader tell us)—what is it? In every other field of action, how completely has he belied expectation! In every other public sphere of action, how emphatic a nullity! As a medical reformer, how entirely has he eluded notice: as a statesman (a statesman!) how entirely has notice eluded him! In every thing, but his one mission of destruction, how true to his great destiny—how in plenitude a nobody!

Many persons, we are convinced, have thus formed humble opinions of Wakley's mental powers—others, of his moral virtues—from not paying attention to this grand guiding, but secret principle of his life. In the darkest passages of morality, in the foulest lanes of literature, Wakley was only taking, if not the straightest, at least the surest way to the goal of coronatorial destruction. Who that hears this disclosure of a purpose so secret when unnoticed, so obvious when once thought of, does not summon up at once as proof, the earnest, if clumsy, re-productions (*en petit*) of Cobbett's powerful style, directed, in the *Lancet*, against non-medical coroners, till the single-minded writer was himself made *medical* coroner? Could any one, reading them, doubt that non-medical coroners were a nuisance as costly as foul? And since Wakley, as a boon to the public, accepted the coronorship, what one thing has he, or could any man have done, so constantly and energetically, as the demonstration of the mischievousness of *medical* coroners? Do our readers believe that, to a man of Wakley's superior senses—nay, to any man not a lunatic—his perpetual wranglings with the reporters (the Mercuries, as it were, of the great Joves of the press) could have had any object less than this? — or his bitter collisions with the chiefs of the police-courts?—or his deadly enmities with the Middlesex magistrates?—or his contemptuous disregard and neglect of his *former* medical brethren? The very notion is absurd: and the ready key to all these apparently anomalous and maniacal proceedings is found in the simple fact discovered by us (and we will not be robbed of the honour of the discovery) that they all form a portion of the grand scheme of this great man's life—THE DESTRUCTION OF CORONERS' INQUESTS.

But though all this was much—so much as to be only excused by the great good of the end such equivocal means were to achieve—Mr. Wakley had the mortification to find the sacrifice useless. Did he, *therefore*, give up the great aim? To answer in the affirmative, would be to indicate a poor acquaintance with his character. On the contrary, as the necessity increased, so did the efforts: much was followed by more; and Mr. Wakley has so far done violence, on the one side, to his hatred of public money, as to hold as many inquests as the utmost ingenuity could manage weekly to manufacture for him; and, on the other side, to his love of public justice, as to make these inquests perfectly inoperative for the detection or prevention of guilt? Could a great man, in a noble cause, do more? We know the incredulity of our age towards transcendant merit, and will not have our eulogiums rest on unsustained assurance. We have been furnished with one instance, which, if taken as a specimen case, will do more in illustration of Mr. Wakley's *modus operandi*, than a folio of the vague panegyrics his friends (if he have any) might be disposed to heap upon him. Here it is:—

For the last few days the little suburban village of Hornsey has been roused from its ordinary quietness in consequence of the sudden death of a young man named Pledger, carrying on the business of a chemist in that neighbourhood. Reports were soon spread that he had died from the effects of poison, which coming to the ears of the parish beadle, that functionary thought it was his duty to circulate the report by waiting upon Mr. Wakley, the coroner, who ordered an inquest to be held. The jury was empanelled on Wednesday last, and on viewing the body with them, the coroner is reported to have used the following words, at the same time lifting up the deceased's head;—"Ah, gentlemen, this is a sudden death; the man has died from a diseased heart. I've no doubt, *and there will be no occasion for a medical man.*" The jury returned to the inquest-room, and, after hearing evidence as to the suddenness of the deceased's death, returned a verdict of "Natural death." The friends of the deceased not being so fond of doing without medical testimony as the coroner, determined on having the body opened, and the actual cause of death explained. Accordingly, Mr. Baker, of the New North-road, and Mr. Hands, surgeon, undertook the *post-mortem* examination, and on opening the abdomen there was a strong smell, like prussic acid. On opening and analysing the contents of the stomach, nearly an ounce of the essential oil of almonds was found, enough to kill upwards of a dozen persons, and from the effects of which Mr. Pledger had died. On the result being made known to the friends, it was understood that the whole facts would be laid before the Middlesex magistrates, and that proceedings would be taken to quash the inquisition. The above shows the necessity of *post-mortem* examinations in all cases of sudden death, without taking the *dictum* of either a medical or a non-medical coroner as to the cause.

If the non-medical journal (the *Times*) expressing this last opinion, wish to imply a censure on Mr. Wakley, because he, a medical coroner, and the former proprietor of a medical journal, to save the fee to a medical man for a *post mortem* examination, —allows crime all the certitude of concealment which the abuse of coroners' law can give it—we venture, with much respect, to express a difference of sentiment. It is plain the accuser has not reached the altitude of the coroner's influencing motive; he does not hold the golden key to those grand views which we have discovered: it was not known to him that this was part of a system—an essential step to the *dénouement* in the drama of a great man's life

—one link in the vast chain of coronatorial extinction!

A small man, aghast at small matters, might be weak enough to stagger in his course by the consequences of such unenquiring inquests, and unveracious *verdicta*. If such off-handed assumption—he would say—of the offices of both witness, jury, and judge, be tolerated, what a rendezvous will Middlesex become for every person inclined to make away with a rich, useless, and everlasting old uncle, aunt, or parent? The murderer has only to introduce his victim within Mr. Wakley's jurisdiction, dose him with a powerful poison, and he will have the honourable gentlemen driving up to his house—"lifting up the deceased's head," exclaiming, "Ah, gentlemen, this is a sudden death: the man has died from a diseased heart, I've no doubt; and there will be no occasion for a medical man,"—and the murderer will carry the immunity of a medical coroner's certificate of his innocence, with the attestation that his relative died a "Natural death" To persons who can thus reason, argument must be thrown away. They can neither see the advantage of centralizing the body of poisoners in the medical coroner's district—(and we wonder in which other's they are offered equal attractions?)—nor feel how incomparably trifling are such petty considerations, when poised against the fulfilment of the great object of a great man's life—the destruction of the institution of coroners!

But seriously—how long are we to have inquests a heavy burden to rate-payers—a severe time-taxer to juries—merely to form a legalized *coverer* of poisonings? Is the administration of justice to be mocked for ever by expensive enquiries, or rather inquests, about *accidents* beyond the possibility of suspicion as to a culpable cause—and to have the sudden deaths which may have arisen either from poison or disease, or both—*the distinction of which, no man can reach, except by post-mortem examination*—and are we to have these placed beyond the pale of legal investigation, by a verdict of natural death, dictated by an ignorant and impatient coroner, and accepted by a silly jury, before whom not the least atom of reasonable, nay, ATTAINABLE, data, is allowed to be produced?

Since the above went to press, Mr. Wakley has rallied the scattered jury, and after due discipline, has succeeded in arraying them against the *Times*' statement of his inquest in formal columns of leaden type.

We were not unprepared for this manœuvre. The day before the version of the daily paper appeared, a gentleman narrated to us all the circumstances, and we delayed their publication from our last number, simply, because we were resolved so to give them, as to leave the worthy coroner no corner in which his cunning might succeed in sheltering him. But though prepared for the trick, we must own we are still surprised at its clumsiness. If we understand the charge, its gravamen is, that Mr. Wakley, in a case of *sudden* and *suspicious death*, caused no post mortem examination, and though the party was poisoned, *Mr. Wakley gave his certificate that he died a natural death*. The jury do not rebut one iota of this accusation. On the contrary, while tacitly admitting all this, they declare what was previously *unstated*, that one of the jurors asked the pertinent question (what a strong presumption against the coroner) "whether the medical man, who saw the deceased after death, should not be called in?" The coroner's answer satisfied the juror that there was no cause for his testimony! That the deceased *was poisoned* is beyond doubt; WE have, for the fact, the personal assurance of a medical gentlemen present at the autopsy: that Mr. Wakley declared, WITHOUT EXAMINATION, that he was NOT poisoned is equally indisputable; it is proved, irrefragably, by the recorded false verdict "NATURAL DEATH."

CURABILITY OF CONSUMPTION.

(Continued from page 328.)

(To the Editor of the 'Medical Times.')

SIR,—When we consider the exquisitely fine gossamer-like tissue of the air-cells, their prodigious number, and immense extent of surface, we need not wonder at the facility and certainty with which they can be expanded, and the important changes consequent on effecting this object. Their free and ample exposure to the atmospheric air is necessary to prepare the blood by arterialisation, for the nutriment of the system, and in proportion as their area is invaded, will the sanguification be imperfect, and the due evolution of the animal heat interfered with, on which the healthy action of all the vital organs so absolutely depends.

The following cases corroborate those already adduced, in proving the power which pulmonary expansion exercises over consumption.

M. Lebeau, physician to the King of the Belgians, and principal physician to the military hospital at Brussels, in the preface to his translation of Dr. Ramadge's Work on consumption, mentions, that having long devoted his attention to this disease, he has been himself struck with the conviction that asthma has the power of arresting, as well as preventing it, and that he could cite a considerable number of facts to illustrate this statement, but confines himself to one of recent date, and complete in its details. M ——, aged 48, a captain of an infantry regiment, presented himself April 26, 1836, at the military hospital at Brussels, with a view to obtain a certificate to exempt him from active service, in consequence of habitual dyspnoea. He complained of no other ailment, and was of full habit; his chest of remarkable amplitude, respiration wheezing, the sibilant râle was heard throughout, the heart's action regular and moderate, the pulse calm and natural, and the face exhibiting no signs of venous congestion. He gave the following account of his case, in the presence of Dr. Coombe, of Edinburgh, who happened to be there at the time, Drs. Limauge and Biefve, of Brussels, and several pupils:—"In 1816, after severe fatigue, I was attacked with cough and copious expectoration, wasted away rapidly, and was subject to shiverings in the daytime, and perspirations at night, with wandering pains below the collar bones. My medical attendants repeatedly assured me I was consumptive, and could not long survive. While matters were in this state, I was seized with a difficulty of breathing, to such a degree, that I was obliged to get out of bed at night and repair to the window to breathe fresh air. From this period my strength began to return, the perspirations ceased, and I soon became of as full habit as you now see me. My chest, which was flat and contracted, enlarged in an extraordinary manner, and I was completely cured, save the difficulty of breathing, for which I could obtain no remedy."

M. Lebeau adds that Dr. Canstatt, a young physician of great merit, had related to him a similar and strikingly illustrative case which had occurred in his own family. Among other remarks worthy of attention in his preface, he makes the following very interesting and curious one:—"Taking into consideration all the circumstances preceding and accompanying this disease, and the appearances after death, I have had the most satisfactory evidence that the compression on the upper part of the chest of young soldiers, caused by the weight of the arms and accoutrements, has contributed very much to the occurrence of phthisis."

The subjoined cases are submitted as examples of the benefits derivable from pulmonary expansion by measured mechanical respiration:—

Miss ——, aged 23, the daughter of a member of parliament, was attacked by consumption, displaying itself in the usual manner by cough, expectoration, night sweats, and gradual emaciation. A few months after its commencement, one of her tonsils acquired considerable size, and coincidently her symptoms showed signs of amendment. This tonsil, after a short interval, suppurated, and the signs of amendment soon disappeared. Her relatives now began to entertain serious apprehensions, more especially as she had lost a brother and two sisters by consumption within a few months. Dr. Ramadge was called in, and felt satisfied, upon examination and enquiry, that disease had commenced in the right lung, and been interrupted by the enlargement of the tonsil. He also ascertained that it now existed in the summit of the left lung. The chest was flat and contracted, both the collar bones very prominent, and the infra-clavicular depression on the left side remarkable. The constitutional disturbance and preternatural heat of the chest were reduced by the application of a few leeches occasionally, between the second and third ribs of the affected side, and the administration of nitre and tartarised antimony, &c. Tonics and sedatives also were prescribed, to support the system and allay irritation. The patient however, was taught to place her chief reliance on the artificial respiration, and not expect results sooner than a month, that is, in a very sensible degree. By perseverance in the use of the inhaling apparatus, her strength gradually returned, the appetite improved, the nocturnal perspirations ceased, the quality of the matter expectorated was amended, a satisfactory respiratory murmur became audible, the frequency of the pulse abated, the countenance resumed its former animation, the chest expanded, and she increased in flesh, and the entire constitution was renovated. Before these desirable results were gained, she had twice or thrice, within six months, fresh liquefactions of pre-existing tubercles attended, of course, with more or less renewal of the constitutional symptoms, during which the expectoration showed the softened opaque tuberculous matter minutely subdivided and suspended in the muco-purulent sputa. With the exception of these changes the cure went steadily on, till recovery took place. The great augmentation of flesh and enlargement of the chest that followed, were particularly noticed by the respectable circles in which she moved, to whom she is in the habit of explaining the improvement that has taken place, by throwing her shoulders upwards and forwards, thus bringing the clavicles greatly in advance of the upper ribs, in imitation of the appearance of the chest in its previous state, that they may judge by contrast. This patient had used the tube for the space of about twelve months, three times a day as directed, and her symptoms had disappeared some months before she left it off.

Hohnbaum, the distinguished German pathologist, who has translated Dr. Ramadge's Work into his native language, strongly recommends this extension of the term of its use for the sake of security. About two years afterwards, at the close of the gay season in London, Dr. Ramadge was again called in to see her. She complained of cough and pain in the lower scapular region, which he attributed to fresh softenings of old tuberculous nodules. Appropriate medicinal treatment, with the use of the tube, soon removed these symptoms of relapse,

and she has not since required any medical advice. The mechanical respiration in this case, has prevented the deposit of fresh tubercles, and altered that peculiar habit which generates it.

Her eldest sister, with whom she had been in the habit of sleeping, a few months previous to her attack exhibited unequivocal signs of consumption; and though having the advantage of the most distinguished advice, experienced no relief till she removed to Hastings. The bracing sea air, and horse-exercise which she here enjoyed, brought about an amelioration, so far as to check the most distressing symptoms, and do away with the cough, but she still remained in a very delicate state. The satisfactory result of her sister's treatment induced her mother to draw Dr. Ramadge's attention to her case also. He found her chest very much contracted, the middle of the collar bones standing out nearly three fourths of an inch in advance of the upper ribs, which were, of course, greatly depressed, particularly those on the right side. Auscultation discovered in the summit of the right lung clear indications that consumption existed in a latent form, attended with an insensible excavation. For the improvement of her general health, tonics, chiefly quinine, with preparations of iron, were occasionally prescribed, and for the local affection, the artificial respiration was steadily employed. The result was, that under this treatment, she rapidly improved, the chest expanded, her complexion from very pale, became somewhat florid, and the functions of the system, which had been deranged by the constitutional debility, were restored to their normal action. She was subsequently married to an individual of noble rank, by whom she has had two children, and her general health has not since been interrupted by any phthisical manifestations.

In examining the chests of the remaining members of the family, Dr. Ramadge's attention was directed to that of a younger sister, which was preternaturally full and large, forming a remarkable contrast to the two preceding. Her general appearance was that of robust health, the complexion florid, and her size and growth beyond her years. From the conformation of the chest, he at once suspected that there was some physical impediment to the respiration, which on inspecting the throat, proved to be the case; the tonsils being so large as almost to meet. This enlargement at times interfered with the voice. There was nothing remarkable in the respiration, except that it was puerile. He explained to her family and her father, who was present, the connection between the tonsils and the highly developed chest, and added, that although he could not by the ear, detect the signs of tuberculous disease yet he had no doubt, the peculiar habit which had given rise to this unusual tonsillary enlargement, had also led to the deposition of tubercles, and that they existed in a scattered form in the lungs. With a view to lessen the susceptibility of mucous irritation in the throat, he suggested the propriety of diminishing the tonsils, by a leech applied occasionally below each ear, to be succeeded at times, by moveable blisters. Sarsaparilla to improve the general habit, and iodide of potassium to promote absorption, were also recommended. This treatment was adopted, and the tonsils were reduced in size. The young lady was sent to a school at Brighton, where the tonsils became still more diminished, from the sea air; and her chest, after some time, began to flatten, and other signs of phthisical disease, betrayed themselves. She had been forewarned to use the tube, to make up by art, for the loss of protection derived from the lessening of the tonsils, but neglected it. She returned to London for advice. Dr. Ramadge, who was called in, pointed out that the reduction of the tonsils, coupled with the operation of some exciting cause, had brought on the softening of the tubercles previously suspected, and that the flattening of the chest with the other symptoms, would have been prevented, had his directions relative to the tube been observed. Finding her constitutional symptoms urgent, he advised the abstraction of blood from the upper part of the chest by leeches, attention to medicinal remedies alleviating and preparatory, and the regular employment of the artificial respiration. These were followed up some months at Brighton, to which place she after a short time returned, and finally got quite well, in the identical locality where the disease had first declared itself in a manifest form.

The eldest son of this family had recently returned from a continental tour, undertaken to improve his general health, which was delicate. On examination, no evidence of disease was detected by the ear, but his chest was very much contracted, and his general appearance by no means healthy. He had spent some time among the mountains of Switzerland, where the climbing of ascents was well calculated to excite his lungs to deep inspirations. But the flatness of the thorax, the tuberculous diathesis prevalent in the family, the absence of tonsillary enlargement, disease of the heart, or any other protective, led to the conclusion that his lungs were extremely liable to tuberculous invasion, if not already tuberculated. He had just obtained a commission in a light regiment and was about to join it, a course which could not fail to be approved of, as the exercise, which includes a great deal of running, would prove highly favourable to the proper expansion of his lungs. The service agreed with him remarkably well, he liked it much, and was exceedingly active; his chest expanded, and his general health was considerably improved. After some months he married, and about a year subsequently, the regiment to which he belonged was ordered to hold itself in readiness for foreign service, on the breaking out of the war in Syria. Being the presumptive heir to a peerage, and by the particular desire of the nobleman whose daughter he had married, he retired from the army, very much against his own wish. This change from an active to a comparatively inactive life, was followed by an impaired state of his general health, and a cough. Four months from its commencement, he came up to town and had the advice of one of her Majesty's physicians in ordinary, who considered his case decidedly phthisical, and exceedingly serious, and directed him to proceed immediately to Tonbridge, giving him the name of a medical man, under whom he was to place himself. This was in the middle of summer, and in the early part of autumn he was to leave for Nice. He had applied to this physician for advice in the first instance, by the particular request of two noble relatives, but before acting on it, consulted Dr. Ramadge, whose treatment of the other members of the family had proved so successful, and who found, on examination, that the right lung was diseased, and that the difference between the semidiameter of this side of the chest and the other amounted to nearly an inch and a half. The usual symptoms, cough, nocturnal perspirations, &c., were present. Considering that it would be highly improper to send him away in such critical circumstances, from the very place where it might be expected he could procure the best attention, that it would be, in fact, a virtual abandonment of the case, he dissuaded him from his proposed journey, and apartments were in consequence taken for him near the residence of his parents, a short distance from Hyde-Park. Due attention having been now premised for the relief of the constitutional symptoms, he was placed under a course of mechanical respiration, and shortly began to show evident signs of amendment, which ended in recovery, and thus superseded all necessity for leaving town or going abroad. Two winters have elapsed, and he still enjoys immunity from any return of the symptoms.

The above cases are not the less interesting from the circumstance of having occurred in one family, shortly after three of its members had been cut off by consumption; and it is not going beyond my own conviction to say, that but for the use of the mechanical respiration, these, in all probability would have shared the same fate. In none of the cases did the mechanical treatment operate injuriously, and the cures have so far proved themselves permanent, that after the lapse of a considerable time, they all enjoy excellent ordinary health. As a proof of the satisfaction this highly respectable family derived from the success of the treatment, Dr. Ramadge has been indebted to their expressions of approval for the confidence reposed in him by some of their friends, who have since applied to him for advice under similar affections. It is not a little remarkable that all its members attacked with consumption who had not adopted this peculiar treatment died, and the remainder—seven in number—who availed themselves of it are now living, and in excellent health. The conjoint features in their history afford at once, negative and positive evidence of the soundness of the principles assumed in the preceding arguments. Some of these details are worthy of remark. In the first case, the pulmonary affection showed itself originally in the right lung, and here we see it retarded, and driven back as it were, by the accidental enlargement of the left tonsil: on the return of this gland to its former size, we find the consumptive indications reappearing, the site of the disease having changed from the right to the left lung.

I may here incidentally remark, that the greatest amount of disease is almost invariably recognisable before and after death in the left lung. I have heard this accounted for by my preceptor, as well as I can recollect, in the following manner. When tuberculous deposition first commences, it is generally in the summit of both lungs, but greater in the right than the left, and therefore solution is first discovered in the former. After this, it will often happen that some accidental circumstance interrupts its progress by expanding the pulmonary tissue in the neighbourhood of the disease, and this expansion will be greater where the tuberculous deposit is more extensive, *i. e.*, on the right side. The more this tissue is expanded, the less susceptibility does it retain of new tubercularization, and hence the disease, if not subdued, as it advances, spreads more on the left side,—makes its first reappearance there, and its most extensive ravages in that lung.

The effect of tonsillary enlargement is also seen in a very marked and unequivocal manner in the third case, where the chest was prematurely full, and well developed during its presence, but sunk into an opposite state of contraction upon its removal. The whole family indeed, evinced a predisposition to the malady. Tubercles had formed in all their lungs, but in the cases adduced, their liquefaction had been kept back, and controlled partially and temporarily by natural antagonistic causes, and ultimately in a permanent way by art, which stepped in with aid, more certain and decisive than nature. Some credit was, no doubt, due to the medicinal treatment, both preparatory and accompanying, and this is a part of the question that will be considered in its proper place, but the complete failure of mere medicinal treatment in similar cases, or its very modified and unsatisfactory results, argue strongly that the mechanical respirator had to bear the brunt of the action, and may with justice lay claim to the credit of success.

The fourth case exemplifies the absence of necessity for removal from town, either to the country or abroad, under manifest phthisis. The practice of sending patients away from their friends and their country in this disease, appears to me incapable of being defended. The chief argument in its favour would seem to be precedent. The fashion has so long prevailed, that the propriety of it has ceased to be questioned. This deference to precedent should be left to the gentlemen of the long robe; it is not at all applicable to medical practice.—No good could have resulted from the patient's removal in this case. He would have been separated from his friends and relatives at a time, and under circumstances, that most called for their attention and sympathy, also from the opportunities of procuring the best medical advice, which it may be presumed are much more numerous in this metropolis than abroad. He recovered without removal, and was thus spared the inconvenience and peril to which a long journey would have exposed him. Liquefactions are of constant occurrence; while they are going forward, patients require all the medical skill and care they can have, to watch and control the symptoms as they arise. Travelling by land or sea, places these in most instances, beyond their reach, and when located in the place of their destination they run the serious risk of falling into the hands of unskilful practitioners, who too frequently, by the administration of improper medicines,—as for instance,

mercury—cut short the work of decay. These considerations are serious drawbacks to the hypothetical benefits of warm climates. Some of our high medical authorities, however, still sanction this practice by recommending migration to many of their patients. When benefit appears to be derived, and the patient has returned alive, I have always been able to trace the cause to some natural protection, such as a contraction of the trachea, disease of the heart, &c., existing before they left home, or to pulmonary expansion, brought about by accidental catarrh caught in the prosecution of their journey, or when the disease has been incipient, to the deeper and more energetic inspirations, which change of air and increased exercise occasion.

The beneficial effects of this regulated respiration are not confined to the pulmonary organs. I cannot point out the collateral advantages better than by quoting Dr. Ramadge's own remarks on the subject. He says in the chapter on treatment. —"It may be advisable to explain in what manner the simple process of inhalation, while it expands the pulmonary apparatus, at the same time regulates the most important of the visceral functions. The mere expansion of the lungs in the first instance, tends indirectly to remove congestion of the liver and also of the stomach, spleen, pancreas, and intestinal canal, all depending on the more free circulation of the blood in the former. The biliary as well as the great salivary secretion, is hereby promoted to a healthy activity, such morbid irritability of the mucous membrane of the stomach as may be present, productive of indigestion, is removed; the chyliferous absorption belonging to the small intestines so indispensible to life is actively carried on, and the injurious retention of excrementitious matter in the larger intestines is obviated by increased mucous moisture and accelerated peristaltic motion. It were easy, did I deem it essential to point out at length the beneficial effects produced on other secretions, and to explain the mode by which inhalation acts on the kidneys; but sufficient has been stated to enable the medical man to draw his own deductions in these particulars."

It may fall to the lot of the truly practical and indefatigable pathologist, whose text I have here quoted, to find these novel and important views of which he is the author, occasionally misunderstood, misrepresented, or neglected, but he endures such treatment in common with many distinguished individuals, who have enlarged the boundaries of science, by invading the established prejudices and erroneous doctrines of the age. It may also be a source of consolation to him to reflect, as Sir David Brewster felicitously observes, that he who contends for truths which he has himself been permitted to discover, may well sustain the conflict in which presumption and error are destined to fall. The present age may not be a tribunal either sufficiently pure or enlightened to decide the issue, but he can appeal to posterity, and rest with confidence in its sure decree.

DISCIPULUS.

Spontaneous expulsion of Uterine Polypus. M. Marchal relates the following case:—A lady, 48 years of age, the mother of several children, had for three years laboured under uterine hæmorrhage, pains in the loins, a sensation of weight in the pelvis, &c. She was treated as for inflammatory congestion of the uterus. One day, when preparing herself for a bath, she felt, while stooping, something become detached and escape through the genital organs. This object, which was a polypus, presented some resemblance to the heart of a fowl, only it was somewhat more flattened. It consisted of a *body* and a *pedicle*; the latter being smooth on one side, but torn on the other, evidently from the violence of its expulsion. On making a vertical section of this body, no doubt could be entertained of its being formed entirely by the uterine tissue, being a true prolongation of that organ.

CASE OF THE LATE MR. R. CARLILE.

BY DR. THOMAS WILLIAMS OF ST. THOMAS'S HOSPITAL.

(For the 'Medical Times.')

Apart from the intrinsic interest which attaches in a medical sense to the facts determined by the opportunities afforded at his own desire of examining his body after death, the case of the late Mr. Carlile has excited sufficient public curiosity to render proper the step of presenting his friends and the public with a succinct and authentic statement of the particulars as determined by the inspection of his body, which it was my duty to conduct. Nor would the history of his life be complete without an open acknowledgment, on the part of those really desirous to extend, by every legitimate means, the practical usefulness of medical science, of the substantial benefit which a public example like his, is calculated to confer. His anxious, and repeatedly avowed wishes were, that every use should be made of his remains in elucidation and furtherance of science, and in contribution to the availableness and certainties of those resources which medical science can now command, to mitigate, where it fails completely to dispossess of its sting, the severity of human suffering. It would certainly be but a partial execution of these wishes, if the obligation and benefit which the bequest of Mr. Carlile is so eminently fitted to produce, alike to the public and the profession, were circumscribed and forgotten within the walls of the limited abode to which his body has been consigned. It is neither my desire nor my province to appear as the eulogist of his peculiar sentiments on the subjects of science and religion. My desire is to facilitate the execution of wishes which dictated a magnanimous, though eccentric, bequest.

I have endeavoured with as much accuracy as possible, to collect from the most authentic and trust-worthy sources, all the facts relating to his latter history. But as the post-mortem examination was made and recorded in detail on the register of the hospital, without any information of a certain character in reference to the nature of his illness, its results may be received as quite uninfluenced by the bias with which a previous knowledge of the case sometimes affects and regulates the interpretation which appearances after death may appear to warrant.

In general formation, the body was distinguished by all the marks of robustness and strength; the chest was broad and well developed. The features and contour of the face were quite symmetrical. In figure, the head, if viewed in profile, approximated, although not closely, to the form which is characteristic of the crania of the American variety of mankind. The anterior segment gradually receded, the plane of this uniform recession terminating in an elevated vertex or summit which occupied a position posterior to a line drawn transversely over the head, from one parietal prominence to the other. In this particular, with respect to the configuration of the head, different families of the human race, and equally as obvious, individuals of the same nation and same family present very numerous varieties. The vertex or summit of the cranial arch offers as many variations in size as in position. In the Hindoo, the highest point is placed directly over the parietal prominences. This circumstance of the plane of the forehead being uniform, while it gives the character of gradual inclination backwards, leaves capacious room for the development of the anterior segment of the brain.

In the North American Indian, the vertex —I use this to denote the apex of the cranial bone wherever placed—is quite over the occipital region; the frontal recession more rapid, the facial angle consequently more acute. In the Peruvian, it coincides with the middle point of the coronal suture. In the Patagonian, it is placed considerably anterior to this suture. In these two instances, the forehead acquires the character of great elevation and expanse. In the crania of the Greeks and the Egyptians, a vertical bias is observed in the lower part of the forehead, from which the line coinciding with the summit proceeds with semicircular uniformity, as far as the point of the occipital prominence This figure always produces the idea of high intellectual development. The prognathous formation of the Ethiopian skull leaves necessarily the vertex at a considerably posterior situation. The position of the vertex has always appeared to me to influence considerably the intellectuality of the *expression* which belongs to the head. Varieties equally marked in the form of the head are constantly observed in individuals without any demonstrable co-existence of variations in the endowments of the mind. While in mere *configuration*, therefore, the head of Mr. Carlile did not attain the standard of perfection which modern taste has assigned for the determination of the highest mental excellence, it may be proved by example, that the form of his head was compatible with the possession of great intellectual powers. While, however, the facial angle was somewhat below the average of European standard, the line carried from one temporal ridge to the opposite, exceeded in length, that which common observation recognises as the average. In volume, therefore, the forehead gained, transversely, the development which it failed to attain vertically. Imagining a line dividing vertically and transversely the cranium, the posterior presented a greater comparative volume than the anterior segment. The circular admeasurement of the head, as formed by a line carried horizontally over the superciliary ridges, and bounding the occiput at the level of the tuberosity, gave 23¼ inches. The vertical, as obtained by a line carried from the tragus of one ear to that of the opposite, afforded 13¼ inches. The former somewhat exceeded the mean admeasurement of the European head, while the latter was not more than equal to the standard. Some of these facts were furnished me by my friend, Mr. Dixon. The countenance acquired breadth and squareness from the prominence of the cheek. The general expression of the countenance conveyed strikingly the idea of resolution and firmness; but withal the expression was placid.

The brain, including the cerebellum, pons varolii, and a portion of the medulla, amounted in weight to 3lbs. 6℥ 2ʒ.—The cerebellum separated from the pons varolii weighed 5℥. 5ʒ. — In proportional value, these weights are in the ratio of 1 to 9½.

This proves a somewhat greater relative development of cerebrum than ordinary; the average, I believe, is as one to about eight in the weight of the cerebrum and cerebellum. The membranes of the brain were healthy: the grey matter, or hemispherical ganglion was healthy in structure and colour; but in the opinion of Mr. Solly, the grey matter did not exceed the average depth. No other morbid condition could be found in the brain than that of a minute apoplectic cavity in the substance of the *tuber annulare*. This was situated on the right of the median line, and superior and posterior to the transverse median plane of the pons. It contained a small quantity of reddish

pus-like substance, appearing like disintegrated cerebral matter. The capacity of this little cell did not exceed the dimensions of a small pea. The structure immediately adjacent indicated only slight marks of softening. The existence of an adventitious membrane or cyst to this cavity, could not be decidedly proved. It is the most probable supposition in regard to its formation, that it was produced by a small apoplectic clot, subsequently disappearing under the agency of absorption, more or less augmented, in proportion, by the softening and disintegration of the adjacent structure.

From the situation of the cavity with reference to the columns traversing the pons, it was obvious that the continuity of the posterior pyramid or sentient portion of the crus cerebri of the right side, was chiefly broken down. Since the cavity existed on the right of the median plane of the pons, and above the decussation of the columns, the paralysis must have affected the left side of the body, and probably, sensation, to a greater extent than motion. The aorta, with the roots of the large vessels attached, weighed 13½ oz. The normal weight of the organ in the adult is given by physiologists at about 9 oz. In general volume, also, the heart had augmented. The cavities of the two ventricles had somewhat enlarged, the left more obviously than the right. The ventricular parietes on the left side were slightly hypertrophied. The mitral and tricuspid valves were quite healthy: the aorta likewise, with the exception of a little deposit, and thickening around the attached borders of one of the curtains. A slight dilatation appeared in the ascending portion of the aortic arch; frequent atheromatous patches were observed underneath the lining membrane. Here, deposits were found also in the coats of the iliac vessels. The heart was covered with a considerable quantity of fat, a circumstance which should not be overlooked in estimating its augmented weight and volume, as evidences of a pathological state.

No satisfactory evidences of disease could be detected in the lungs: the right was universally adherent to the costal pleura: the adhesions were obviously of old formation. The base of the lungs was attached in the same way to the diaphragm. The parenchyma of the lungs, immediately subjacent to the pleura, presented no decided proofs of having been involved in the neighbouring inflammation. The lining membrane of the bronchial tubes on this side, was congested to a slight degree: a little dilatation of the smaller channels likewise, in some places, in others, thickenings of the lining membrane were observed. The smaller divisions of the bronchi contained the product of bronchitis: this, however, was small in quantity. No proofs could be discovered of the existence of pneumonic consolidation, although it was reported that he died of inflammation of the lungs. Notwithstanding the congested state, it was very different from that form of congestion which belongs to the first stage of pneumonia. Some impediment was offered to the escape of air from the air vessels, for the collapse of the lung was less complete than that which is observed to occur under the conditions of health. On the left side no pleural adhesions existed. In structure this lung was healthy; but the bronchial tubes presented nearly the same appearance as those on the right. All the organs of the abdomen were found in a perfectly healthy state. As formerly stated, the facts thus determined by the examination of the body, at a period of four days after death, were recorded without any previous knowledge of the case. It will be now seen what correspondence there is between the condition which the inspection of the body has enabled us to discover, and the signs by which those conditions were rendered manifest in the living state. I can hold myself responsible for the correctness of the following facts, in relation to the history of his health for the last eight or nine years. Care has been taken to gather them from the most authentic sources, his own immediate friends.

For a period of nearly ten years before his death, the late Mr. Carlile laboured under a peculiar form of asthma: it was marked particularly by attacks or paroxysms of more or less extreme difficulty of breathing. During these attacks, the more prominent sensations were those of great pressure and tightness across the chest. These paroxysms did not terminate in copious expectoration, as in the humid form of asthmatic affections. His difficulty of breathing suffered almost immediate and excessive aggravation, even by a stay of a few days duration, at his residence in Fleet-street, so that for some years he was compelled to return to the country for his nightly rest. Breathing thus, for a portion only of the four-and-twenty hours, the less salubrious atmosphere of his town residence, he succeeded in alleviating, to a great extent, the continued oppression and distress of breathing which his complaint would otherwise have inevitably produced. His habits were temperate and regular: he never referred any uneasiness to the region of the heart: he was not subject to palpitation or faintings. While breathing the country air, he felt almost entirely free from all restraint of breathing. During the paroxysms which came on in the city, his exertions for breath frequently became distressing, and his countenance was thrown into the livid anxious condition which so peculiarly belongs to the paroxysm of asthmatic oppression.

In the year 1841 he became the subject of a singular attack of paralysis. One evening, after rather severe exertion in walking, he found that the power and sensibility of the left side of the body were being gradually lost, or, as he expressed it to one of his family at the time, "all the life of the left side of his body appeared to be flowing in the most strange way, to the *right*." In a short time the paralysis was complete. It is important and interesting to recollect that during the whole progress and development of the paralytic seizure, his mind stood undisturbed, a conscious witness to the approach of that mysterious and singular change, by which the extremest commands of volition, the proud mandates of the mind, were long dispossessed of the power to excite respondent agency in the formerly obedient hand. He conversed freely and as intelligently as ever with his attendants. After the lapse of some time, he recovered to a great extent, the power of voluntary motion and sensation; the loss of sensibility was more complete in the face than the remaining parts of the affected side. The return of sensation on the left side of the face was slower and less complete than in other parts. He died in one of his usual asthmatic attacks, at his house in Fleet-street. This fatal attack came on suddenly, and too rapidly to render it safe or practicable to remove him to his country residence. It is believed that if his removal to the country had been earlier and promptly made, he would have survived, with his usual impunity, the effects of his last illness. In the history of the paralysis with which the late Mr. Carlile was affected, in their physiological references, there are several points of no uninteresting character. It is a rare occurrence to discover a spontaneous extravasation into the substance of the pons varolii; and it has been stated by the most practical authorities, that death is the inevitable consequence of such extravasation. According to the statistical records of Andral, out of 392 cases of cerebral hæmorrhage, nine only of effusion into the pons varolii were found. The original attack in the case of Mr. Carlile was accompanied by no convulsions, no extinction of mental consciousness, no stertor. The question may be raised: could the physiologist have predicted the situation in the brain at which the rupture and extravasation had occurred? Are the cases of apoplectic effusion into the pons always characterised and distinguishable by an absence of stertor and coma? The converse of this is generally held to be true; but as a general fact it is certain, that under all circumstances of extravasation within the limits of the cranial cavity, whatever the situation in which it occurs, the phenomena are dependent upon, and are referable to, the pressure which the general mass of the brain sustains. The pressure may oppress almost equally any part of the organ, and may be explained and understood on the principle of hydrostatic diffusion in the case of Mr. Carlile. It may, therefore, correctly be argued, that the undisturbed presence of consciousness was due only to the minuteness of the vessel ruptured, and therefore, of the quantity of blood effused. It is quite easy to understand, from the immediate proximity of the spinal centre, in cases of effusion in the neighbourhood of the base of the brain, that under the condition of any serious and bulky extravasation, the cord will suffer, and convulsions, dysphagia, and other spinal phenomena, will strongly mark the approach of death. It is, therefore, the limited extent rather than the seat of effusion which explains the peculiarities of Mr. Carlile's case, and which enable us to account for the comparative impunity with which he survived the attack. The slight softening of structure adjacent to the cyst in this case, is calculated, likewise, to suggest some few reflections of interest. In all cases of cerebral hæmorrhage, from the closed box-like limits of the cranium, it is obvious that the pressure of a clot must operate equally in every direction, and, that, consequently, it must compress every part of the enclosed mass, with as much severity, as the portions in the immediate neighbourhood of the extravasation, and yet the disintegratory process affects only the parts in direct contact with the clot. It is, thus, that the total volume of the mass is diminished, and the aggregate brain allowed to recover its normal density. In the case of Mr. Carlile, as already remarked, the cyst, and formerly the clot, was situated in the sentient segment of the pons, in the substance of the posterior pyramid, and at the distance of about an inch and a half from the locality to which the sentient root of the trigeminus has been anatomically followed. If induction from physiological facts be allowed, it is not improbable that the slowness with which the restoration of sensation occurred in the face, comparatively with the period of its return in other parts, was dependent upon the extent to which the point of origin of the fifth nerve was involved in the pressure. In a case of this description, if the clot had extended in its bulk and influence, beyond the median line of the pons, the singular pathological experiment would have been performed, by which a complete separation would have been accomplished between the sentient apparatus of the cerebrum, and that of the cerebellum. Even under the partial isolation of the cerebellum, which happened in the case of Mr. Carlile, a competent physiologist, if confident in the accuracy of his diagnosis,—might have elicited facts of no inferior value and interest to the physician.

This case proves the fact which has been denied by the highest authority, that an apoplectic clot into the pons varolii may happen to a great extent, not only without entailing the immediate consequence of death, but without the manifestation of a single formidable sign. In conclusion, it is by no means desirable to withhold the re-

mark, that in contemplating the instructive facts which this imperfect analysis of Mr. Carlile's case has developed, it must be a source of compensating gratification to those whose feelings and affections his stern and philosophical bequest was most likely to violate and appal, to find, apart from the advantages which may occur to medical science from an example, thus magnanimously shewn, of indifference to the over-wrought delicacy of popular taste, that his own individual case should have accomplished *something*, and should have added an interesting store to the treasury of useful knowledge.

HUNTERIAN ORATION.

Delivered at the Royal College of Surgeons, Feb. 14
By J. M. ARNOTT, Esq. &c.

In the same class of medical improvers as Bell, we may also rank one whose loss was recently felt, not only in the nation where it occurred, but by all Europe which he had instructed,—Larrey.

Larrey was born in 1766; became a pupil of his uncle, who practised surgery at Toulouse, and, after seven years' professional education, was appointed surgeon in the navy. He returned to Paris at the outbreak of the revolution, and, in 1793, was sent as regimental surgeon to the army of the Rhine. If we would have a specimen of the extraordinary energy and indignant resistance with which France then stayed the attack of the first coalition, we may look to Larrey, the most zealous individual of the important class to which he belonged. He invented the *ambulances volantes*, and was the first military surgeon who, having dressed the wounded, carried them off from under the very fire of the batteries. "It is to Larrey," says one of his panegyrists, "that we owe our place of honour on the field of battle." Such zeal could not fail to win applause; and Larrey obtained special mention in the report of Genl. de Beauharnais after a battle fought before Mayence in July 1793.

At the siege of Toulon, in 1794, he gained the friendship of that Lieutenant of Artillery who was destined to shake the world! He accompanied the French army to Egypt, and served in all the subsequent campaigns of Napoleon throughout Europe. It is needless to detail the honours successively conferred upon Larrey until his social position became equal to his merits; but I may mention that, after the battle of Wagram, he was made Baron of the Empire, and that in 1812 he was made Chirurgien en Chef of the Grande Armée. He liked to be called by the title of nobility which he had earned: nor was this a childish vanity; for he knew that neither the chance of birth, nor the favour of a court, had made him a Baron; but that the dignity had been bestowed by a discriminating hand which never conferred honours upon incompetency or inefficiency.

His arduous duties did not prevent him from recording a host of facts selected from the myriads presented to his observation. Among the works with which he enriched surgical literature, some of the best are:—A Memoir on Amputation of the Extremities after Gun-shot Wounds—A Historical and Surgical Account of the Expedition of the French Army to Egypt and Syria.—Memoirs of Military Surgery: an elaborate work in four volumes.

Among the valuable principles which he established was the necessity of immediate amputation after gun-shot wounds, pointing out, with nice discrimination, in what cases the operation was indicated. The propriety of immediate amputation had been advocated at intervals for two centuries; but the large experience and strong sagacity of Larrey first raised it into a canon of military surgery.

Previously to his time, it had been a maxim of practice, when the extremities were invaded by spreading mortification, never to amputate till nature had fixed a line of demarcation between the sound and gangrenous parts. He first shewed that the rule, though general, ought not to be universal; and he drew attention to the important distinction between gangrene dependent on a constitutional cause, and that which springs from the severity of a local injury. In the latter he advised immediate amputation, without waiting for the establishment of a boundary between the dead and living parts; and the instances which he gave of the successful application of this new distinction, have been amply confirmed by the experience of others.

Fortunately for mankind, the clearest intellect is commonly accompanied by a benevolent heart, and the perspicacity of Larrey was equalled by his humanity.

Of all Napoleon's campaigns, that of 1813 was the most equally, the most severely, the most fiercely contested. It was then that Prussia, rising almost to a man, displayed a spirit at least equal to that of France in 1793; and in the combats which ensued, the effects of science and art in war were heightened by the heroic, it may be rancorous, feelings of those engaged.

After the battles of Bautzen and Wurchen, it was suggested to Napoleon that the number of the wounded had been increased by voluntary mutilation; and that all who had lost a finger, or whose hand had been pierced by a ball, were traitors who wished to escape from the service.

Napoleon ordered that the wounded of this class, to the number of 1,200, should be separated from the rest; and that a commission, consisting of several principal surgeons, should examine each of these soldiers. A council of war, moreover, was appointed to try the guilty, and cause them to be executed on the spot. Larrey had been named president of the surgical board. The day before it met, a certain personage, who, believing the accusation, desired its success, ordered him to find four culprits in each division, who should be taken before a council of war, and shot instantly. Larrey, filled with terror and indignation at such an order, was about to send in his resignation, and quit the army, when a friend made him give up the project by observing that he might be useful to these unfortunate men.

Larrey did not hesitate one moment. The examination was extremely rigorous, and lasted four whole days. Larrey shewed, by reasoning on the character of the wounds, that all the accused were innocent. He then addressed a report to Napoleon; and, believing that he had displeased the emperor in this affair, composedly awaited the disfavour which was to follow. But Napoleon was not insensible to the claims of truth and justice when clearly demonstrated and resolutely maintained. The conduct of Larrey was not lost upon him. In the middle of the ensuing night, Baron Fain brought Larrey a most flattering letter from the Emperor, in which he was congratulated on his firm, honourable, and humane conduct. This letter was accompanied by a present of 6,000 francs, and the warrant of a pension of 3,000 to be paid from Napoleon's privy purse. —In his long exile Napoleon did not forget his great surgeon: besides bequeathing him 100,000 francs, his will records the honourable fact, that Larrey was the most virtuous man he had ever known.—His own escutcheon might have been saved from its darkest blot, had he always encountered the moral fearlessness of Larrey and of Desgenettes.

But I must now approach the great object which has to-day brought us together, and endeavour briefly to describe the peculiar and more prominent points of Hunter's career.

John Hunter was born in 1728, and began the study of his profession at the age of 20. He died in 1793, leaving a reputation as a surgeon and a naturalist beyond that of any other man in the annals of fame. Some few may have been his equal, nay, his superiors, (though that is a bold word) in either department singly; for excellence in both combined, he stands without a rival.

He was snatched away too soon from the pofession which he adorned; and if we number his years alone, his death may appear premature; but if we adopt the theory of the Roman philosophical poet, and measure time by what has been performed in it, we might suppose that Hunter had lived an age. Half a century has now elapsed since his death, and few of his contemporaries are with us; the voices of envy and of partiality are alike silent in the tomb, and we are called on to estimate what Hunter attempted, intended, accomplished.

The materials for our judgment are to be found in his books, both printed and manuscript, as well as his numerous drawings. But it is most of all in his museum that we appreciate the prodigious extent of his views, bounded only, if that can be called a boundary, by the limits of animated nature.

John Hunter early shewed the characteristic features of his mind, the interest he took in physiological inquiries, his capabilities of minute anatomical investigation, and his powers as an original thinker. Within ten years of his arrival in London, he had solved the problem as to the cause and mode of the descent of the testis in the fœtus, had closely examined the connection between the uterus and placenta, had made that preparation, the oldest in the museum, where, tracing the branches of the fifth pair of nerves in the nose, he was led to the conclusion that the organs of sense receive their endowments of ordinary sensation from that nerve, and to the more general proposition, "that if we consider how various are the origins of the nerves, and how different the circumstances attending them, we must suppose a variety of uses to arise out of every peculiarity of structure;" thereby approaching more closely than any one else had done to the principle subsequently established by Sir C. Bell: and, moreover, he had instituted a very ingenious set of experiments, with the view of determining whether the veins possess the power of absorption.

When, soon after, he accompanied the army to the coast of France and the Peninsula, his duties as Staff-Surgeon did not prevent him pursuing those physiological inquiries in which he took so much delight. He was then engaged in determining, by experiment, whether digestion continues in lizards and snakes during their torpid state; and he made other experiments on the faculty of hearing in fishes, the organ of which sense he had discovered in these animals before leaving London. At this period, too, were made those observations on gun-shot wounds, with which seems to have originated that inquiry which, in its published form only, appeared 30 years afterwards. And in an incidental remark in his paper on the vesiculæ seminales, "that he took the opportunity of opening a man immediately after he had been killed by a cannon-ball, to be more certain of the nature of their contents," we perceive how strong was his physiological zeal, and how eagerly he seized every opportunity of adding to his knowledge.

There is reason to suppose that when he returned to London in 1763, the scheme of his future life and operations had been already formed. The College possesses a manuscript catalogue in his own hand writing, apparently written a few months after his return from Portugal, briefly defining the nature of about 200 specimens of natural and morbid structure, grouped together according to organs—the germ of that museum in which he sought to display all the types and modifications of animal structure.

The great object of Mr. Hunter in the formation of his museum was the illustration of life, in its natural and diseased condition, in plants as well as in animals. Physiology, in its largest sense, was the aim and scope of his labours; whether we view him investigating the properties of the seed or of the egg, where life lies sleeping; displaying every form and variety of organization; tracing its developments; observing its aberrations; dedneing the laws of life; or applying his knowledge of these laws to the explanation of the phenomena of disease, to the prolongation of the existence, or to the relief of the sufferings of his fellow-creatures.

Of the vast basis on which Mr. Hunter raised his superstructure, and of the soundness of the materials of which it is composed, his museum is the best evidence. At the period of his death, and he was adding to it with unabated zeal up to the last day of his existence, the number of preparations of natural structure alone amounted to nearly 4,000.

It is impossible to form a just conception of the beauty and value of these preparations without a detailed examination of the museum itself, and of the excellent catalogues which have now been drawn up. But you may form some idea of the industry and vast labour expended in its formation, when I state to you, on the authority of one who has had the best means of knowing, Mr. Owen, that there is proof of Hunter having dissected above 500 species of animals, exclusive of repeated dissections of different individuals of the same species, besides those of plants to a considerable amount. And of his diligence in recording the details of his observations, that at the same period he possessed original records of the dissections of 315 different species of animals.

Not contented with displaying the peculiarities of their structure, and recording them, Hunter caused most elaborate and accurate drawings to be made from recent dissections of many animals, and for this purpose retained in his family, many years, an accomplished draughtsman.

(To be continued.)

PERISCOPE OF THE WEEK.

Anchylosis.—M. Malgaigne speaking of recent anchylosis resulting from various affections of the joints, or from prolonged absolute quietude of a limb, directs especial attention to the dictum that these forms of anchylosis do not require any specific treatment, and that they will be removed in the course of time without medical assistance. This he combats very strongly, as also the advice not to attempt passive motion of a limb as long as there continues any pain in the joint. He illustrates both his positions by cases, some of which serve to demonstrate that time alone cannot cure a commencing anchylosis, but tends the rather to increase the mischief, while the others show that the forcible flexion of a limb, even while some degree of pain in the joint continues, provided all the inflammatory symptoms have been dissipated, is far from being as injurious as has been represented, but, on the contrary, has led to a cure by the rupture of the anchylosis. This forcible movement is attended with considerable pain at the time, but its beneficial effects soon become evident. M. Malgaigne does not restrict the application of passive motion to a limb labouring under commencing anchylosis from inflammation of the joint, or from a too protracted state of rest of the part affected, consequent on fracture or luxation, but equally applies it to the same diseases when subsequent to white swelling, provided always that the increase of sensibility of the part has ceased. The persistence of the swelling is not with him a sufficient reason for not having recourse to forcible extension and flexion. The following case will show that even where there is a degree of deformity of the articulation sufficient to give rise to the fear that more or less erosion of the articulating surfaces has taken place, still something may be done for the unfortunate patient. A person was brought to M. Malgaigne, who had been obliged to keep his arm in a state of perfect rest for white swelling of the shoulder. All pain had then ceased, and he could perform some slight movements of the limb, but the deltoid muscle was completely paralysed, and half the head of the humerus had been destroyed, so that none of the movements of the limb were effected properly. Notwithstanding, by steady and well regulated passive motion, gradually increased in power and extent, the patient so far recovered the nes of his limb that he can perform the most difficult gymnastic exercises.

Natural Strangulation in Birth.—Dr. Henderson, of Edinburgh, publishes a case where a healthy woman of 30, gave birth to a full-grown child, after a labour of fourteen hours, accompanied with circumstances of extreme interest in a medico legal point of view. The pains were neither frequent nor severe; the os uteri was thick and dilated slowly. Latterly, the head becoming impacted in the outlet of the pelvis (which was rather narrow anteriorly), required to be relieved with the forceps. When the head was born, the child breathed twice, and cried once distinctly, though feebly; during the next three or four pains no progress was gained although forcible traction was made; indeed, each pain, instead of forthering the labour, rather drew back the head, the face becoming rapidly black and tumid. On inserting the finger, the thickened os uteri was found grasping the throat tightly as a ligature, and arresting the flow of blood in the jugular veins. A few more pains served to extricate the child, which was quite dead, strangled by the spasmodic contraction of the os uteri around the neck, after the birth of the head. There were two distinct black rings, one at the top, the other at the root, of the neck, corresponding exactly with the parts which the os uteri had successively grasped and rested on. The right shoulder, from the apex to the lower ring on the neck, was ecchymosed. The left shoulder was nearly in a similar condition, showing the strong spasmodic contraction of the mouth of the womb, and the force necessary to overcome it.

Cinchovatine.—M. Manzini obtains a new alkaloid from the cinchona ovata, which he calls cinchovatine, by the process adopted for the preparation of quina. Cinchovatine, is found in very long prismatic crystals of a beautiful white color; it is inodorous, and possesses a bitter taste, which is slowly developed. It is scarcely soluble in water, but very readily so in hot alcohol and æther. The salts which it forms with acids are soluble and crystallisable; their solution is precipitated by tannic acid, the iodnret of potassium, the bichloruret of platina, the dento chloruret of gold, and some metallic chlorurets. Heated to 400 deg., it melts into a brownish liquid, which solidifies like a resin on cooling. The formula of its composition is expressed by C_{46}, H_{31}, A_{21}, O^8, or carbon 69.80; hydrogen, 6.83; nitrogen, 7.19; oxygen, 16.21.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, Feb. 10, 1843:—

D. Morgan, A. L. T. Cooke, T. Graham, S. P. Goddard, W. K. Park, G. F. Fox, H. Payne, J. C. Bonnett, J. S. Woollett, R. Chambers.

Admitted Friday, Feb. 17.

W Thom, S. H. Steele, R. Brown, T. D. Martin, J. C. Sproston, H. Gavin, A. C. Ayres, R. Nugent, G. Allen, C. H. Duck, W. J. Bryant, 7. Growse.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 49, Essex Street, Strand, in the Parish of St. Clement Danes, Westminster, Middlesex.—[illegible] 1844.

THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs

PRICE FOURPENCE. STAMPED EDITION, 5d.

No. 180. VOL. VII. LONDON, SATURDAY, MARCH 4, 1843.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Punch Office), London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute of the Academy of Medicine, Professor at the Museum of Natural History, Paris, &c. &c. &c.

SUMMARY.—*Double state presented by organs in the course of their formation—Principle of determination in comparative anatomy—Determination of organisms by form, by function—Insufficiency of these two principles in the determination of the organs of the life of relation—New direction given to this study by Geoffroy Saint Hilaire—Principle of connections and of balancement in organisms.*

We thus see that in the course of their formation, the organs present two different states; that which corresponds to their transitory forms, and that at which they are definitively arrested, and which constitutes their normal state in different classes. The transitory forms of an organ are so much more numerous, and its changes of form so much more multiplied as its composition is more complex, a form of greater complication being always preceded by one of greater simplicity, wherein the various parts of the same organ become alternately balanced in their dimensions, until arrested at their definitive composition. In the system of organic pre-existences, the primitive form was presumed invariable; an organ was of necessity at its origin that which it was bound to remain: the heart, the brain, the stomach of a mammiferous animal, of a bird, a reptile, or of man himself, appeared at first sight to possess the same complication as in the adult being. Hence was there no attempt at establishing a resemblance between these organs, no analogy beyond the analogies and differences presented by adult animals. Now, as in the adult state the analogies are effaced, while the differences become more striking than at any other period of existence, it resulted that the organic differences became the object of the researches of anatomists, and, so to speak, the principal rule of comparative anatomy. But in proportion as researches multiplied, these organic differences diminished; those unperceived analogies presented by the organs in the course of their metamorphoses from family to family, or from class to class, became more and more developed, till finally that mass of organic analogies was accumulated of which the anatomy of adult beings had not even induced a suspicion. Organs, which in the animal of full development appeared exceedingly complicated, were found to be progressively simplified, in proportion as they were traced towards their original conformation in the young fœtus. This first observation was followed by a second still more important. Comparative anatomy had already unfolded the gradual decomposition of organs in the series of organised beings; the heart, so complicated in man, the mammifera and birds, was found in reptiles and fishes, to constitute a simple contractile sac, in which the venous and arterial circulations terminated; in the mollusca the place of this organ was seen to be supplied by a simple swelling of the canal containing the blood, while in insects, a single vessel (the dorsal) was found assimilated to this organ. The difference between this dorsal vessel, the sac of the mollusca, and the complicated heart of the mammifera and man, was so great and remarkable, that the only common point between them was that of *function*, or *use*, namely, to accelerate the movements of the venous and arterial liquid; thus was function the only character which could then lead anatomists to confound under the same denomination, organs so different in their structure, in their form, and sometimes even in their position, as in the mollusca and in insects. Finally, by considering this organ in a general manner throughout all beings, its anatomy was found to become more complex from the inferior to the superior animals, until arrived at the highest degree of its composition. Now, by tracing it towards its early conditions, transcendental anatomy has shown that the self-same organ, however complicated it may be in its permanent forms, repeats in its transitory conditions the organic simplicity of the inferior classes. Thus the heart in birds is primitively a canal, then a sac or simple cavity, and lastly the complex organ of this class. Comparative anatomy is thus repeated and reproduced by embryogeny; and embryogeny, hitherto neglected because it presented to the mind but sterile result, now offered a degree of interest in pursuit, which threatened to exhaust all the energies of those who had the courage and patience to give themselves up to these difficult and minute researches.

If it be true that the organs of the embryos of the superior classes repeat and reproduce the permanent organic states of the inferior [illegible] becomes doubly useful [illegible] and why this embryogeny having been neglected, and why this neglect had not extended itself to comparative anatomy. We may in this place consider the principles according to which comparative anatomy made its first advances. On the one hand the anatomy of the adult man being the only known species, the only one which could serve for the purpose of comparison, and the organic dissimilitudes of animals reproducing themselves from class to class, these latter were of necessity in the first place pointed out and seized upon; they constituted as it were the prominent points of comparative anatomy. Thus the kidney of man is single on either side; that of many mammifera, of birds and reptiles, is multiple. Comparative anatomy pointed out this unity on the one hand and this state of multiplicity on the other, without considering whether there was not a period in the life of man when this organ resembled that of these animals. It ascertained the facts, but did not explain them.

But the differences became multiplied to such a point; the forms, in consequence of their great variety, became so widely separated from those which served as their type, that, without some other rallying point, anatomy would infallibly have lost the thread which directed it. This new guide was *function*. By this aid the apparatus, by means of which an individual function is executed, were traced and compared one with another, so that organs, apparently the most heterogeneous, were thus reduced to their organic analogy. The liver, for instance, differs so greatly in the monkey tribe (some excepted), the mammifera and man, that for a long time this difference was made a point of objection against the doctrine of Galen, and his disciples. In birds, a class so remarkable for the fixity of their organisation, the liver (single in the mammifera) is double, of a symmetrical form, and placed upon either side of the intestinal canal; in reptiles and fishes it resembles more that of the mammifera, notwithstanding its infinite variations in this latter class. Still it was impossible not to perceive the organic analogy, whether on account of the connection of the liver with the digestive canal, or inasmuch as the determination was merely based upon the organ *en masse*. But true difficulties presented themselves in the invertebrata; and assuredly if form alone, or even form aided by the relations of position, had been the only guide to determination, no analogy could ever have been discovered between the secretory apparatus of the bile in the hepatic cœca of the crustacea, and in the thin and spongy vessels of insects; the yellow colour of the former, as also, most frequently, of the latter, and the constantly bitter taste of the liquids which they contain, have alone established the relation of these parts with the biliary organs of the upper classes. Function, in this case, takes the place of form. The same may be said of respiration, which is sometimes performed by means of lungs, sometimes by branchiæ or gills, and at others by tracheæ. So also with respect to the heart and the vessels, which have in many cases been recognised by the presence of the blood alone.

Results so striking restored to function all its former importance: unity of function, diversity of organs to produce it, such was the base of anatomical determinations. Although this method was followed with such great success in the comparison of the apparatus of the life of nutrition, it was far different with respect to those of the life of relation. Here, in fact, all the elements of incertitude and the chances of failure were combined to render research unsuccessful. Sometimes the function being completely unknown, this rule of determination could no longer be applied; at other times the function was known or presumed, but the organic [illegible] were so totally changed, the elements [illegible] completely disassociated [illegible] that the form rather led astray than directed in the pursuit. Thus function and form, whether considered apart or united, which in their application to the apparatus of organic life had been so fertile in results, threw but a doubtful or unsteady light upon the apparatus of relation.

The prejudices of paganism interdicting the dissection of the human body, the anatomy of man was primitively deduced entirely from that of animals. But in the sixteenth century, science taking an entirely opposite direction, the dissection of man became pursued, and the anatomy of animals was in its turn deduced from that of man. Consequently, anatomists sought at first those resemblances in the brains of animals, which were perfectly known to them in that of man. These resemblances were soon found in the mammifera, for in them the brain is, in great proportion, a repetition of itself in the various families of which this class is composed. In them it was found similar to what it is in man, and received the same denominations. But in birds this resemblance no longer existed. The cerebellum posteriorly, and the cerebral lobes in front were recognised without difficulty; but in the middle part a pair of new lobes was discovered, which had no analogy either in man or the mammifera. Thus were mistaken ideas engendered and extended even to the surrounding parts: the whole middle region of the brain in this class appeared new, and as science possessed no fixed terms of relation, a wide field of conjecture was opened to anatomists. The chain of resemblances appeared from that point broken; and on coming to the class of fishes, it seemed impossible to renew it by reason of the many circumstances which we will now explain.

The consideration of form, which had so successfully guided anatomists in the study of the mammifera, which had also enabled them to recognise the cerebral lobes and the hemispheres in birds, lost all application in fishes. Nothing could be found, at first view, which bore a resemblance in this class either with the brain of the mam-

mifera or of birds. This organ is composed, in fishes, of a double series of bulbs ranged in lines from before backwards, and varying in number from two to four or six. Which of these pairs should be named cerebral hemispheres? The anterior, the middle, or the posterior? To what part of the upper classes are the other lobes to be compared? On what bases are their analogies or differences to be grounded? No fixed data are ascertained on these points. All is individual opinion and conjecture. The same lobes have received different names, and have been by turns compared to parts altogether dissimilar. The cerebellum itself, which it is so difficult to mistake in the other classes, was also, in fishes, a subject of incertitude. Sometimes this organ is single, as in the bony class of fishes; at other times, as in some cartilaginous fish, it is a double organ composed of symmetrical layers rolled up together and placed along the parietes of the fourth ventricle. In a very great number, an especial body is found detached from the posterior lobes, rendering the organ still more complex. This body, which sometimes resembles the uvula in man, and at other times the epiglottis, is placed, like a cover, over the fourth ventricle. Most frequently, it is simple; at other times, as in the skate, it is double. How, in the midst of all these transformations, are we to recognise the cerebellum?

The base of the brain in fishes is scarcely less variable than its upper surface. What is especially deserving of notice at the under surface, is the appearance of two rounded tubercles, which, in their situation and form, bear some resemblance to the mammillary eminences in man: this analogy has been pointed out by various writers, who have not failed to express their astonishment, that these mammillary eminences, which are the most elevated character of animality, should be found in fishes, which appear so low in the animal scale! These eminences, which exist only in man, which have disappeared in the monkey tribe, in the mammifera, and in birds, are suddenly reproduced in fishes; an evident proof that their brain belongs to a very elevated degree of organization. Consequently, their posterior lobes have been assimilated to the cerebral hemispheres. In these lobes are found the optic thalamus, the corpus striatum, the pes hippocampi, the fornix and the corpus callosum. Considering, therefore, that some of these organs have disappeared in birds and reptiles, the pre-eminence of fishes over these two classes was considered to be established.

I ask, then, how, with conclusions so opposed to the anatomical and zoological relations of vertebrated animals, could the comparative anatomy of the brain be rightly appreciated? The confusion resulting from all these false relations and dissimilitudes was still further increased by the extreme variation of the brain in fishes. In the mammifera all the parts of the brain are almost a repetition the one of the other. In birds, this organ is more fixed than in the mammifera. Reptiles present some differences; but these differences, altogether unimportant, produce no alteration in the fundamental characters of the organ. The converse of this, however, takes place in fishes: the elements of the brain are with them in a perpetual oscillation. In the first place, the brain of cartilaginous fishes is not the same as that of the bony fishes. The general forms being so changed from one series to another, that the principal parts, such as the cerebrum and cerebellum, become quite incapable of recognition. In the second place, this organ varies not only from one family to another, but it presents the greatest differences in the various genera and even in neighbouring species. It was thus impossible that science, without some powerful guiding principle, could progress upon so difficult and uncertain a foundation.

Such had been the results obtained by the principle of form unguided by function in the determination of the various parts of the brain in vertebrated animals. The spinal marrow could, however, not be mistaken. Encased in a canal formed by the contiguity of the vertebræ, its determination was derived from its position, in the same way that the determination of the brain, *en masse*, was derived from its enclosure within the osseous or cartilaginous box of the cranium. The containing body served, so to speak, to distinguish the contained. But this containing medium suddenly disappearing in the invertebrata, the central nervous system became, as it were, abandoned to itself. Thus, some referred to the great sympathetic, the whole nervous system of the invertebrata, forgetting that, from the time of Rufus of Ephesus and Galen, this nerve has unanimously been devoted to the nutritive functions alone.—Others (and this is still the opinion of many anatomists) not being able to explain the invertebrata from the structure of the vertebrata, have followed a totally opposite course. They considered the double chain of ganglia in the articulata as analogous to the spinal marrow of the vertebrata, which they supposed to be similarly enlarged at each vertebral segment. But direct observation soon destroyed this hypothesis, and left all in doubt. On comparing this state of uncertainty in reference to the fundamental system of the apparatus of relation with the so succesful exposition of the apparatus of nutrition, one cannot help enquiring why the laws, which were so successful in their application on the one side, should prove so inefficacious on the other. The cause must be that the method which is applicable to the one, is unsuited to the other order of apparatus.

Having now shown the imperfection of these laws in reference to an entire system of the organization,—the nervous system, I shall proceed to demonstrate their inefficacy in some circumscribed apparatus as those of the senses, choosing smell and taste, which are intermediate to the functions of nutrition and relation, and the hearing, which belongs exclusively to the relative functions. In the example which we have been considering, the obscurity of the function might cause the analogy of its instruments to be overlooked. The pieces of bone, however, composing the cranium and face, will furnish us with new proofs. Their purpose is evidently, in all classes, to protect the brain and afford a covering to the organs of sense. The anatomy of the adult man had shown that the cranium is composed of eight principal bones. In like manner it had demonstrated that fourteen bones enter into the composition of the face, excluding, of course, the teeth from this enumeration. Altogether, the human head is composed of thirty-four bones. Each of these bones has a particular name; each forms a distinct osseous species. Comparative anatomy sought to discover these different bones in the series of vertebrata, and to point out their analogies and differences in the mammifera, in birds, in reptiles, and fishes. In the mammifera, the bones of the cranium and face are reproduced with such slight modifications that the analogy was easily recognised. Thus the double parietal bone of man becomes simple in many mammifera; the inferior maxilla, single in man, is constantly divided into two in the animals of this class. Again, the varieties in form of the ethmoid, sphenoid, and temporal bones, leave no doubt as to their true signification. In this class we find the bones of the head, as well as the various parts of the brain; the proportions are changed without fundamentally perverting the forms. In birds, however, it is different. In them we find forms entirely unusual in the mammifera; the bones of the face become decomposed and re-united to such a point, that the individuality of the osseous species of the mammifera becomes very often doubtful. It is thus with the bones of the head as with the parts of the brain; the chain of analogies is broken in fishes and birds. We must, moreover, remark that the bones, in immediate relation with the brain, undergo the least variation. The differences are especially manifested in the bones enclosing the organs of sense and forming the frame-work of the face. This is, to a certain point, explained by the comparative anatomy of the brain. The brain in man being very extended, the bones corresponding to it are generally very large. In animals the cerebral mass gradually diminishing, these bones are contracted upon it, undergoing different modifications. But, in proportion as the brain contracts, the organs of sense gain in extent that which the brain loses. Hence, the variations and divisions of the bones constituting them.—Thus, in birds, the frontal bones are prolonged forwards to form the roof of the orbits. The most variable portion of the sphenoid bone, is that of the pterygoid processes, corresponding to the palate; that of the ethmoid is the lower or nasal plate, entirely devoted to the organ of smell. The more the sense is extended, the further do we find the bones constituting it removed from the centre, dividing and becoming so altered as not to be recognizable, even when subjected to the same use, as with the superior and inferior maxillary bones in the crocodile and the vomer in fishes.

Thus organic form had commenced to direct anatomists; but form becoming decomposed *ad infinitum*, these metamorphoses were successfully explained by function, in the apparatus of the life of nutrition. The function, however, being unknown in some apparatus of the life of relation, the form could no longer be reduced to its type. At other times, the use being known, the parts were so altered in form, so multiplied, that it became impossible to combine these various portions together. Lastly, and this it is especially which increased the difficulty, the apparatus changing in function, their forms becoming completely altered, so as to accommodate themselves to their new uses, the usual laws of anatomy lost all application: the inquirer was, in spite of himself, dragged into a labyrinth, and wandered, he knew not whither. It has been remarked, that he who strikes out new *routes* in science has almost always immense difficulties to overcome. Geoffrey Saint-Hilaire gives us a striking exemplification of this truth. Endeavouring to trace the analogy between the osseous head of the fish and the skull of the human adult, he perceived that the latter furnished a smaller number of bones than the former. Rejecting ancient notions, he then conceived the idea of seeking the *analogues* of these absent bones in the osseous *nuclei* corresponding to the bones of the head in the human embryo. He thus entered on a wide career, the first steps of which were crowned with the most brilliant success. The bony head of the fish, reduced to the natural type of its relations, opened a new path to the solution of a multitude of questions hitherto deemed incapable of explanation. But the variety of observations to be made, and the precautions which were necessary to be taken to avoid falling into error, alarmed the fears of anatomists; especially when viewing the animal kingdom, which Geoffroy St.-Hilaire described, in its *ensemble*, as a mere organic unity, diversified in a thousand ways by the variety of life in each grand division of beings. But the analogy of organic composition once proclaimed, it remained only to justify it by facts, the discovery of which, however, required guides of a certain and convincing character. From the necessity thus engendered sprung those two general principles in this branch of science:—1st. The principle of connections:—2d. The principle of *balancement* in organic masses; principles of which we shall find such frequent and striking applications. I shall in the next lecture commence with the consideration of the cerebro-spinal nervous system.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

By C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine and of Clinical Medicine, in University College.

GENTLEMEN,—At the conclusion of the last lecture, I was mentioning a view taken of the manner in which the sounds of the voice are transmitted to the chest, by Dr Schornel of Vienna; and it may be necessary to refute this, because it may lead to a good many more. He considers that they are owing to the principle of consonance, or the production of a sound in the tubes in the interior of the chest harmoniously with the sound produced in the larynx. In this consonance there must be a certain given and fixed relation between the sides of the cavity and the vibrations of the body; this may be illustrated by the experiment of the tuning fork, which, when sounded, communicates its vibrations to different objects, and may be transmitted to the air. If you bring it over a hollow, like that of a bottle, you have a

little vibration; the sound or note of the tuning fork is the same as that of the bottle. This is what Dr. Schornel calls consonance, and through this experiment the phenomena of consonance may be fully developed. But for this consonnance there must be a relation between the sound and the size of the cavity, without which it cannot be produced. This may be shown by applying the tuning fork to the mouth of the patient, though it is difficult to fix it there. There is no such consonance between the size of the tube and the sounds produced in the voice. You hear that consonance in pectoriloquy and bronchophony, and in all cases the sound is very feeble; but it has nothing to do with the existence of any peculiar phenomena that become signs of disease.

I have pointed out to you that this very principle does obtain, to cause some sounds to be louder than others, and I have distinctly expressed this in one of the earliest editions of my work on auscultation; that the reason why some notes are louder than others, and why some notes are heard and others are not, is that there is a sort of acoustic relation between the tubes producing the sound; that where there is a difficulty in the transmission of the voice, then certain notes may be transmitted, and some will not be transmitted. Those most likely to be transmitted are those that correspond with the vibrating cavities of the tube itself. All that is new in attempting to give an explanation of this phenomenon seems to be erroneous, and what is true is that which I have already stated, that the phenomena are nothing more than modified sounds transmitted or produced by a diseased state of the tubes: transmitted in the same way as in respiration, with this difference, that the sound of the voice communicates with the trachea, and that all the large tubes vibrate in unison with it; that unison being in all the notes, and not in any particular set of notes. In the same way you have a perfect and full vibration in a room where the voice is said to fill the room. It is very difficult for the voice to be transmitted in the faint form of the speaking tone which is just audible across the room, but you know some voices fill the room completely, so that the whole mass of the air is thrown thoroughly into vibration. So in the resonance, or vibration in the tubes; some strong murmur of whatever key is very easily transmitted, if there is no obstruction in the tubes, no pulmonary tissue intervening,—and then you get a steadfast amount of bronchophony, or pectoriloquy, or whatever the sound is. On the other hand, if any obstacle occur and the voice is modified, a part only is transmitted: the squeaking notes will pass through, but the deeper tones will not pass through. This may be in consequence of this law of harmony, which causes some sounds to go through because the capacity of certain tubes corresponds with the tone of the voice, and others do not.

Now I will explain the manner in which the phenomena are produced. Bronchophony is the sound of the voice in a greater number of tubes transmitted to the surface by the superficial and vesicular parts of the lungs, being condensed either by consolidation, as in the case of hepatization, or compression of the external layer of the lung. Ægophony, another variety of sound, is produced in cases where there is liquid, and where the pressure is great, so as to injure the transmission of the voice. This is not so deep a sound as bronchophony. Not only in the variety of sound are some tones of the voice transmitted and others not, but the sounds which are heard have that peculiar character which led Laennec to call it ægophony, or like the bleating of a goat. Another characteristic of this sound is, that it is as it were distant, like a silvery echo; this is not only owing to the interposition of the liquid, causing a difficulty in the passage of the voice, but also it may be owing to the flatness of the tubes. Pectoriloquy again, corresponds with cavernous breathing; here the voice communicates with a cavity in the lung, and the voice becomes transmitted into the cavity, and takes the form of that peculiar apparatus. Here you have not only the voice but the division of the voice into words; you hear the articulate voice,—this Laennec called pectoriloquy.

With regard to bronchophony, and in some degree, to, bronchial respiration, you must remember another circumstance that leads to increased sound of the voice; not only, that the sound is transmitted with greater power, but that it is not muffled or destroyed, as it is naturally in the spongy tissue of the lung, which is calculated not only to cut off the communication between the interior and the external parts, but to destroy and muffle the vibration. When the trachea is consolidated and hard, the cause of obstruction ceases, and there is a hard resistent body which increases the vibrations. This is what Dr. Schornel has confounded with consonance. It is the substitution of a good conductor and reflector for a bad conductor and reflector; this is the reason why the sound is so extremely loud that the patient is sensible of it himself, and it can be felt by the hand in soms degree. On the other hand, where the voice is transmitted by a liquid interposed, although the liquid does allow some vibrations to pass through, it is in a slender way. But remember what I have said before, that the sounds of the voice may be cut off altogether by the contents or condition of the tubes; if they are much narrowed by solid effusion, as in the case of hepatization or tuberculous disease, by a great deal of mucus in them, this liquid will prevent the transmission of the voice from the treachea to the larynx, and to the tubes; and under these circumstances you will not have that peculiar phenomenon, although you may have the conditions capable of producing it in the lung. This is one reason why you do not have that peculiar phenomenon so constantly developed as you may be led to expect from the consolidation of the lung. Sometimes it may be absent, sometimes temporary, and sometimes permanent; or sometimes from the tubes being impervious to the fluid, you have bronchial respiration, and after all bronchophony. The reason is this: the air will pass through the orifice, though the vibrations of the voice will not pass through. The other kind, metallic tinkling, I will not enter into in detail; but I merely advert to it as a phenomenon that may accompany the voice; not only the voice but the cough.

Now a few words on the subject of the absence of *pectoral fremitus*. I mention it because it has been called in question whether it is a valuable sign or not. I have mentioned to you that there is a natural fremitus perceptible in the chest, in healthy persons even. Now in cases of bronchophony this is very much increased in degree; on the other hand, in ægophony, where this sound is transmitted through considerable layers of liquid, the pectoral fremitus is altogether stopped. These are the rules that obtain constantly with these conditions; but sometimes, where there is a great deal of liquid effusion, there is a great deal of resonance of the voice; for this reason—that the lung, instead of being pushed away, is pushed into close contact with the chest. On the other hand, although there may be consolidation of the cavities to produce bronchophony, you do not always have the vibrations transmitted to the exterior, because there may be liquid in the tubes and various other circumstances preventing the free transmission of the voice.

Now a few words as to the mode of listening to these phenomena. Sounds are produced by or may proceed from various causes; but the sounds of the voice mainly depend on air, which transmits sound better than solids. The interior of the chest transmits sounds by air alone, but it is a different thing when the air becomes mixed up with membrane, and where there is a succession of the vesicular texture of the lung, whsre the sound has to pass successively through a great number of different media. Sounds produced in the air are best transmitted by air: hence the sound of the voice is freely transmitted in the direction of the voice; and whenever the air communicates freely with it, the voice is heard. So likewise in disease; the shrill sounds are best transmitted to the air, through air; but inasmuch as they are confined within a solid body, they are not easily transmitted through the open air; and inasmuch as the open air is an imperfect conductor, where you can get the air confined in a tube, you get it into a condition capable of transmitting vibrations very freely. This is the principle upon which the stethoscope was constructed by Laennec.

But some sounds are produced by vibrations of solids, as in the sounds of the bronchi, where the vibrations are such as may be felt outside by the finger. Then, again, as to the conditions of solids best calculated to transmit these vibrations. Sound is motion, and motion has a certain degree of strength in it. Those motions that are less strong are less easily propagated, and with more difficulty transmitted from one body to another; and those vibrations that are strong will pass through almost any medium. Suppose, for instance, there was a partition in this room, my ordinary voice would not be easily transmitted beyond it to the other compartment; but, if I exerted my voice very strongly, it would pass through the partition with facility. So with the chest. A greater number of stronger sounds pass through any medium, by air or solids, or sometimes without any intermediate agent; such as the sounds of the larger bronchi—the large and coarse bronchi—and the sounds of the heart; some are heard without a medium, or any close contact. But the more delicate sounds become the test of a good conductor, and it is where these delicate and slight sounds are put forth, that it becomes necessary to construct instruments more adapted to transmit the vibrations, and in some degree to exaggerate them.

Now, there are circumstances which improve air, and render it a complete conducting medium of the sounds produced in it; they are means of enclosing it, so that an impulse transmitted to one part is easily transmitted to another. Sound is, as I said before, merely motion; it is not something hidden. When you apply your hand with force to the end of an open tube, you can force out air with sufficient strength to blow out a candle—so, in the same way, is it that sounds transmitted to a tube like the stethoscope, vibrate with precision and accuracy, and more so if the ends are closed. The impulse communicated to one end is transmitted to the other, because there is no room for dispersion: hence it is, that a column of air is one of the best means of obtaining a communication between a sonorous body, producing sounds in the air, and the ear.

These matters are more curious than instructive; and the question that we have now to deal with is, what form of cavity is best adapted t transmit sounds. With respect to a close column of air, it does not matter much; it transmits sounds as well, and they will pass round angles and through crevices, with such a degree of facility, that if a flexible tube be applied to the chest, the sound conveyed through the tube will be transmitted with considerable force. The reason of this I have explained with regard to mechanical impulse. There is a disadvantage in having large cavities, or large hollows of any kind—tubes containing great excavations—and it is this, that there are new sounds produced in these hollows, such as the sound I have been adverting to—metallic tinkling, which arises from an echo taking place in the hollow, like the reverberation in a bottle, which you may hear on applying your ear to the mouth of the bottle; or which arises from a succession of echoes in a large body, such as the conch-like sounds heard in various degrees. This is heard in a flexible tube, and under these circumstances, with an improvement of this kind, you hear the sound very distinctly, but it is accompanied by a sort of metallic sound. The great object is to have a close column of air, which shall be as small as possible, and yet come as much in contact with the walls of the chest as will enable you to elicit from those walls the vibrations that have been transmitted. This object is accomplished by the trumpet-shaped stethescope, and this form of instrument answers better than any other, for the transmission of air sounds. I refer you to a paper read at a meeting of the Manchester Association, for the reasons for and against this form of instrument.

I now proceed to speak of the production of sounds from the solid wall of the chest. Some are produced indistinctly, as the sound of the *rhonchi* We must t. l.e solids with as little density, and as great rigidity, as possible. These ...

is better transmitted through air is—sound, being motion, light and rigid bodies are more easily moved than dense bodies. A soft body, such as a silk handkerchief, instead of propagating the impulse it receives, disperses and destroys it. On the other hand, rigid bodies are easily thrown into vibration, and the lighter the body, and the greater the rigidity, there is less dispersion. This is the reason why the sounds of solids are so much better transmitted by light and expanded bodies, than they are by dense solid bodies. It is, that the motion is more freely communicated by these light bodies, of great rigidity, than it is by dense bodies.

This, therefore, should lead us to select instruments of great rigidity, but with little density, and as light as possible. The instruments for this purpose should be either pine, or deal, or sycamore, they are very rigid, and answer the purpose very well. The form should be very light, in order that it should not interpose too great a bulk. The instrument invented by Laennec has been used for a long time, and there are many others of a very inferior kind in point of power, particularly for the weaker sounds; and, therefore, we must get an instrument as portable as possible, and as thin as we can have it, consistently with durable strength and rigidity. The trumpet-shaped stethoscope extends over a large surface, and therefore the contact is better, and I doubt if any instrument for the purpose is better. The only objection to this instrument is, that it is fragile, and soon gets broken; Laennec very effectually modified the shape of the instrument, by carefully listening to the sounds of the chest.

The theories in regard to the sound of the instrument were very erroneous. He found that an instrument without a stopper transmitted the sounds a great deal better than that with a stopper; yet he found that a sound, produced in a particular spot, of considerable intensity, could be heard through the stopper, but the sounds that are more diffused would be shut out by that means. This afford a means of distinguishing between the diffused fremitus of the voice, sometimes the natural bronchophony, and the more perfect bronchophony; and by using an instrument with a stopper, those sounds only that are intense and isolated and produced in a given spot can come through; whereas with the instrument used without a stopper, these sounds are not so readily transmitted. Now this is obviated by having a head-piece made of the same thickness and density, so that the solid part shall shut out the vibration of the chest, and the vibrations transmitted chiefly by the central channel.

I now proceed to some practical illustrations of these phenomena, and the mode of examining the chest usually pursued. First of all with regard to the visual examination of the chest by sight and touch. The patient should be placed in a good light, and you should place yourself in such a position that you can see the motions of the chest, and you should then desire the patient to take a deep breath rather freely. (The lecturer here proceeded to exemplify this mode of examination by a living model.) In order to secure accuracy, it is necessary not merely to use percussion by several strokes, but also it is requisite to vary the state of the respiration, in order to try whether there are any differences in the full expiration. Great care should be taken to keep the arms in a symmetrical position. In the application of the stethoscope, the object is to get the sound as perfect as possible; and to do this, you should place the instrument in firm and close contact with the wall of the chest, so as to get no superficial sounds from the exterior; and when you have so placed the instrument, apply your ear flat upon it. This instrument is made use of in measuring the respiratory movements, and as we shall see when we come to examine the subject of the heart, it is a valuable instrument in measuring the impulse of that organ. The following is a table of the

SOUNDS PRODUCED BY THE PASSAGE OF THE AIR SOUND OF RESPIRATION.

NATURAL.	By collision of the air against the sides and angles of air tubes.
Tracheal.	Heard in the neck at the top of the sternum.
Bronchial.	Near the upper parts of the sternum between the scapulæ, &c.
Vesicular.	In most other parts of the chest.
MORBID.	Modified in production or transmission.
Bronchial.	Or whiffing, transmitted from the bronchi by the condensed tissue of the lung.
Cavernous. *Amphoric.*	Produced in morbid cavities communicating with the bronchi.
RHONCHI.	Produced by increased resistance to the air moving through the lungs.
Sibilant. *Sonorous.* *Dry Mucous.*	Produced by viscid mucus in the bronchi, or by swelling of the membranes, or by pressure upon them.
Mucous.	Produced by the bubbling passage of air through liquid in the bronchi.
Submucous.	Produced by the bubbling passage of air through liquid in the finer bronchi.
Subcrepitant.	Produced by the bubbling passage of air through liquid in the smallest bronchi.
Crepitant.	Produced by the bubbling passage of air through liquid in compressed smallest bronchi.
Cavernous.	Produced by the bubbling passage of air through liquid in a morbid cavity.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

(LECTURE VIII., Delivered December 10, 1842.)

GENTLEMEN.—I have gone over the subjects of inflammation, congestion, apoplexy, and other diseases of the brain, which may be called *dynamic*; before I dismiss this subject entirely, I will just make an observation or two on those diseases which may be called *adynamic*; which as you have already perceived, I have not been able to enter into more fully. One of the diseases which I call *adynamic*, is the disease called *delirium tremens*, and another disease that may be called adynamic is that state of the cerebral system which comes on in cases of extreme loss of blood. It is a very common kind of disease, and it appears to be connected not entirely with the loss of blood, but with a state of the intestinal canal, and the general system, at the same time.

With regard to *delirium tremens*, congestion gives you the true principle and the diagnostic symptoms of the disease, and, as I said before, there is nothing so much to be avoided in this disease as blood-letting. I never can forget having been called to a patient, an athletic young man, by no means apoplectic, affected with *delirium tremens*. Before I went to him, the practitioner had taken from that young man twenty ounces of blood. He was an athletic young man, whose powers were entirely at the healthy standard. He never recovered from that loss of blood; he could not be recovered from that state of depression into which the blood letting had thrown him. I believe that blood-letting was altogether, from the beginning, erroneous, and therefore ought not to have been instituted at all. I need hardly tell you the remedy is opium. The object is to get the patient to sleep, to quiet the symptoms by opium, whilst you are attending to other symptoms that may be wrong.

Respecting that state of things that comes on in puerperal disease, which arises from intestinal irritation and also partly from the loss of blood, this is very important to be attended to, and requires active treatment from the beginning; there is an unhealthy state of the intestinal canal. There are two other sources of it which ought not to be overlooked, and one is the administration of mercurial purgative medicines: and I have known this to be the immediate cause of the symptoms I am alluding to; and the other exciting cause is indigestible diet, which tends to produce that series of symptoms I have before described; excruciating pain, violent intolerance of light, and violent intolerance of sound. I have to tell you that this is by no means an uncommon disease, for puerperal disease is the most common that you meet with in practice.

One remark more I must not fail to make:—that this state of things has frequently laid the foundation of puerperal delirium; and frequently, even, it comes on at once in a number of cases after confinement. What then is the practical remark to which I am led? It is this; in puerperal delirium you must view the causes of the disease, and must consider the patient under the influence of gastric or intestinal irritation; and under a state of exhaustion from a previous loss of blood. There are other causes;—mental alienation, and fever are among the principal causes of puerperal delirium, and puerperal anæmia. And without reference to these causes, it is impossible for you to go to the disease aright. Dr. Davey used to say, "the question is not *whether* the patient will recover, but *when* the patient will recover?" I have known many cases of fatal puerperal mania, and I could propose another question in the place of that of Dr. Davey,—whether the patient had been bled or not? For if the patient has been bled, be assured there is great danger, but if the patient be not bled, there is no question of danger at all; and then the question is just that put to the profession by Dr. Davey, not whether the patient will recover, but when he will recover? I consider a copious blood-letting under these circumstances, at any rate, to bring the patient into extreme danger, if not to a fatal end; therefore, above all things, in such a case, avoid blood-letting.

Now I want to go to the spinal system; and I must say a word respecting those diseases I have already alluded to, paralysis and hemiplegia. This may be partial or total. It may attack an arm or a leg, or the speech alone; it much more frequently affects the arm or the leg, and very frequently, the arm, the leg, and the speech. But sometimes it affects the entire side of the body; so that the patient loses the sensibility of the whole side of the body; he loses the power of the muscular system on one side of the body, yet never entirely. Cerebral paralysis is rarely complete. There is a case, last of all, in which a clot has passed into the vertebral canal; that may be attended with complete paralysis. However, in most cases it is partial.

The next remark I have to make is as to the state of things in long continued paralysis. First of all let me remark, that in cerebral paralysis, in the general form, the arm is much more affected than the leg, more frequently, and more permanently than the leg. It very often happens that the leg recovers, and the arm does not. Look as you go along the streets, and you see many a paralytic person with an arm in a sling, yet walking very well. If the leg were affected as well as the arm, that could not be the case; and incapability of walking would be the terrible effect of paraplegia. Remember then, the arm is affected more than the leg, and it does not recover so easily. The arm always suffers, comparatively speaking, more than the inferior extremities.

Now there is a very curious subject, I want to bring before you very briefly. I have told you about the arm being more affected than the leg:—now the fact I want to impress upon your minds is, that although the arm is more affected than the leg—the effect of a state of hemiplegia,—it is only the cerebral power that is paralysed, because the true spinal system remains intact; the true spinal system remains unaffected. What are the reasons of the true spinal system being unaffected though the cerebral system be paralysed? Why, the true spinal system is the source of tone to the muscular system. Now, suppose my hand is affected, and has more tone than usual; suppose it has nothing of voluntary power; I open my hand, and what is the consequence? The flexors will be in antagonism with the extensors, and the consequence of that will be, my hand will be more or less closed.

Then from other causes than hemiplegia the hand will be closed. I have known a hand drawn forcibly to the side, as if there was extreme and sudden pain at the side. Another thing, I told you that it was the cerebral system that was affected; how do I prove this? Why, in this manner. Suppose a patient be yawning; you uniformly find the paralytic arm raised and the other arm not affected at all. The paralytic arm is raised during the act of yawning. Suppose the patient is agitated by any means; it is always the paralytic arm that is agitated. If from any cause the paralytic arm moves, it shakes.

Now, gentlemen, as to the cause of all this. Look at the irritability of the muscular fibre. You may test this by galvanism; put the hands in a basin of water, and let the galvanic shock pass through the water, and the muscles are completely irritated. Now submit a paralytic patient to the same thing, and you will find that the paralytic hand will shake. All this will prove that there is a greater irritability in the paralytic limb than in the non-paralytic limb. You thus account for the whole phenomena respecting emotion. Go to a patient, and you find that patient agitated by your approach. Why is it that the paralytic limb is agitated more than the non-paralytic limb? This is the reason. The same power of motion passes into all the extremities, all alike; it passes along the channels unaffected, to the right, and to the left, equally. Why does it shake the paralytic limb more than the other? Gentlemen, because it is more irritable than the other. How do I show this? In the first place, I must take it as a principle, that every time a muscle is exerted, its irritability is diminished—every time you use a muscle, that muscle loses its degree of irritability; and, therefore, a person after violent exertion, will have less irritability in the muscular fibre than a person after sleep. Sleep restores it, and exertion diminishes it. Now compare the two limbs, the one used, and the other not used. In one case, the irritability of the muscular fibre is exhausted—diminished; in the other, it is allowed to remain. Now, trying the effect of emotion, that would go to show that the shock would affect the limb most irritable. I exemplified this in a peculiar way on one of my patients. I told him to put one hand in a basin of water, and pass the galvanic shock: he came to me and told me the paralytic limb shook most. Therefore, you have these phenomena accounted for.

There is one other fact I must notice. If you give strichnine to a hemiplegic patient, what happens? By and by, you see the spasmodic effect of the strichnine in the contractions of the muscular fibres, but the paralytic limb is affected first, (the power of the strichnine extends to the right as well as the left,) and the paralytic limb is affected more than the other. This may be said to be through what appears to me a connexion with the cerebral function, which diminishes the irritability of the muscular fibres.

I will just now conclude this subject with one brief observation; that however true all I have said to you is with regard to cases that have lasted long enough to produce these changes, yet in exceedingly old cases there is an exception to the rule. Suppose the case of a paralytic limb of very long duration, in hemiplegia, so long is there an increased irritability in the muscular fibre of the limb in connexion with the spinal marrow—a considerably augmented irritability,—but in the limb in connexion with the brain, there is an exceedingly diminished irritability.

I am afraid I have taken up too much of your time with this matter, but I thought it quite necessary to give as much to the subject of cerebral diseases. I must now draw your attention to the diseases of the true spinal system. These diseases like those of the cerebral system, are divided uniformly into two classes, those which for the most part affect the membranes, and those which for the most part affect the marrow itself. It is rare that an inflammation of the membranes of the spinal marrow exists without inflammation of the membranes of the cranium; so, therefore, it is rare to have inflammation or spinal arachnitis, without the complication of cerebral arachnitis at the same time. But it sometimes does happen. It is, therefore, important that I should describe the disease itself. Now what are the symptoms of arachnitis in the spinal canal. In the first place, I believe, you may often trace it to the common cause of exposure to cold. I remember a patient who suffered from this disease from having got chilled in a pouring rain. He came home attacked with spinal arachnitis. I must, however, observe, that a blow or any other violent concussion may be the cause of spinal arachnitis.

Now for the true symptoms. They are pain and spasmodic affection. If there are any other symptoms beyond these, they may be said to be spasmodic affections affecting particular parts of the muscular system. Now with regard to pain; you constantly find in practice, that a proposition is made, to press along the spinal canal and the vertebræ, and to determine whether there be pain. If this is done with any other view than to determine whether there be any affection of the vertebræ themselves, or the muscles, or the tendons, or the ligaments about the vertebræ, the practice is an utter fallacy, because no pressure along the spinal column will affect the parts *within* the spinal canal. If the object is to ascertain if there be any disease of the spinal column, the bones, or the ligaments, or the contiguous muscles, I have no objection to the proceeding. I have seen it commonly had recourse to when the question has been, not whether there was disease of the bone or ligaments, but whether there was any disease in the spinal canal. I say with regard to pressure, it does not assist your diagnosis, as to whether or not there be any disease in the spinal canal. Schofield recommended the passing of a sponge taken out of hot water along the spinal canal; this appeared to me better *a priori*. I tried the experiment, and found it to fail; I never could detect any symptoms of pain in the canal, even when the patient said there was pain in that spot. I do not believe that the pain is aggravated by this pressure. There is one measure that has been adopted, that of counter irritation along the spinal column: I have seen it tried, but not with any good effect. Generally speaking, if there is pain, the patient points out the locality of the pain, and you can point it out.

With the pain, as I said before, there is spasmodic affection, and in one case I remember, the patient could not open the two forefingers; that case consisted of pain between the shoulder blades, just about the origin of the nerves supplying the arm; the patient saw double,—there was a little strabismus, confirming the observation I made, that with spinal arachnitis there is probably cerebral arachnitis; these were the three symptoms:—pain about the nerves running to the arm, a little strabismus, from affection of the nerve of sight, and a peculiar contraction of the fingers. In other cases you have other spasmodic affections; for suppose it is higher up in the spinal canal,—you have some affection of the breathing. One of the most common symptoms of true spinal affection is the sensation of a cord tied tight round the waist; I suppose that must depend on some contraction of the diaphragm. I do not pretend to say it is so; indeed I am not able to trace it to any peculiar affection of respiration, and I am not able to connect it with any peculiar state, except this state of things. This cord, or tightening round the waist, however, I have noticed over and over again, in cases of this description. It is mentioned in all works that treat on the subject.

What other parts seem most liable to be affected? Those parts below the abdominal viscera; for instance, the sphincter of the rectum, in some cases, is partly contracted, and the sphincter of the bladder is partly contracted. In some other cases you find spasmodic affection of the lower extremities, so that the toe is drawn under towards the heel. In cases of spinal arachnitis, the symptoms are various in duration, but eventually they almost all terminate in a transition from spasm into paralysis. When it is no longer irritation of the spinal marrow, but compression, you have a transmission from spasm to paralysis; and when you trace that state of things having passed into paralysis—that paralysis being, not hemiplegia, but paraplegia, cutting the body as it were asunder, you may be pretty sure of some disease within the spinal canal.

What is the difference between spinal arachnitis and inflammation of the substance of the spinal marrow itself? I believe, there is much less pain, much less spasm. In softening of the spinal marrow itself, you have no inflammation of the membranes of the spinal marrow; therefore, in these cases, if you find pain and spasm, or any symptoms of that kind that imply the early state of paralysis, you may look rather to the affection being in the substance of the spinal marrow, than in the membranes. In one case, the most sudden I ever witnessed in my life, attended by the late Dr. B.——, the patient came to have complete paralysis in three or four days. Such a case I never before witnessed. Such was the rapidity of the disease, that one might be said to have been taken with amazement. I thought it would be like most cases of hemiplegia, but it was complete in less than five days. I was struck with that point, and so was the physician who attended the case, and who is now no more. That case was one of ramollissement of the spinal canal. Sometimes, gentlemen, you have the spinal canal affected by accident, or the spinal canal may be affected by compression from that cause. Here the case was represented by a person who fell from a height on his head, so as to fracture the spinal vertebra, dividing it into two. Here you have perfect paraplegia, suddenly brought on by that accident. There is another case of a very different kind—the most interesting you can imagine; on the posterior part of the body of the vertebra, and, therefore, touching the anterior part of the spinal canal was a very small exostosis. It was a patient attended by the late Dr. B.—— the patient was drawn as it were double. All that could be done was to allay the irritation of the anterior column of the spinal marrow; for years and years he had been suffering agony of pain. You see what an important confirmation this is of the theory of Sir Charles Bell, namely, that whilst the posterior column of the spinal canal is for sensation, the incident nerves of the anterior column are for motion. Here you have an exostosis, a sort of vertebral cyst irritating the anterior column of the spinal marrow and producing a doubled state of the animal frame, the patient suffering torture and spasmodic affection.

Such, gentlemen, is a general description of disease within the spinal canal; there are various others to which I can hardly do more than just refer. You find ossification of the membrane; portions of the arachnoid ossified, ramollissement of the spinal marrow. Now I have to introduce a subject I have not yet touched upon, and it is a point which requires a careful attention, in order to understand to what it leads. You are aware of what I said respecting reflex actions; you dash cold water on the face, and an impression is made on the nerve; it produces some effect; that is carried to the spinal marrow and sent back through all the other nerves to the muscles of inspiration. If you irritate the fauces, the impression goes round the nerve, goes to the spinal marrow, and is sent back again to the muscles of respiration, and vomiting is produced. In a child suffering from encephaloid diseases or hydrocephalus, you have this state of things; the eyelid closes by reflex action, and if the eye does not close there is an absence of reflex action. Why do I introduce this just at this moment? —Just to show what in the case of spinal disease does in fact form your diagnosis. You come to a case in which there is disease of the spinal canal at a certain point. Suppose the disease is severe, and the action of the spinal canal below that diseased portion of the spinal marrow is left; if then you were to apply any stimulus to the foot—and the best stimulus, I tell you, once for all, is a sponge taken out of hot water—not too hot, lest it should scald the skin,—or taken out of cold water; in either of these cases you will have the foot drawn up, and it will be by reflex action. Another means is to prick the heel—this produces reflex action, passing to the other leg. This is observed in cases of paraplegia, but in some cases it is not observed; and I believe that in the first stage of

this investigation respecting the true spinal system, that was considered almost a proof, an incomplete one it certainly was for the reason I now allude to. Suppose the disease, instead of being as before, is lower than the *cauda equina*, and all the spinal nerves close where the *cauda equina* terminates, between the last dorsal and the first lumbar vertebra,—suppose the disease is there, can you expect reflex action there? You observe the part that is cut off: you observe there is no spinal marrow; in order to have a reflex action, you must have the incident nerve left, and the reflex nerve left, and without this you can have no action. Therefore, you see the distinction between disease below the last dorsal vertebra, and disease above the last dorsal vertebra. In the former case you have no reflex action, in the latter case you have.

Now we come to the diagnosis of that. There is a fact of great interest in a physiological point of view. In some cases of entire paraplegia, you find that the patient is capable of becoming a father—of producing a child; and in other cases such an event cannot take place. If the disease is above the lower part of the spinal marrow, and a portion of the spinal marrow be left, there is no reason why such an event as this may not take place: but if there is no portion of the spinal marrow left, if the reflex part is not continued, it is obvious that such an event cannot take place; for the whole act of generation depends on the true spinal system, and you cannot have this in operation unless this organ be entire.

There is one more observation I wish to make to you, because it is interesting in a practical point of view, and in a diagnostic point of view. It seems that it is the opinion of many persons, and especially of one of the most eminent of our surgeons—that you may have in some cases, disease of the arms—extreme paraplegia of the arms, yet no paraplegia of the legs. Now it is quite plain that if you have disease above the origin of the brachial plexus, that all below that will be in a state of paraplegia. I believe the above phenomenon is diagnosticated from disease of the bone, but not from disease of the spinal marrow. Suppose there is disease of the bone above the origin of the *brachial plexus*; that will produce irritation of the parts through which the *brachial plexus* passes, the nerves will contract, and there will be paralysis of the extremity as the consequence. What then is the consequence of disease of the bone, not affecting the spinal marrow? You may have the arms affected and not the legs.

This terminates the diseases of the spinal centre. What have I to say respecting their treatment?—However, before I come to the treatment I must make one observation. There is an interesting paper by Louis, of Paris, showing that wherever there is disease in the bone, there is disease with it in the spinal marrow,—affecting the spinal marrow just as inflammation or ramollissement. Why do I mention this just now?—because the case is a curious one. Louis says, "we learned that in case of disease of the bone which produces paralysis, it is not by compression of the spinal marrow, because that is rare, but the contiguity of the disease of the bone leads to ramollissement" and he says that in this case an issue proved available, and the conclusion come to is, that in all cases of ramollissement or inflammation of the spinal marrow, an issue is the remedy. You must cup the patient along the spine until you produce some impression on the system; and I would recommend you to add to the cupping, counter irritation. Now I go further, and say that I believe of all the remedies for disease in the spinal canal, the most important is deep seated counter irritation. What do I mean by this? Superficial irritation is that produced by the application of blisters, mustard poultices, and other things of that kind; but deep seated irritation is produced by setons and cupping. I need not tell you that it is important the patient should remain in the recumbent posture, and every means of producing quiet should be attended to; purgative medicines should be administered: the patient should be kept extremely quiet, and nothing should be taken of a stimulant character; barley-water should be almost the sole diet during the first stage of the disease. After this, active measures may be adopted—as much as the patient can bear—leeches or cupping. Other remedies may be adopted, which I will not now advert to, because I cannot sanction them by saying that I have met with any decided case in which they have had a good effect.

Before I conclude, I must first advert to one or two points; the first of which is that the urine under the influence of the ganglionic system, is apt to become alkaline. I do not know that this leads to any mode of treatment; but it is a fact that every one should know; and the second point is that the skin on the sacrum is very liable to become affected with mortification. I need hardly say how important it is to attend to this point; I suppose it partly arises from continued pressure, partly from the escape of the fæces and the urine, and also from a morbid state of the ganglionic system in that part, by which nutrition and secretion are not complete. Another point is the case of stupor, as in cerebral diseases, in which the bladder is very apt to become distended, and the patient is only relieved by the passing of the catheter. Not only the bladder, but the rectum itself is disordered in this way; and, therefore, in all cases you must adopt measures, such as aperient medicines. This concludes my observations respecting spinal diseases.

HUNTERIAN ORATION.

(Concluded from our last.)

But Hunter's object was not only to dissect, observe, detail, and exhibit a mass of detailed facts in anatomy; he had far higher aims than that of a mere collector of facts, even in comparative anatomy; and his feelings on this point were sufficiently expressed when, in reply to an invitation on the part of Sir John Pringle, to collect all his dissections of the turtle, and send them to the Royal Society, he stated, "that the publication of the description of a single animal, more especially of a common one, had never been his wish."

Mr. Hunter was not only in possession of numerous and precise facts in anatomy: he approximated them—he compared them together, and by his superior genius, arranged them in the true order to be followed in comparative anatomy—that of organs; for, as has been well observed, if species is the object of comparison in zoology, organ is evidently that in anatomy. Of the successful manner in which Hunter disentangled and unfolded these organs, tracing them from one species of animal to another, and exhibiting their modifications, museum is his the faithful record; and his labours in this respect must assuredly be regarded as the first great attempt to arrange in systematic order the detached facts of comparative anatomy. When I represent his arrangement as that according to organs, perhaps I ought to add, to function, for although the former was the visible manifestation, the latter was the presiding idea. And the 4to. manuscript catalogue, the most valuable Hunterian document remaining to the College, derives its chief importance from the information it supplies respecting the scheme of arrangement, and the general physological principles intended to be illustrated by the different series of preparations. It was this circumstance which distinguished Hunter from the other most successful cultivator of comparative anatomy of modern times. He studied this important subject with a view to physiology—Cuvier with a view (chiefly) to zoological classification.

Unfortunately for the earlier recognition of Hunter's high claims in anatomy and physiology, these could not be fairly or fully estimated until his manuscripts were published, within the last few years, by the College, in the physiological catalogue explanatory of his collection. And what must not science, as well as his reputation, have lost in those ten folio volumes of manuscript so shamefully committed to the flames.

But Mr. Hunter's Memoirs and Essays on various parts of the Animal Œconomy distinctly shew the vast range of physiological subjects which his mind grasped. And those who seek to know what his powers of observation, reflection, and investigation, were capable of, would do well to read his papers on digestion, animal heat, respiration, and generation, and consult the corresponding parts of the physiological catalogue.

As the vital organs and their functions had occupied a large share of his physiological inquiries, it is not surprising that the views which he thereby acquired were made available by him in his investigation and explanation of disease, and in his treatment of it. The powers of the absorbent system, and structures and properties of blood-vessels, the properties of the blood, the reciprocal influence of the different organs on each other, and a number of other physiological truths, all occupied their place in his pathology and practice. If he may have rated the powers of the lymphatics too highly, and sometimes given them too prominent a place in his views of morbid action, he did not over-estimate the power of absorption—an estimate which, with his true appreciation of the cause of failure in the old operation for aneurism, led to one of the most brilliant improvements in the treatment of disease to be found in the whole history of surgery.

It is scarcely possible to praise this improvement too highly, so great in itself, so fertile in its results, for it has conferred life upon hundreds. It was not only that a safer and more successful operation was introduced, but this very safety and success led to its application to numerous cases of the disease, which, under the old method, durst not be meddled with, the patients being left to their fate.

Knowing that Mr. B. Phillips had been for some time collecting from English and foreign works the number of various surgical operations recorded, and their relative success, I applied to him to furnish me with the number he had been enabled to collect upon the subject of aneurism treated according to Hunter's method, and he has been so obliging as to furnish me with the following return. 389 cases of aneurism had been so treated, and the result 277 cures.

	Cases.	Cures.
Subclavian . .	80	46
External iliac .	79	62
Carotid . . .	74	59
Femoral . . .	113	77
Humoral . . .	30	24
Various . . .	13	9
	389	277

And when you consider that the operation, as an established one, has, of late years especially, been often performed without any record of it being published, you will perceive that I have not gone beyond the truth in asserting that it has conferred life upon hundreds.

Among his pathological essays, the one on inflammation of the veins may be mentioned with especial praise. He was the first who understood and explained the nature of the malady, and opened the road to the additional discoveries made since his time. In his paper on Intussusception, he ingeniously shews how the different varieties of the disease are produced; and in his Essay on the Formation of

Loose Cartilages in Joints, he satisfactorily explains their presence by a reference to pathological preparations. But the loftiest efforts of John Hunter are to be found in his work on the Blood, Inflammation, and Gun-Shot Wounds. The mode of investigation in this masterpiece—the application of physiology to practice—suffices to distinguish him from all preceding writers, and may be considered as the basis of modern pathology. Its influence is felt not merely in surgery, but in medicine, for its principles are catholic. Up to the time of Hunter, surgeons were content to take their general view of the nature of disease from physicians. He emancipated them from their trammels, and established a body of doctrine so sound that it has wholly superseded the airy theories of medicine previously current. Nay, it seems to have stifled similar phantasmata in their birth, for since the days of Cullen and Brown no new *system* of physic has obtained the slightest vogue in England.

Hunter's consummate skill in the experimental investigation of physiological questions has been often and most deservedly extolled. That famous experiment with the egg—the most brilliant thing done with an egg since the days of Columbus—has set the question of vital heat at rest for ever.

"I put an egg," he says "into a freezing mixture at zero, and froze it, and then allowed it to thaw. Through this process I conceived that the preserving power of the egg must be lost, which proved the case. I then put the egg into a freezing mixture at 15 deg. and with it a new-laid one, to make the comparison on that which I should call alive, and the difference in the time of freezing was seven and a half minutes, the second one taking so much longer to freeze."

This experiment, and those which follow, may serve to shew John Hunter's mode of advancing in knowledge. By a scrupulous observation of facts, he gradually ascended from the particular to the general, instead of assuming a principle *a priori*, and bending facts to square with theory. I cannot, in short, praise his method more highly or more justly than by saying it was the one pursued by all who have obtained a lasting reputation, in ancient or recent times, as natural historians. It was this which enabled Aristotle to carry off laurels in the field of zoology, as immortal as those which he carried in metaphysics and dialectics. He was one of the greatest observers that ever existed, says Cuvier, and had the most extraordinary genius for classification that nature has hitherto produced. Some of his aphorisms, adds the same great authority, from their generality presuppose an immense number of observations.

It was upon this that Galen's great reputation was primarily founded. He was one of the most successful prosecutors of anatomy of his time, although obliged by its prejudices to content himself with the examination of animals, and consequently falling into error when the structure of man differs from theirs. He made many discoveries in anatomy and physiology. He was the first to prove by experiment that the arteries did not during life contain air, but blood; and the first to shew by their section the influence of the recurrent nerves on the voice, which nerves he discovered and traced to the larynx.

It was this method, which, revived by the great triumvirate of Italian anatomists of the sixteenth century, Vesalius, Eustachius, and Fallopius, was followed by Fabricius and our countryman Harvey, and which was established by Bacon, as the true logic of science. Their undying reputation proves its success, and when we impartially weigh what Hunter accomplished, we need not fear to compare him with the shining lights that had gone before.

In order, however, to form a just estimate of his comparative merits, we must look at the circumstances in which his rivals in the fasti of science were severally placed.

Thus, the position of Aristotle was most favourable, and both he and Galen received the best education which opulence and the severe discipline of Ancient Greece combined, could confer in philosophy and literature. In modern times Fabricius and Harvey, with the triumvirate I have mentioned, were equally fortunate, and if we pass from these eminent forerunners of Hunter, to Cuvier, his distinguished successor, we shall find that he also had walked from his childhood in the paths of learning and science. His early education was the chief employment of his mother—a woman of superior understanding united with the greatest tenderness. Without knowing the language, she made him repeat his Latin lessons to her; thus practising unconsciously perhaps, a precept of Locke. He drew under her eye, and she made him read numerous historical and literary works. "It was thus," says M. Flourens, "that she developed and fostered that passion for reading, and that extended curiosity, which, as Cuvier says in his memoirs, were the mainsprings of his life."

At the academy of Stuttgardt, Cuvier received an excellent education, and when driven to battle with the necessities of life at 18, and seek a subsistence in a foreign land, he was rich not only in knowledge, but in the confidence acquired by the constant successes of his scholastic life.

The career of John Hunter differs from the others I have enumerated in one very important point. His father died early, and it was his misfortune to have a carelessly indulgent mother, so that he passed his boyhood in sauntering, in country sports, and in cabinet-making. It was not till the age of twenty, that hearing of his brother's success, he gave up the *dolce far niente* for the rest of his life; came to London—entered William Hunter's dissecting room, and worked as few have worked before or since. Poverty and contempt had been imminent, but he burst with giant strength the bonds of habit which confined him, and escaped from the threatening spectres for ever.

This triumph achieved, the rest was comparatively easy. After this, we must no longer consider his career as an instance of "the pursuit of knowledge under difficulties." On the contrary, he had many special advantages.—"He began," says Sir C. Bell, "to work for himself on the excellent basis of his brother's labours." William was a man of good education, an accomplished anatomist, and rising into practice as an accoucheur. He had begun to form his museum, and his house gradually became the resort of those who wished to advance the art which they practised. Nor must we omit the important fact, that this brother, whose public and private tuition was destined to develope the genius of John Hunter, was ten years older than himself; a difference which would enable him to add something of paternal authority to brotherly persuasion. The same advantage was enjoyed by Charles Bell, and we have already seen with what fruits.

Yet, great as these advantages were, backed, too, by splendid genius and unwearied industry, did they entirely compensate for the want of early education? Some answer, "Yes;" nay, it is even a question with them whether a better and more learned training might not have stunted that eager curiosity, that faculty for observation, that power of generalizing, which he possessed in so eminent a degree.—This cannot be determined now; for instead of knowing the whole history of his feelings and attainments, some fragments alone have reached us: but it is very certain that a learned education had not this freezing power with those distinguished men to whose career I alluded just now. And then, reflect on the advantages which good training gave them.—Take Cuvier, for example. Whence did he derive the clearness of his descriptions, and the facility of his style both in written compositions and in oral communications? Whence but from the literary toils of his boyhood at Stuttgart? who, that sat on the benches of the amphitheatre at the Jardin des Plantes, will ever forget the impressions which he produced?

This clearness of expression cannot be predicated of John Hunter. When he gets beyond mere description, his language becomes obscure, and it is evident that composition was not easy to him. As a consequence of this, many of his MSS., among others the catalogue of his museum, were never completed. When we view him as a teacher, however, censure is swallowed up in admiration.

Nevertheless, it is said, that he was deficient as a lecturer; and he certainly seems to have wanted that vivid diction by which some men are enabled to enchain the attention of their audience, and lend the charm of novelty to the most familiar details. Sometimes, too, he appears to have been unable to express what he meant; and it has been boldly assumed, that, on such occasions, he had no meaning at all, and was "labouring with the delivery of nothing." Let us deem more nobly of John Hunter. Who can doubt that, in such instances, his mind was often wrapt in the dim vision of heights which he was not fated to ascend? What labourer in science or art, has not felt the force of the *nequeo monstrare et sentio tantum?* Without fluency and vivacity, however, a lecturer can rarely be popular; and hence John Hunter's lectures were but thinly attended. Like Milton, he probably was content if he could "a fit audience find, though few;" and he might, indeed, have been satisfied could he have anticipated the future glories of his pupils. Let us estimate his lectures, not by a cold analysis, but by their effects. When Demosthenes had thundered forth a Phillipic, the Athenians did not say, "What a fine oration!" but, "let us march against Philip."

The notes of John Hunter's lectures which have come down to us do not contain many specimens of his peculiar manner. The account of the treatment of cancer, however, is an example of his strong, unsparing good sense conveyed with extreme familiarity of style.

"No cure has yet been found; for what I call a cure is an alteration of the disposition and the effects of that disposition, and not the destruction of the cancerous parts, which extirpation, however, will often cure, as well as we could do by changing the disposition and action. Arsenic seems to have some power of this kind; and its effects might be increased by being used internally and externally; but its use is very dangerous, and, I am afraid, insufficient for the disease. This is a remedy which enters into the empirical nostrums which are in vogue for curing cancer; and among which Plunkett's holds the highest rank. But this is no new discovery; for Sennertus, who lived the Lord know how long ago, mentions

a Rodriguez, and Flusius, who obtained considerable fame and fortune by such a composition. I was desired to meet Mr. Plunkett to decide on the propriety of using his medicine in a particular case. I have no objection to meet any body. It was the young one. The old one is dead, and might have died himself of a cancer for aught I know. I asked him what he intended to do with his medicine. He said, 'to cure the patient.'—'Let me know what you mean by that. Do you mean to alter the diseased state of the parts? or do you mean by your medicine to remove the parts diseased?,'—'I mean to destroy them,' he replied. 'Well, then, that is nothing more than I or any other surgeon can do with less pain to the patient. Poor Woollett, the engraver, died under one of these cancer-curers. He was under my care when this person took him in hand. He had been a life-guardsman, I think, and had got a never-failing receipt. I continued to call on Woollett as a friend, and received great accounts of the good effects: upon which I said, if the man would give me leave to watch the appearance of the cancer, and see myself the good effects, and should be satisfied of its curing only that cancer (mind, not by destroying it,) I would exert all my power to make him the richest man in the kingdom: but he would have nothing to do with me, and tortured poor Woollett for some time, till at last I heard the sound testicle was gone, and at length he died."

I have stated that Mr. Hunter's lectures were but thinly attended, but that he might have been satisfied could he have anticipated the fame of his pupils. Among those who lived in his house, there were several who attained great eminence in their profession. But there were other pupils of his who had not these advantages, and yet drank deeper—far deeper—of the spring open to all. Among them may be ranked Poli, Scarpa, Blumenbach; and others who, fortunately for the progress of surgery, developed some of his favourite ideas with more fulness and precision than their master himself, and strove to instil into their scholars the doctrine and practice of their great instructor.

One of the most distinguished of these was Abernethy. In his Essay on the Constitutional Origin of Local Diseases, he has most ably made out his point; and, both in the treatise and in his lectures he surpassed John Hunter in the clearness with which he laid down the principle, and the practical tact with which he followed this law into its consequences.

Sir Astley Cooper, a still more illustrious man, was numbered among his pupils, and excelled him as a practical surgeon as much as he fell short of him in the qualities of a philosophic teacher. Every work of his was based on the most patient anatomical examination, and thus became a faithful commentary on nature herself. His treatises on Hernia, on Fractures and Dislocations, and on Diseases of the Breast, might found a reputation singly: what have they done united?

John Thomson, too, still left to us, was another pupil of Hunter's, who, in his celebrated work on Inflammation, followed out in a kindred spirit the views of his great master.

It is probably not going too far to say, that to the veneration in which these three distinguished men held the opinions and example of John Hunter, and their constant reference to him in their lectures, the propagation of his doctrines, and their influence on English surgery, has been mainly owing.

I will not detain you by observations on the personal peculiarities and failings of John Hunter; but there is one anecdote, which exhibits so strongly his practical tact, as well as his Johnsonian style of coming to the point, that I cannot refrain from quoting it.

He happened one day to call on Mr. Nicoll when his wife was pregnant for the sixth time, and took the opportunity of asking him whether he intended to kill this as he had killed all the rest of his children. Mr. Nicoll, it seems, had adopted what is called the hardening system with all the previous ones. Not understanding the question, however, he asked John Hunter what he meant. "Why," said John Hunter, "do you know what is the temperature of a hen with her callow brood (chickens), because if you don't, I'll tell you." He then proceeded to explain the necessity of warmth to young animals, and convinced Mr. Nicoll of the propriety of changing his plan, which he did, and with complete success.

It was finely said by Dr. Beddoes, that "when one heard that Hunter was at length the first surgeon in London, one felt a satisfaction like that which attends the distribution of poetical justice at the close of a well-told tale."

With this sentiment the intellect and the heart must alike agree; the honest and the clear-headed must equally exult in the ultimate success of John Hunter. Yet I will observe, in conclusion, that, had his career been cut short at an earlier period, he would not have laboured in vain, far less would he have lived unhappy. Unlike him who toils for gain alone, and whose praise is measured by the wretched gold which he has accumulated—unlike the warrior or the statesman, who must appeal to success for justification, and whose failures are reckoned as crimes by exasperated nations—the man of science labours in a genial field, where exertion is its own reward; for while the worshippers of power and wealth are sickened by each trifling disappointment, the humblest acolyte in the temple of knowledge feels that it is good to be there, and that even failures are but lessons. The pursuits of the scientific inquirer, when carried on in a right spirit, stand second to none among all the subjects which can occupy the human mind. Though faction and avarice unceasingly murmur in the vicinity, his mind remains unruffled by their clamour. Like the fleece of the Hebrew leader, while all around is parched, he alone is fostered by the gentle dews of heaven.

A SURGEON'S EXPERIENCE ON MESMERISM.

To the Editor of the 'Medical Times.'

SIR,—Allow me through the medium of your scientific and impartial Journal to state one or two points, more particularly for the information of the learned editor alluded to in your paper of the 11th inst., as to the importance of mesmerism in the alleviation of disease. I was called in haste in September to visit S.P., aged 18, affected with fits; on my arrival I learned that she had twelve in the previous four and twenty hours; she complained of great tenderness, in the spinal cord on pressure, region of the liver and pubis: catamenia suppressed for the last two months, in consequence of cold caught after their last appearance: she presented altogether an aspect of great debility. Leeches and blisters were applied to the spine and side; hip bath, with Mist. Ferri Co. and sulphate of quinine, and on the accession of the fits, assafœtida, enemas, &c. Notwithstanding these and other active remedies, the fits obstinately persisting, I mesmerised her at the first sitting in five minutes; she awoke in fifteen minutes, expressing herself inclined for further sleep; the next day I mesmerised her again, the fits having decreased to six in the 24 hours; in short I continued to mesmerise her every second day till quite free from fits. Her strength has returned, and it is now two months since she has had a fit. The other was that of a young woman, aged 19, similarly affected with chlorosis and fits; the chlorosis was removed by the usual remedies, but the fits still continued. I mesmerised her at the first sitting in two minutes, the fits have not returned, and she expresses herself as feeling the next day increased spirits and appetite. Now, Sir, I do not mean to recommend the indiscriminate employment of this agent in every case, nor substitute it for acknowledged remedies, but where there is no cerebral affection, I should not hesitate to employ it: it strengthens the nervous system, improves the digestion, and tranquillises the mind.

I have the honor to be, Sir,
Your obedient servant,
W. BOYTON, Surg.

Watlington, Oxon.

NOTICE.

Our next number will be one of extra size, containing 72 columns, and will be exclusively dedicated to pharmaceutical medicine. The chemist, the druggist, the general practitioner, will on seeing it, own that so much interesting scientific matter was never presented to them at so cheap a price, viz. 4d., or 5d. stamped. The ingredients of all the celebrated patent medicines—the improvements and discoveries in medicine during the last thirteen months, will be two among the numerous articles published. We shall feel obliged if our medical friends will communicate this intelligence in quarters where it may be of service.

TO CORRESPONDENTS.

Mr. Hands is thanked.

A. H. and others.—*The Excise prosecutions of Druggists will form a subject for observation next week.*

Mr. Eggis.—*Of course the Coroner has the power to award him remuneration, and if he refuses under the circumstances will be held guilty of a misdemeanour.*

M. R. C. S.—Mr. H. W. Y.—Inquirer—Spes—*declined.*

The case by Dr. W. does not suit us.

A. Z.—*Of course it is illegal.*

Mr. Prankard's communication has been received and will be noticed in our next number.

Quiz is severe on Mr. Burgess, the former chiropodist and subordinate attendant of the subordinate ambulatory infirmary lately in Blenheim Street, and now Heaven knows where. But not more so than he deserves. The accusation we launched against him lies unrebutted, an accusation which no gentleman could have deserved, and which no innocent man would lose an hour in disproving. We are sorry that we cannot, from want of space, insert our correspondent's note.

M. D.—*The fee for attendance, with a post-mortem examination, at a Coroner's Inquest is fixed by the Medical Witnesses Bill at two guineas.*

"*An enemy to injustice" will see that attentive to our duty we have anticipated him. If we do not compel Mr. Wakley to do justice to medical men it shall not be our fault.*

Mr. Self.—*We like not that paradoxical entity "Old News." This is our explanation.*

THE MEDICAL TIMES.

SATURDAY, MARCH 4, 1843.

Let me wring your heart, for so I shall
If it be made of penetrable stuff,
If damned custom hath not brazed it so,
that it be proof and bulwark against sense

PREPARING our readers for a rude shock to their sensibilities, we solicit their attention to the following alarming announcement in the last week's *Lancet* :—

"*Scandalous Trick subsequent to an Inquest.*—In inserting the following communication, which appeared in the *Times* newspaper of Wednesday, February the 21st, we have merely to remark, that we shall have something additional to publish on the same subject on another occasion. The *inquiry* cannot rest at its present stage. That *a scandalous fraud* has been committed, little doubt can be entertained by any *impartial* person, and we believe that we shall be enabled at no very distant time to drag the REAL CULPRIT before the public."

We are thus, then (if, forgetting our usual rule of interpretation, we do not hold this as Mr. Wakley's solemn pledge of future silence), to have an inquest on an inquest, and as Mr. Wakley—at least, while it pends—lies under a suspicion of Coronatorial incapacity, we will do him the favour of conducting it ourselves. The honourable member's reputation, as defunct *pro tempore*, is of course the subject of our inquest, and it will certainly be no fault of ours, if our exertions shall not aid—as he anxiously wishes—in "dragging the *real* culprit before the public." As, however, it is quite possible that our verdict may reveal a case of *felo-de-se*, we must, for the present at least, deprecate any more active interference on the part of Mr. Wakley, than may be justifiable in a suspected character, on his trial. Expert as he is in London life, he knows that "Stop thief" is the usual refuge of the humbler brethren of his craft, when hotly pursued by the inexorable policeman: and too much splutter about "scandalous frauds," and "dragging real culprits before the public," might sadly perplex simple and impartial "*Coroners*" like ourselves, novices in the infinite highways and byeways of roguery.

The first witness we shall call shall be a witness for Mr. Wakley, with whom, by *temporary* circumstances, he is condemned (so he intimates) to hold for the occasion common cause. The gentleman's name is Rowley, and carefully forewarning the public that he really is not the celebrated Old Rowley whom Chatterton thought it worth while to personate, we publish his important evidence *verbatim et literatim.*

"*To the Editor of the Medical Times.*

SIR,—In your weekly journal, published on Saturday, the 25th February, you have measured your opinion of the coroner and jury in terms not very liberal, nor with even-handed justice to either party, respecting the inquest held on Mr. Pledger. You say, 'The verdict was dictated by an ignorant and impatient coroner, and accepted by a silly jury, before whom not the least atom of reasonable, nay, attainable data, was allowed to be produced.' In justice to myself, to the fellow-jurymen with whom I acted, and to the coroner, I must request the favour of you to insert in your journal the enclosed statement, which appeared in the *Times* last week. The facts are there stated as they occurred; and having given your own version of this statement, I think it but fair that you should insert the statement itself, and leave the public, or those who take an interest in these matters, to judge for themselves. What you have set forth is far from being true, viz., that the jury had no data to form an opinion upon. I have no desire, or wish, to put myself between you and the public, as an advocate of Mr. Wakley's conduct as coroner, nor to discuss the opinion you entertain of that gentleman. He is able to defend himself. I, personally, know nothing of Mr. Wakley; never having seen him, or spoken to him, but on the occasion upon which the inquest was held; but, as you have attacked the common sense of the jury upon the false premises you have assumed, in a public journal; you should, by the same means, acquit them of the silly and culpable conduct that you have attributed to them.

I am Sir,
Your obedient servant,
THOMAS ROWLEY.
Foreman of the Jury.

Hornsey, 27th Feb., 1843.

Now, in acquitting our office impartially, we feel bound to notice, as attaching more weight to Mr. Rowley's testimony, the important fact (*duly* and *impressively* mentioned) that his respectability is not impeached by even a single hour's acquaintance with Mr. Wakley. If we well understand our friend, the essential difference between us is, whether it shall be *we*, or *he*, who shall write him down "silly." Though having evidently the stoutest opposition to be written down by special desire, Dogberry-like, "an ass," he seems the readiest creature in the world to lay down the same truism in an autograph; and while making him our acknowledgments for his humble and most obliging facility, let us hope that as we have both tried our hands at the game, to his especial humiliation, the duplicate assurance will not render his Christian conviction the less satisfactory, nor his night's rest the less composed.

The document to which Mr. Rowley refers us is certainly one of *peculiar* interest. It is signed by the jury, and affects to give "refutations to *certain* of the allegations" contained in the *Times'* statement, published in our last number. Here it is:—

The inquest was held on Tuesday, the 7th of February, and it is stated by the writer of the paragraph, published in *The Times* of the 16th inst., that "reports were soon spread that he (Mr. Pledger) had died from the effects of poison." We reply that no such reports existed at Hornsey,—no suspicion whatever was entertained there that Mr. Pledger had either destroyed himself or had taken poison.

The writer further states that the report that Mr. Pledger had so died "came to the ears of the parish beadle," who "thought it is duty to circulate the report, by waiting upon Mr. Wakley, the coroner." The beadle, Mr. Crouch, has this day stated in our presence that, previous to the inquest, he never heard, and therefore never conveyed to the coroner, any such report.

Lastly, it is stated in the paragraph that "the coroner is reported to have used the following words, at the same time lifting up the deceased's head, 'Ah, gentlemen, this is a sudden death; the man has died from a diseased heart, 'I've no doubt; there will be no occasion for a medical man."

At the inquest one of our number said to the coroner (after the testimony of three witnesses had been given), "Should not the medical man who saw him after death be called in, Mr Coroner?" to which the coroner replied in the following words:—"I have no opinion to give, Sir; but, if you have any suspicion that he died from any other than a natural cause, then there must be an examination of the body, as it is quite useless to have him here for the mere purpose of stating that he does not know what was the cause of death, for it is certain that he could not tell you that cause unless an examination was made."

One of us then stated that not the least suspicion was entertained that the death had occurred from any other than a natural cause, and another juryman confirming this (and the opinion was unanimously agreed to), added (as expressive of the feeling of the whole jury), that we did not consider, as neighbours well acquainted with the deceased, that there was the least necessity for the evidence of a medical gentleman.

On the coroner being asked what he himself considered was the cause of the death, he replied, "that he had had too much experience in the office of coroner to speculate on so obscure a matter;" that an external view of the body was in nineteen cases out of twenty of sudden death, medically considered, perfectly useless, and afforded no medical information whatever;" and that "if any doubt or suspicion of wrong doing in the present case was entertained by only one of the jury, a majority of them had the power to direct him to summon a medical witness to appear at the inquest to satisfy their doubts by a post-mortem examination of the body." The jury again gave the coroner to understand that no such doubt or suspicion existed amongst them.

The first witness who was called before us was Caroline Martin, a servant of the deceased, who stated, on oath, that she found him, at eight o'clock in the morning of the 4th of Feb., lying insensible, and perhaps dead behind the counter in his shop, which he had just before gone to open; that she at once called in her fellow-servant, and that the dead body was taken into the parlour adjoining the shop; that a surgeon, Mr. Hands, was sent for immediately, and came and examined the body externally; that she had seen the deceased on the night before, that he then seemed to her to be perfectly well and in good spirits, and that he did not complain of anything being the matter with him or of anything else, that he had not, that she knew, met with any injury or violence; that she had not the least reason for believing that he had taken anything to destroy himself, but that she believed he had died a natural death.

Martha Tribe, also a servant of the deceased, stated that she was called by the last witness to see the body of Mr. Pledger as he lay in the shop; that she had not seen him on that morning before, but had seen him at eleven o'clock the previous night; that he

most certainly, as she believed, did not destroy himself, that she had never heard him talk of destroying himself or wish that he was dead; that she felt perfectly assured that he had died from a natural cause, and not otherwise; that nothing whatever had occurred while she had been in his service to induce her to think that he had taken, or had ever contemplated taking, poison to kill himself.

Ebenezer Pledger, brother of the deceased, stated that he had seen the body of the deceased about an hour and a half after he was found dead; that no circumstance whatever had occurred to raise a suspicion on his (the witness's) mind that his brother had destroyed himself, and that he was thoroughly and perfectly satisfied that his brother had died from a natural cause.

In short, Sir, there could not be elicited from the witnesses, during the examination, the slightest evidence to induce us to believe that Mr. Pledger had taken anything to produce his death. He had resided in the village of Hornsey for nearly nine years, and from his general conduct, not one of us entertained the least suspicion of his having taken poison. In fact not any doubt was felt amongst us that his death arose from any but a natural cause. No influence was used by the coroner to affect our decision other than the clear exposition of his views that he stated as above quoted.

This document is followed by a letter of Mr. Crouch, constable or beadle, in which Mr. Hands, the surgeon, is made to say to him, in private conversation, immediately after the death, that the cause of the catastrophe was diseased heart and apoplexy. The worthy witness further attests that, *till ten days after the inquest*, and thirteen after the death, neither he, nor any one he had seen, had heard any rumour that the death was caused by poison; and that, up to the moment of writing (Feb. 20), he firmly believed "that the death was natural!" The only remarks this calls from us are, the rather incredible condescension of the truly respectable Mr. Hands, in giving the worthy beadle gratis, off-handed, medical opinions; and the absence of village gossip characterizing Hornsey, when an autopsy, performed the day after the inquest, in the presence of four persons, and revealing such an extraordinary result, should have been utterly unknown in the extended gossipping circle of the veracious Hornsey beadle and constable!

We have, next, Mr. Ebenezer Pledger, a very young man, brother of the deceased, who thus writes:—

After a careful consideration of all the facts and circumstances relating to the death of my brother, Henry Pledger, and all the recent events of his life, I feel perfectly assured, notwithstanding the allegations contained in a paragraph in *The Times* of Feb. the 16th, under the head of 'A Slight Mistake,' that my brother died a natural death, and did not take poison to destroy himself.

Now, the first fact we have to mention is, that the jury's statement, though recording conversations with the verbal precision of an able short-hand writer taking them down at the moment, was written on the *fourteenth* day after the inquest. The second is, that the statement does not profess to give an account of all that occurred, and, being *ex parte*, may be presumed, of course, to give nothing but what suited the defence of men who thought themselves on their trial. The third fact is, that the statement does not deny the assertion, though it distinctly mentions it, that the coroner, lifting up the deceased's head, said, "Ah, gentlemen, this is a sudden death; the man has died from a diseased heart, I've no doubt: there will be no occasion for a medical man." The fourth fact is, that none of the statements were written by the parties pretending to write them—THEY WERE WRITTEN BY MR. WAKLEY'S CLERK! *He dressed them up—carefully, ingeniously dressed them up—and it was from no deficiency of diplomatic finesse, that, after much difficulty, he got them signed.* This is an important fact, on which too much stress cannot be laid. The jury could not be trusted to give their own story: and the wily clerk concocts a tale for them, which, when they were all assembled, at a *public-house*, (at whose expense?) for the benefit of *one* of them *(for the landlord was a juryman)*, they were, after some little *troublesome scrupulosity*, poor honest countrymen, diplomatized to sign! Do we find scintillations, *here*, of the "Scandalous trick subsequent to an inquest?" Do we discover, *here*, matter that tends in some little force "to drag the *real culprit* before the public?" "That a scandalous fraud has been committed, little doubt can be entertained by any impartial person!" We thank thee, Jew, for teaching us that word!

That the jury believed, or thought, Pledger to have died a natural death, we have no doubt. Had they known him to have been poisoned, we could not have given them the epithet, "*silly*." But whose the fault? Scarcely theirs; for, to do them justice, they did enquire from two of the three witnesses they were allowed to examine, and with a care that apparently amounted to *strong*, but ill-directed suspiciousness, whether the deceased had said or done anything intimating the design of suicide. The brother, the third witness, is asserted—we know—by the clerk, to have been also asked a similar question; but as he has admitted, in the presence of a gentleman connected with our office, that he *knew* of his brother having deliberately spoken of suicide as a desirable consummation to him, we must be pardoned for disbelieving, on the interested writing of a clerk—that clerk the coroner's dependent—that the young man unnecessarily and uselessly perjured himself at the inquest. We say, the fault was the coroner's, though the weakness and silliness was the jury's. He it was that gave them the notion of there being a diseased heart—who told them that none of the jury were free, more or less, from unsound hearts how admirably must they have harmonized with their chief!—nay, that the very children of the landlord-juror were doubtless not more free than *they* were, from disease of the heart! When one of the jury—whose apprehensions were awakened by the fact which came out, that the deceased had been in low spirits for some time—asked whether the medical men should be called who saw the deceased; what (throwing the clerk's gloss aside) really said Mr. Wakley? "Do you suspect, Sir, there's been anything wrong?" directly intimating to him, that, unless he were prepared to go so far in assuming the ungracious character of an accuser, and in insulting the survivors living about him, by expressing a deliberate opinion against them, it was something very absurd to call in a medical man! Of course, the bullied country jury could not think of avowing an invidious suspicion, which ought not to have been asked from them or from any jury;—especially could they not avow it, when they saw that it was directly against the inclinations of the great man, the M.P., who wanted to be back to town after holding some half-dozen other inquests, in time (it was a *Tuesday* afternoon) for his Parliamentary duties! Yet—silly, silly jury!—after being thus misled into making themselves a public laughing-stock, by their solemn declaration, after *due* enquiry, that a man, with an ounce of essential oil of almonds within him, died a natural death—they are palavered into making their appearance before the public, with their convicts' ropes placed by their own hands around their necks, and declaring themselves the idiotic culprits! Since the time that Reynard persuaded the goat to descend into the well, into which he had fallen, that, with the vantage ground of his horns, he might be enabled to spring out, we have verily heard of nothing resembling the juridical scapegoats of Hornsey—and their honourable friend, Mr. Wakley!

We have no further space except for the shortest facts. The medical man usually attending Mr. Pledger, we mean Mr. Baker—the medical man who saw him immediately after his death, we mean Mr. Hands—the sister-in-law who knew perfectly his circumstances and character—the man who, with his son, first saw the body on the alarm of death, and who moved it from one room to the other—all these *real* witnesses who could have thrown light on the death, if any persons could, WERE UNCALLED: and a frightened little girl, a temporary nurse, and a boy brother, composed the corps of witnesses—the whole inquest lasting but half an hour! Is this the way public money should be earned? Is this the way public duties should be discharged?

But Mr. Wakley's has the daring—the flagitious impudence, in the hope of hiding his extraordinary delinquency as a Coroner, to charge *without the least shadow of evidence*, some unnamed party with the abominable act of inserting poison in the corpse. Marshall Hall's procedure to our excellent reporter was morality itself to this. The servant girl affirms that the phial of the essential oil of almonds was placed by the deceased on the marble place of his back parlour—that its contents were much lowered in the morning when the deceased was found dead near it—

the autopsy was performed at the request of a surviving relative—four persons, three of them medical, were present during the whole time—and finally the Coroner's clerk, no later than Monday, the 27th inst., affirmed—after an enquiry, too—to a gentleman whom we can name, that "he had no doubt in the world that Pledger had poisoned himself." What means then this foul—this hideous accusation? Is it part of "the scandalous trick subsequent to an inquest?" Does it afford us fresh aid "in dragging the REAL CULPRIT before the public?" The questions are serious to a man who would value a character for something approaching to decent morality; we pray thee Mr. Wakley answer them if thou canst?

REVIEW.

An Exposition of the Pathology and Treatment of Tubercular Phthisis. By Samuel Flood, M.R.C.S., &c. &c. London: 1842.

THIS is a rambling essay or memoir upon a very important subject, in which the author, with more boldness than prudence, forces upon the medical public, two novel ideas. The first is, that Phthisis is not a disease of the lungs, but of the digestive apparatus; and secondly, that consumption is not only curable, but that our author has discovered a *specific* for this formidable malady. In proof of his first assertion, the author endeavours to show that phthisis and scrofula are identical affections, and that the most prominent symptom of phthisis is *emaciation.* From these two positions the seat of the disease is *deduced.* Such questions are obviously not to be decided by reasoning, but observation; and we think, had the author ever made *post-mortem* examinations of phthisical subjects, we would have been spared the trouble of refuting such absurd paradoxes. Even admitting the identity of scrofula and phthisis, it does not follow that phthisis is a disease of the digestive organs; for scrofula may show itself in various and different situations, besides the digestive organs. Do we not see it sometimes confined to a bone, or bones; sometimes to an articulation; sometimes to lymphatic ganglia in the neck, in the chest, in the abdomen? &c.; or the scrofulous deposit may be chiefly, if not exclusively, confined to some one internal organ, as the lungs. Every one knows that in phthisis the lungs are the seat of the disease, and it appears to us as absurd to locate the disease in the abdomen, as it would be to aver that it is a disease of the gluteus maximus muscle. We need not refer to the physical signs of phthisis as having a reference exclusively to the lungs, nor to the evidence of the fact which *post-mortem* examinations afford, for in our mind the conclusion is already established, and it would be a work of supererogation to refute what is so obviously erroneous. After death, although other organs are sometimes found affected, we have sufficient evidence that the cause of death exists in the lungs, and that the disease called phthisis has its seat exclusively in the pulmonary tissue. We regard, therefore, our author's views on this point, as perfectly chimerical, and his treatment of the mesenteric glands in this disease, as worse than foolish. Our author's treatment of phthisis, consists in generous diet the internal use of iodine and cantharides, and topical applications to the abdomen, such as blisters, iodine plasters, &c. We cannot speak favourably of the work; the style is faulty, the views of the pathology inculcated, crude, indigested, and contradictory; and his principles of treatment partial, defective, and calculated to mislead the young and inexperienced. We would recommend the author to cultivate his *observing* faculties, and leave reasoning and deduction, for which he is by nature incompetent, to others; and above all, we would beseech him never to write on any medical subject which he does not fully comprehend.

PHRENOLOGICAL SOCIETY.

THE meeting on Monday the 20th ult. was numerously attended. Dr. Elliotson in the chair. Mr. Atkinson, F. G. S., read a paper on the late John Varley, the eminent painter; he described him to have been a man of wonderful genius and intellect, original in all his conceptions, grand in all his designs—an ardent admirer of nature and nature's works; he loved the sublime and beautiful, the cloud capt mountain, the lowly valley, the placid lake, the umbrageous wood "impervious to the sun;" these were his delight to view, and these he so inimitably transferred to canvas. In landscape painting he stands pre-eminent—none have excelled him, few can equal him; he was the founder of this species of art in water colours. In manners he was mild, affable, benevolent, and communicative; his charity was as large as his expansive heart; he knew no distinct country or creed. "Friend to no sect, he took no private road, but looked through nature up to nature's God." As every mirror has its dark side, so has human nature its frailties. Varley's might have been called amiable, it was credulity; he believed nearly all he heardorread; hewasan astronomer, and deeply impressed with the truth of the occult science of astrology: he imagined the starry host to possess an influence over the actions and feelings of men, and "that there were more things in heaven and earth than were dreamt off in our philosophy. Varley was wholly devoid of worldly prudence, and was consequently always in difficulty. The cast of his head was exhib ted. The coronal region was large; the moral faculties highly developed, and the intellectual, to a high degree. Ideality his predominant sentiment, was strikingly large, also benevolence and constructiveness. Mr. Atkinson at the close of his address was much applauded. Dr. Elliotson said he wished to call the attention of the meeting to the report of the Hunterian Oration, which he had read in the *Medical Times* of the 18th inst. The Doctor said here was a gentleman addressing the first surgical college in the kingdom, and asserting that to Sir C. Bell belonged the honour of the greatest discovery made in the nervous system for 20 centuries. The passage is as follows: "In a word there belongs to Bell the great discovery, the greatest in the physiology of the nervous system for 20 centuries—that distinct portions of that system are appropriated to the exercise of different functions." Dr. E. in no way detracted from the merit due to it; it was a discovery, and as such entitled to praise; but when compared with those of Gall it shrunk into insignificance, "it was as a wart to ossa." What Gall years before discovered with respect to the brain, Bell applied to the excito-motor nerves. The former said that separate parts of the brain have distinct functions; the *latter* had found out after twenty centuries "that distinct portions of the nervous system are appropriated to the exercise of different functions."

WESTMINSTER HOSPITAL.

CLINIQUE OF MR. GUTHRIE ON SOME POINTS CONNECTED WITH DISEASE OF THE URINARY ORGANS.

Delivered on Saturday, 25th February, 1843.

The Clinique at this hospital on Saturday last embraced *three* important points of surgical practice connected with morbid states of the urinary organs:—the first the mode of introducing the catheter into the bladder · the second, the method of tunnelling obliterated portions of the urethra, and the third, that of crushing stones in the bladder, and extracting fragments of stone from the bladder and urethra.

The first case introduced into the operating theatre, was that of a patient who was long supposed to be laboring under stone in the bladder, while no stone existed. Upon introducing the sound, a sensation was felt as if the instrument had struck upon a hard surface. This arose from a diseased condition of the bladder, but the kidnies were also seriously diseased, and the case did not fall strictly within his province. Mr. Guthrie brought the patient before the students, more for the purpose of showing the mode of introducing the catheter, or bougie, in treating affections of the urethra, than for any other *purpose*. Mr. Guthrie then took the catheter into his hand, and exhibited the way of *holding* the instrument, and *commencing* the operation, and insisted upon the student carefully examining the structure of the urethra in all its relations, before he attempted to introduce a catheter into the bladder. He showed the method of introducing the instrument in succession through, 1st. the pendulous part of the urethra—2d, the perineal portion—3d, through the triangular ligament of the pubes—4th, through the membranous part of the urethra—and 5th, through the prostate portion,—pointing out the peculiarities and difficulties of each subdivision of the urethra, and summed up the whole by some excellent practical proofs of the adroitness which practice alone can impart in the introduction of the instrument.

Mr. Guthrie's remarks upon the foregoing case were introductory to an interesting case of *stricture*, which was next brought before the pupils. The case was that of a soldier admitted into the hospital about four months ago, with a stricture of eight years' standing. When the patient was received into the hospital, he was in a truly deplorable state. He could hardly pass one drop of urine, and the No. 1, or smallest bougie, could not be carried into the bladder. Upon examination, the urethra was found constricted, and nearly obliterated, to the extent of about two inches at the deepest part of the pendulous portion of the urethra. This contracted part of the tube was throughout the whole of its extent cautiously transfixed by an instrument essentially consisting of a straight silver tube, which is carried down to the stricture, and of a lancet shaped *stiletto*, made to project from the tube, and open up the canal. After incising in this way the urethra, an ordinary sized bougie was immediately after carried through the stricture. Beyond the pendulous, and in the perineal portion of the urethra, anterior to the pubes, another stricture was found to oppose the transit of the bougie. This was also transfixed by the lancet-shaped stiletto. The strictures being thus overcome, and the passage re-opened, a bougie was then carried with ease into the bladder. An untoward accident, which arose during the treatment, was next adverted to. The subsquent introduction of the bougie, which was necessary for effecting the cure, occasioned so much irritation, that the case was retarded for some weeks, by the formation of

an abscess around the exterior of the contracted portion, which Mr. Guthrie compared to those abscesses, or blind pistulæ, which sometimes form around the rectum. By the regulated and daily introduction of the bougie, the canal has been gradually dilated till it can now let pass, as was shown, a No. 11 bougie, and in another month, Mr. Guthrie thinks that the largest sized bougie will easily pass, when the patient will be dismissed cured. In expatiating upon this case, Mr. Guthrie directed the attention of the pupils to the *thinning* of the corpus spongiosum, concomitant with stricture of the *pendulous* part of the penis, and to the thickening, or hypertrophid state of the parts surrounding strictures in the *non-pendulous* parts of the organ. The causes of these differences of result, Mr. Guthrie did not attempt to explain, but he considered the facts as established.

The third case brought before the pupils was one of no small interest. The young man had been operated upon for stone some months ago, by Mr. White, the senior surgeon of this hospital, and was dismissed apparently cured The patient returned, however, with a fragment of the stone that had been previously crushed by Mr. White, obstructing the urethra. As the symptoms were urgent, Mr. Guthrie, in the absence of Mr. White, picked out some of the smaller pieces from the urethra, and succeeded in pushing the largest fragment back into the bladder. Mr. Guthrie then entered into some explanations regarding the operation of lithotrity, and described the instrument he is in the habit of using. He first injects four or six ounces of water into the bladder—carries the crusher cautiously into the bladder,—then separates the blades of the instrument. Mr. Guthrie never searches for the stones: he merely passes the instrument to the most depending part of the bladder, when the stone falls upon the instrument, and is seized. If the stone is very small, (smaller than a split pea,) it cannot be seized by the instrument. In this case, Mr. Guthrie recommends a dilatation of the urethra, and the forcing of the stone, out with the urine, and related an interesting case of a private patient of his own, who was eased in this way. The patient suffered much, and many unavailing attempts were made to seize the stone. Mr. Guthrie then dilated with bougies the urethra, and one day, during the evacuation of the bladder, a very small stone, consisting of an aggregation of acicular chrystals, was expelled, with an immediate and complete cessation of all the painful symptoms

ADVERTISEMENT.

(To the Editor of the Medical Times, and Gentlemen of the Medical Profession.)

Sir,—Permit me to offer you my thanks for the kind manner in which you were pleased to notice my new farinaceous productions for infants and invalids, and allow me through the medium of your excellent and widely circulated journal, to present my warmest acknowledgments to the gentlemen of the medical profession generally, for their countenance, and particularly to thank those who have so kindly favoured me with similar testimonies. Trusting that the opinions so freely given will be kindly seconded by recommendations, in accordance with their recorded certificates.

I have the honour to be Sir,

Your obliged and obed. servt.

JOHN BRIGHT.

Brixton Hill, March, 3, 1843

CURABILITY OF CONSUMPTION.

(Continued from page 349.)

(To the Editor of the 'Medical Times.')

Sir,—I now proceed briefly to notice the principal concomitant affections or complications of phthisis, over which measured mechanical respiration exercises a beneficial control. One of the more frequent and troublesome of these, is ulceration of the larynx. The vicinity of the morbid action to the brain, determines the blood to that organ; and the obstacle to its return, presented by the peculiar stifling character of the cough, keeps the patient in a constant state of excitement and irritability, equally distressing to himself and his attendants. The sense of constriction in the throat, dryness of the fauces, dysphagia, rejection of the food through the nostrils, lancinating pains shooting in the direction of the ear, all conspire to torment the unhappy sufferer, and diminish the value of any addition to the term of his existence. It is astonishing how long this affection may protract life. I have known it to do so in some instances for five or six years; this is effected by the impeded expiration, consequent on tumefaction within the larynx and adjoining portion of the trachea, which renders the lungs voluminous. Thus, we may account for the small size of the cavities so commonly observed on dissection: traces of obliteration are also of frequent occurrence, indicating the repairs, nature was carrying forward by the aid of the obstruction.

M. Cruveilheir, in his "Anatomié Pathologique" records a case in point. He says:—" A labourer, aged 40, entered the Maison Royale de Santé, with all the symptoms of laryngeal phthisis. He had been seized with hoarseness about ten months previously to his entering. On examination, his lungs appeared healthy, with the exception of a dry and sonorous cavity in the summit of the right lung. The patient died, suffocated by the laryngeal affection. On opening the body, the vast cavity in the summit of the right lung was perfectly cicatrised." The affection of the throat, in this case, obstructed the expirations; the lungs, rendered voluminous by the detention of the air, brought the sides of the cavity into apposition, and cicatrization ensued. This was, however, but the substitution of one evil for another, equally, or, I might say, more dangerous, and certainly more distressing. So little do the lungs exhibit of the characteristics of disease,occasionally,—so masked are all phthisical signs—that the affection of the throat is often regarded as primitive, and hence we hear laryngeal phthisis sometimes mentioned as an idiopathic disease. In all cases supposed to be so, the lungs, on autopsy, will be found to reveal the unequivocal tokens of primitive pulmonary tubercularization, or the versed auscultator will have discovered it previously. The use of the tube has been found eminently serviceable in averting this complication, or modifying its character; it will rarely happen that prevention is not secured by its timely employment. Its power will be in proportion to the length of time intervening between the commencement of its use, and the period when, without it, in the course of nature, the laryngeal affection would have supervened. If other circumstances should not contraindicate—even after the supervention—it may be advantageously employed to relieve the difficulty of breathing present. All these desirable results are obtained without the drawback of any aggravation of the symptoms, danger, or pain.

Another most alarming complication is diarrhœa. When it sets in, the patient's death-knell, in the great majority of cases, begins to toll; the chances remaining of a lengthened respite are very few indeed, but even these are increased by the careful and judicious use of the respiratory tube. I recollect the case of a man, named Swedenburg, who was admitted into the Infirmary for Diseases of the Chest, in 1838, with every bad symptom of consumption, and, among the rest, diarrhœa. His lungs were extensively diseased, yet he lived more than two years, during which, under this treatment, all the constitutional symptoms were greatly moderated, and existing cavities healed up. He died at last of diarrhœa. I have already stated that, in old catarrhal cases,tuberculous diarrhœa i rarely indeed met with. Inhalation in the late stages produces a similar effect to catarrh: littl apprehension of diarrhœa need be entertained, i its use has been previously practised for an reasonable period. Thus, it would appear, that i may be employed to execute palliative and pro phylactic, as well as curative, intentions. It ma be thrown out as a sheet-anchor, even at th eleventh hour. I am in possession of the name o a clergyman's daughter, who had been despaired o in phthisis, by several medical men, among whon was a physician some time retired from his con nexion with St. Bartholomew's Hospital, who ha been consulted, and yet she dishonoured thei prognosis by surviving six years. As a *dernie resort*, she made trial of the inhaling apparatus fo two or three months, during which a decide retrogression of all her bad symptoms was esta blished. Considering herself well, she left it of It is not improbable that, had she persevered til her disease had been more completely brough under, she might, so far as it was concerned, hav been still alive. I have met, besides, with thre other consumptive cases, despaired of by the sam physician, who did well under this treatmen Two of them are now, after the lapse of a fe years, alive, and in good health.

Pleuritic adhesions in by far the greater num ber of cases, are occasioned by irritation from tu bercles in the subjacent tissue of the lungs. What ever expands the air cells, seems to take away thi disposition to form pleurisy. In cases of asthm we find pleuritic adhesions of very rare occurrence except at the summits of the lungs: when me with, they may be often considered antecedent i origin to the latter disease. The lungs in thi state afford the finest specimens of exemption fro morbid pleuritic agglutinations, or thickening it is interesting to observe in those cases,where the do occur, how the air cells of the portions cover by healthy pleura are greatly dilated, hypertr phied, and as it were ready to burst their bond The respiratory tube by its expanding power in similar manner prevents these adhesions.

Its value in catarrh, which it supersedes as curative agent, must not be overlooked. By du exercise and expansion of the bronchial ramifica tions, it contributes to allay or indispose to, irrita bility of the lining membrane, and I have ofte heard patients state that after its use in the morn ing they have been better, and more freely able t bring up the accumulated phlegm. When con traction of the trachea exists, the pulmonar exertion required for the expulsion of the air b the pressure from below upwards, dilates the grea air passage, and counteracts the tendency to spas modic action and superficial ulceration or thicken ing. Hence it may be advantageously resorted t a few months before the approach of winter, o before removing to cold humid climates, particu larly by persons who are very susceptible of th repetitions of this affection from exposure to th ordinary exciting causes. It contributes to preven and remove congestion of the mucous membran by the healthy cuticular action consequent upo improved sanguification. As a prophylactic it ma also be ordered when the constitution is scrofulous it alters the habit, and renders not only the lungs but also all the other viscera less susceptible o tuberculous deposit. Hence we might deduce th propriety of its general adoption by the member of those families in which the hereditary taint i suspected, or already begins to develope itself.

In cases of empyema its employment is calculate to add to the chances of recovery by improving th condition of the lung on the side opposite to tha affected, and producing slight expansion of th diseased lung even in the face of the accumulate fluid, if timely resorted to,before the conversion o the investing pleura into fibro-cartilaginous tissue The disease is kept from advancing: the empye matous matter thus left to itself may,under favour ble circumstances, determine to the surface. subjoin two cases that have come within my know ledge illustrative of this result.

About five years ago, Mr. S——, of the Entré Office, at the Custom House, Liverpool, came u to London for advice. He was found on examina tion to be labouring under consumption, with em

pyema of the left pleural sac,and his general health was less impaired than might have been expected from the nature of his malady. The condition of the chest, and all the symptoms were further improved by the use, for several months, of the respiring tube. A tumour at length formed which soon began to fluctuate, and matter pointed externally. It was opened by a surgeon in Liverpool, and the contents of the pleural sac allowed to escape. After some short time he improved surprisingly, became robust, and considered himself perfectly restored, with the exception of a slight oozing discharge, which rarely amounted to a wine-glass full in a day. During this progressive state, he was in the habit of practising the mechanical respiration, but on his health appearing to him so very satisfactory it was laid aside. He now married, and mixed in general society, visited and frequented parties as a person in perfect health would do. A few months subsequent to his marriage, fresh liquefactions in his left lung brought about a return of alarming symptoms, which becoming gradually worse, he came to town once more for advice. His case being considered interesting he was shewn by Dr. Ramadge to several of the gentlemen attending the infirmary. He survived about six months, and was visited towards the close by Mr. King, an intelligent practitioner in the Hackney Road, in conjunction with Dr. Ramadge. He acknowledged that he had neglected the directions sent to him in Liverpool, the principal of which were, to persevere in the use of the tube, and avoid exposure to the night air. Had he carefully observed these directions, he might have recovered instead of sinking as he did under the disease. His well marked improvement in the beginning when he strictly acted upon them countenances this supposition. His death took place about eighteen months after the operation, and was attributable to exhaustion from fresh liquefaction and its sequelæ. The discharge never entirely ceased, but did not increase during his last attack.

The other case was that of a young lady living at Gravesend, a friend of a very intelligent practitioner, Mr. Beale of Bedford Square, Stepney. She had been confined to her bed for some weeks, constantly lying on the left side. Dr. Ramadge visited her at the request of this practitioner, and pronounced it to be a case of empyema supervening on consumption. The constitutional symptoms were then absent, but had been exceedingly well displayed, as appeared from enquiry, before the occurrence of effusion. It is worthy of note here, that when empyema takes place in phthisis, the constitutional symptoms become equivocal,—are either very slightly marked, or nearly absent. Leeches were recommended to be applied to the side, followed by blisters, with a view to lessen the vascular action of the serous membrane and promote absorption. It is unnecessary to enter into the case more minutely than to state that the mechanical treatment was adopted to obliterate phthisical excavations, and produce a general pulmonary expansion. After the lapse of about two months the matter pointed; an opening was made by a surgeon, and was followed by a purulent discharge, which continued for some weeks. Meanwhile, she persevered, as directed, in the practice of inhaling, her symptoms being at the same time watched by her usual medical attendant. A few months afterwards, being perfectly restored, she came to town to present herself to Dr. Ramadge. More than two years have since elapsed, and she still remains without any pectoral disorder, and in a very satisfactory state of general health.

This instrument was originally prohibited in affections of the heart generally, but further experience has proved that it may be resorted to here with advantage, when the lungs are not congested, but simply voluminous in consequence of mucous bronchial intumescence or tracheal spasm. It has been 1een found useful in heart affections symptomatic of chlorosis, and in most of the nervous complaints of females attended with dilatation. Its beneficial effects on the sanguification are exemplified by altering the complexion from a pale to a healthy sanguineous tint, and on venous congestion by removing sub-lividity of the lips and turgescence of the veins of the neck.

I might enter into various minutiæ under each separate head above glanced at, as the pathological materials and illustrative facts at my command are abundant; but enough has been said to shew that I have not been an inattentive observer of phthisical phenomena, and am not chargeable with excessive credulity in assenting to the value of mechanical pulmonary expansion,or ill-directed zeal in my endeavours to make proselytes to doctrines I believe to be important and incapable of successful contradiction. I feel convinced I shall succeed to the extent of inducing many to give them a fair, patient, and judiciously conducted trial, with a view to fulfil either palliative or curative indications. That which courts investigation and experiment from scientific men, must possess some of the attributes which command professional attention and esteem. The more this question is sifted will its merits be appreciated.

DISCIPULUS.

[The literary merit of these letters make them attractive—but their insertion interfering with courses of lectures we are pledged to give, the correspondence must here terminate.—ED.]

PERISCOPE OF THE WEEK.

CAPACITY OF THE LUNGS.—M. Bourgery states that in examining the relation existing between the structure and functional capacity of the lungs in both sexes, and at various periods of life; experiments were made with a hydro-pneumatic apparatus on 70 persons (50 male, 20 female,) from which the following results were deduced:—The respiratory act, *cæteris paribus*, is more forcible in proportion to the youth and slender make of the individual. No condition of strength or health is capable of supplying the place of youth. Respiration in the male is double the volume of that of the female for the same age. The maximum for both sexes occurs at the age of thirty years. In a well-formed person of that age forcible respiration represents the quantity of 2.50 to 4.80 litres for the male; and of 1.10 to 2.20 litres for the female; in the boy of fifteen years 2. litres; and in the old man of eighty 1.35 litres.* The volume of air required for ordinary respiration gradually increases with age. The ratios between the ages of seven, fifteen, twenty, and eighty, are geometric, and represented by the numbers 1, 2, 4, and 8. The well-formed adult respires habitually the quadruple of the young child, and the double of the female or child of fifteen years, while the old person respires the double of the adult. This progressive increase, or necessity for a greater volume of air, expresses the diminished power of the lung as an organ of hæmatosis; hence, the latter decreases from infancy to old age, in proportion to the following numbers: 1, $\frac{1}{2}$, $\frac{1}{4}$, and $\frac{1}{8}$.—In forced respiration the permeability of the lung to air presents two periods; one ascending from infancy to thirty years, the other descending from thirty to old age. The former increases in a regular ratio 1, 2, and 3. from seven to fifteen and thirty years; the latter decreases from 3 to $2\frac{1}{2}$ between thirty and fifty years; and from $2\frac{1}{2}$ to $1\frac{1}{2}$ between fifty and eighty years of age.—Taken on the whole, the respiration is trebled within the space of twenty-three years in youth, and increases by 1-9th for each year. After manhood it diminishes by 2-5ths in twenty years, or by 1 000th for each year. From fifty to sixty years it decreases by 1-5th in ten years, or 1-50th for each year. And in old age, from sixty to eighty, it diminishes by nearly $\frac{1}{2}$ or 1-20th for each year. This gradual decline of the respiratory power must contribute in great measure to the gradual extinction of the powers of life as old age advances.—This latter proposition is further confirmed by the fact that the ratio of ordinary to forcible inspiration diminishes as the age advances. At seven years of age this ratio is as 1 to 12; at fifteen, as 1 to 10; at twenty, as 1 to 9; at twenty-five and thirty, as 1 to 6; at sixty, as 1 to 3; at eighty years of age, as 1 to $\frac{1}{2}$ or $\frac{1}{4}$. Thus, the young man has in reserve for violent exertion an immense respiratory faculty, while the aged person is quickly "winded."—The respiratory faculty is gradually worn out by the laceration of the capillary aerian and sanguineous canals; this laceration occurs, in a greater or lesser degree, in all powerful respiratory efforts. It begins at an early period, and increases gradually to old age, as a simple consequence of repetition of the respiratory act. It is increased by all diseases of the lungs. In its most aggravated form this state of the lung causes a circulation of imperfectly oxygenated blood, and reduces the decrepid octogenarian to the locular lung and imperfect respiration of the reptile.

* The *litre* is 1.760 of an English pint.

ADMINISTRATION OF MURIATE OF MORPHINE BY THE ENDERMIC METHOD IN NEURALGIA AND SCIATICA.—M. Rougier, of Lyons, speaks in the highest terms of the beneficial effects derived from this remedial agent in the above complaints. He commences by denuding the skin over the course of the affected nerve of its epidermis. For this purpose he employs an iron, heated in boiling water, which is to be left for an instant on the surface and then quickly withdrawn; the part afterwards being gently rubbed with a piece of linen rag. This mode of proceeding is preferable to ordinary blisters, inasmuch as it causes less pain, never fails in producing its effect, is more prompt,and produces less suppuration, thus favouring the absorption of the medicine. The hydrochlorate, which, according to M. Rougier, is the most soluble salt of morphine, is then applied upon the surface, having previously moistened it with a drop of water. M. Rougier usually commences with a grain and a half, which he increases by a grain, every second day, according to the susceptibility of the patient. He states that minute doses have little or no effect, and that it is necessary to saturate the constitution, as it were, before any good effect will be induced. The symptoms announcing this condition are, headache, somnolency, nausea with or without vomiting, dysuria, heat of skin, perspiration, itching of the skin, &c. M. Rougier states that he has sometimes carried the dose as high as 12 grains, in which case he creates a greater number of absorbent surfaces, so as to correspond in some measure to the quantity of medicine to be introduced into the economy. In ordinary cases, or where the disease is recent or simple, the pain is generally checked at the second or third application; but in disease of long standing, the cure is generally more tedious. M. Rougier states that he has applied from 30 to 50 blisters successively in the same patient. The surface is to be dressed but once a day, a plan which thus allows the individual, at the expiration of a few hours, to go about his usual business. The pain once removed, the remedy is to be continued for a few days in decreasing doses. A sense of weakness and prickling are frequently felt for a long time along the course of the nerve, owing both to the long continued disease, as well as the action of the morphine, which has in some measure paralysed the sensibility of the nerve.

Abscess in the Uterine Parietes communicating with the Rectum.—A lady who enjoyed good health up to her thirty-seventh year, when she married, was soon afterwards attacked with acute deep-seated pain in the hypogastric region, radiating to all parts of the pelvis, and increased by micturition and defecation. It was accompanied by the usual symptoms of inflammation of the uterus. Although the attack was relieved by the treatment adopted, it was not removed, and when an examination per vaginam was instituted, the uterus was found lower in the vagina than usual, with morbid enlargement more especially of the posterior paries, and the os and cervix uteri were painful to the touch and tumid. Between three and four months after the invasion of the malady, about half an ounce of pus suddenly escaped from the rectum, with immediate relief. Persistent diarrhœa with discharge of more or less purulent matter now set in, the patient observing that when the pus was not discharged as freely as usual the local pain was aggravated. All this while menstruation was very irregular, and attended with much pain in the loins and discharge of coagula. Profuse menorrhagia next set in, the uterine pain became exceedingly severe, attended with a relapse of the previous symptoms, to which was superadded a neuralgic condition of the genital organs, the slightest pressure upon which produced extreme suffering. The patient gradually sunk exhausted.—A post-mortem examination was made twenty-four hours after death. On laying open the abdomen, the omentum, small intestines, and all the pelvic viscera were found agglomerated together by peritoneal adhesions of old date. On raising the uterus it was seen to be firmly attached by its upper and posterior portion to the rectum; it presented an irregular form, having the fundus enlarged to about thrice its natural size. A longitudinal section showed the enlargement to have been produced by an abscess seated in the substance of the wall of the fundus uteri, the cavity of which contained about an ounce of dark thick pus: the walls of the abscess varied in thickness from one to three-fourths of an inch, the thinnest portion being nearest to the cavity of the uterus. A communication by means of a short sinus could be traced passing from the cavity of the abscess to the adhering portion of the rectum, and opening into that intestine by an aperture sufficiently large to admit of the passage of a thick probe, and evidently of old formation. No communication existed between the uterine cavity and that of the abscess. The os and cervix uteri did not present any evidence of malignant disease. The Fallopian tubes and ovaries were adherent to the uterus, and could with difficulty be distinguished. The uterus had never been impregnated.

Researches on Electro-Puncture.—M. Schuster gives the following conclusions as the result of his experience on this subject:—1. Galvanic electricity, introduced by means of acupuncture into the substance of the affected tissues, is the most powerful, as well as the most harmless, stimulant and resolvent agent that we possess. 2. The resolvent action of electricity is exercised with so much more energy and promptitude, as it is seconded by a more marked causticity and power of decomposition. 3. The action of electricity upon living tissues has only its full effect so far as we introduce, by means of the metallic points or needles, this fluid into the substance of the parts, the structure or vitality of which is to be modified, and upon using due care, on the one hand, to proportion the intensity of the currents to that of the effects to be produced, and on the other, to alternate, where necessary, the action of a *continuous current* with that of an *interrupted* or *broken current*. 4. Electro-puncture will generally be successful in those affections, in which we wish to stimulate the diminished or destroyed sensibility or contractility, to attack the enervated or perverted conditions of vitality, to cause the reabsorption, or evacuation, of effused or accumulated matters, to decompose or destroy morbid productions, to obtain adhesions, and lastly, to coagulate the blood.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, Feb. 24, 1843:—

A. P. Hamilton, C. P. Ring, W. Cantrell, J. S. Kirkman, T. H. Cooper, J. Currie, G. B. Irving, J. C. Robinson, J. J. Hely, E. C. Johnson, J. N. Morse, H. H. Price.

LAMPS for COMMON OIL.—Egyptian Hall, Piccadilly.—A. REEVE (late with S. Parker) is now SELLING the PATENT UNIVERSAL and PATENT ECONOMIC HOT OIL LAMPS, the only lamps that can be warranted to burn with common oil for ten hours without charring the cotton, giving a light equal to nine wax-candles, at the cost of about one halfpenny per hour. Also the PATENT OIL PURIFIER for preserving and purifying the common oil, and the PATENT STEAM FOUNTAIN COFFEE POT, the only coffee-maker now in use which extracts the pure aroma from the coffee, and in the prices of which A. B has made a considerable reduction. Also the Patent Argyll Lamps, for burning under the puncha protectors in India. Purified Southern Oil to burn in any lamps, 4s. per gallon. Lamps repaired and lent on hire. Pure Mocha Coffee in sealed canisters.

By Her Majesty's Royal Letters Patent.

A. ELAM AND BROTHERS,

403, Oxford Street, London,

Inventors, Manufacturers, and Sole Patentees of the New Invented AERATED ELASTIC TRUSS & ELASTIC SPRING UTERUS SUPPORTER, for Prolapsus and Procedentia Uteri, or Falling of the Womb, and for Prolapsus Ani, by external application.

MESSRS. ELAM BROTHERS beg, most respectfully to announce to the medical profession and the public in general, that their new invention continue to be patronized by the most eminent Surgeons in England, Ireland, Scotland, France, America, and many of the British Colonies, they have met with the most decided approbation of every person who has seen or employed them. Columns might be filled with testimonials were it necessary, but a mere trial, or even inspection, will convince any one of their great superiority to all other appliances.

FOR PROLAPSUS UTERI.

This most invaluable invention, invented and patented by Messrs. ELAM BROTHERS, is the only apparatus now in use whereby relief and comfort can be obtained in all bearing down sensations, in a great many instances performing a complete cure, where that is possible it does not interfere with dress, no inconvenience any part whatever, completely doing away with pessaries of all kinds, to which both surgeons and patients have such well founded objections. It is perfectly light and elastic, always keeping its position in every motion of the body. A trial is all that is necessary to test the apparatus.

FOR PROLAPSUS ANI.

This invention is the most complete ever known, giving instant relief, and may be applied either externally or internally. It has never yet failed where it has been applied to give relief and comfort, and is the only apparatus recommended by the Faculty.

RUPTURE.

Persons afflicted with this complaint, to which all ages are liable, may now meet with relief and comfort by ELAM'S NEW PATENTED PATENT TRUSS, to which E. B. wish most especially to solicit attention. 1st. The pressure is constant, agreeable, immovable, and invariable, under all circumstances and positions, this results from the peculiar elasticity and continued softness, over which perspiration has no effect. 2d. The truss is so anatomically constructed and so adapted to the part affected, and from the delightful softness and pressing itself agreeably into the orifice, it forms as it were, an irresistible obstruction on the surrounding parts, thereby totally preventing any escape, even under the most violent exertion. A mere trial is all that is required to test this invaluable discovery.

Messrs. ELAM BROTHERS beg also to solicit the patronage of the public for their superior Bandages, which they are now making upon the most improved principle. The following is a list.

ELASTIC LACED STOCKINGS, for Swelled Varicose Veins.
ELASTIC SOCKS, for ditto.
ELASTIC KNEE-CAPS, for ditto.
ELASTIC BELTS, for Lumbago.
GENTLEMEN'S RIDING BELTS.
ELASTIC ABDOMINAL BELTS, for the Support of the Abdomen during Pregnancy.
ELAM'S NEW INVENTED ÆRATED TRUSSES, for Rupture, Single and Double.
ELAM'S ditto UNIVERSAL for Femoral Hernia.
COLE'S expired Patent.
SALMON & ODY'S ditto.
SINGLE and DOUBLE, COMMON.
ELAM'S PATENT SPRING ELASTIC UTERUS ABDOMINAL SUPPORTER.
SPINAL INSTRUMENTS, for the Curvature of the Spine.
ELASTIC SUSPENSOR BANDAGES, with Silk and Cotton-net BAGS.
DUMB BELLS.
CORSETTS, upon Improved Principles.
ARTIFICIAL LEGS made to Order, and Warranted for Six Months, upon an Improved Principle, without Springs.
ARTIFICIAL HANDS and ARMS, ditto.
SPRING CRUTCHES of every description.
MACHINES for DEFORMITY of the HUMAN FRAME made upon improved principles.
BACK BOARDS.
LITTLE'S NIGHT BOOTS, for Tendon Achille.
LEG IRONS.
LISTON'S FRACTURE APPARATUS.
ENEMAS, for SELF-INJECTION.
ELASTIC BANDAGING of every description.

The following is a Testimonial from a Gentleman who has tried, and witnessed the effects of the new Apparatus.

Russell Place, Nov. 1st, 1841.

GENTLEMEN,—It gives me great pleasure in informing you of the beneficial results derived from your Patent Apparatus, where every other mode of relief had been applied in vain. After submitting your apparatus, I applied it with great success. The patient, who for the space of two years had been confined to her room, is now enabled to go about with the greatest of ease and comfort, and can say, with much confidence, that it fully answers the purpose it was intended for, and gives great credit to the inventors, and superior to every other mode of relief and cure for Prolapsus Uteri.

I remain, Gentlemen,
Yours, respectfully,
To Elam Brothers, DR. DAVIS,
403, Oxford Street, London. Lecturer on Midwifery.

A Female in constant attendance, and Mrs. ELAM waits upon ladies at their own residence if preferred. Mr. ELAM waits upon parties either at home or within a few miles from Town.

Orders by post, with a remittance, punctually attended to.
403, OXFORD STREET, LONDON.

WILLIAM GRAY,

19, DAVIES STREET, BERKELEY SQUARE, LONDON,

(Under the Immediate Patronage of the most Eminent Surgeons.)
Manufactures

THE MARQUIS OF ANGLESEY'S IMPROVED ARTIFICIAL LEG.

Improved Artificial Arms
Improved Instrument for Division of Tendons
Extending Machine, for Contraction of Knee and Arm
Crutches of all kinds
Trusses of every description
Weak Leg Instruments
Exercising Swings, Reclining Planes, &c., for Distorted Spines
Invisible Spinal Machines
Boots for Weak Ankles and Contracted Legs
Elastic Lacing Stockings for Enlarged Veins, &c.
Elastic Knee Caps for Weak and Rheumatic Affections
Hunting Belts and Suspenders
Elastic Ankles Socks for sprained or Weak Ankles

Directions for Measuring, &c., will be forwarded to any part of the country to a sufficient as above.

DR. GREEN'S

SULPHUR, FUME, MEDICATED, AND VAPOUR BATHS,

40, GREAT MARLBOROUGH STREET.

FOR more than twenty years DR. GREEN,s attention has been directed to the remedial agency of Baths of different kinds upon the human body, and to the same length of time he has superintended an establishment for their due and proper administration.

Judiciously employed Fume and Vapour Baths are beyond all question invaluable, as principal or auxiliary means in the Treatment of many kinds of Chronic disease, particularly Rheumatism and Rheumatic Gout, Affections of the Skin, and Impaired Functions of the great Abdominal Viscera.

The Baths are accessible at all hours of the day to the public at large, and to members of the medical profession, with their patients, in cases where it is desirable that the medical attendant should witness and direct the administration of the Bath.

EASE AND COMFORT FOR TENDER FEET.

HALL & Co. Sole Patentees, Wellington-street, Strand, London. The PANNUS CORIUM, or LEATHER CLOTH BOOTS and SHOES—ease and comfort in walking, combined with durability, are the recommendations of these articles, they never draw the feet, and are softer, easier, lighter, and more elastic than any other Boots or Shoes. The SPRING BOOTS are much approved, they supersede lacing or buttoning, and are a great support to the ancle. Also, the much-improved PATENT INDIA RUBBER WATERPROOF GOLOSHES, and H. & Co.'s portable WATERPROOF DRESSES, for Gentlemen, 21s. the suit. LADIES' CARDINAL CLOAKS, 18s. they can be carried in the pocket with convenience.

DIGESTIVE BROWN BREAD.—JAMES TURNER begs to inform the nobility and gentry, that his days of Delivery at the West End are Monday, Wednesday, Friday, and Saturday. Turner's Digestive Brown Bread is strongly recommended by the faculty for its nutritious qualities. The purity of the meal from which it is manufactured, and the improved method of making it into bread, render it the easiest of digestion and the most nutritious bread in use. Turner's Superior Household Bread, Fancy Biscuits, Cakes, &c. Presburger Wine Biscuits, in tins at 2s. each. Families supplied within five miles of the Royal Exchange. Orders, post-paid to James Turner, Family Bread and Biscuit Baker, 17, Bridge-street, Walworth, and 4, Queen's-row, Dalston, will receive prompt attention.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, beg to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

JEREMIE'S

SEDATIVE SOLUTION OF OPIUM,

First prepared at Patna, in Bengal.

THE great merit of this Preparation is its peculiar freedom from the noxious properties of Opium and has, therefore, been found available in cases where other forms have been inadmissible, from its not disturbing the nervous system. The rest procured through its instrumentality is divested of the heaviness and stupor usually the effect of Opium, and the patient, though taking it continuously, is left in free possession of his faculties. It has for several years been supplied to the H. C. Dispensary, by order of the Medical Board of Bengal, from its being found to arrest Cholera in India beyond any remedy that had been applied to that fatal disease. Captain Jeremie, from whose formula it is prepared, is well known to scientific persons as the talented improver of the Patna Opium. It will be found not to constipate the bowels, and to keep any time in any climate. It is exceedingly powerful in Cough, especially Consumptive Cough, wherein many have found it a great blessing, in Influenza, Gout, Tic Douloureux, Cholera, and Bowel Complaints, Rheumatism, and Cancers, in Accouchement, and all cases where Opium may be desirable. The exceedingly innoxious properties of the preparation have been proved by an intake of a few weeks old having taken it without any cerebral disturbance. The testimonials of many talented Gentlemen of the Profession are on the envelopes of the bottles, a few only of the names are given here of those who have approved, viz.—

Medical Board of Bengal.
Sir Phillip Crampton.
Sir David Dixon, Physician to the Royal Naval Hospital, Plymouth.
Dr. Cookworthy, Physician to Plymouth Dispensary.
Dr. Watson, Physician to Middlesex Hospital, London.
T. G. Perry, Surgeon, Foundling Hospital, London.
Dr. Rae, Royal Hospital, Chatham.
J. R. Martin, Esq., (late of Calcutta) Grosvenor-street, London.
Dr. Jackson, late Apothecary-General, Bengal.
Dr. Graves, Meath Hospital, Dublin.
Dr. Hannay, Professor of Physic, Glasgow, and Physician to the Royal Infirmary.
Dr. Yonge, Dr. Hingston, } South Devon Hospital.

Prepared only by Francis Leon, 27, George-street, Plymouth, whose signature is written in red ink, on the pound and half pound bottles, put up for dispensing, as well as on the envelopes of the bottles, sold at 2s. 9d., 4s. 6d., and 11s., accompanied by the stamp of Barclay and Sons, Farringdon-street, London, Wholesale Agents. Agents abroad.—Scott, Thompson, and Co., Calcutta, Binney and Co. Madras, Treacher and Co., Bombay, Menzies and Co., Jamaica; W. Blake, Montreal for the Canadas. Sold also by all respectable Druggists.

WRIGHT's PATENT DRAG.—The use of a drag to carriages being admitted, parties wishing for safety and relief to their horses have now an opportunity of having one on the most improved principle, such as has never been offered to the public before—the carriage being skidded or released at pleasure by the person driving without leaving his seat or stopping the vehicle.

All who are in the habit of driving must see the great benefit derived of unskidding the wheel before reaching the bottom of a hill, so that if another is to be ascended the velocity shall not be impeded, whereby time is saved and the horses relieved from the draught, as well as the danger avoided in backing the carriage, which must be done under any other system to relieve the skid.

An obvious saving is also effected, the great wear under all former plans being, when the skid is not required yet cannot be released.

Wright's Patent Drag has now been in use for the last two years, being fixed to the Rocket Ventnor Coach, travelling daily on one of the most hilly roads in the Isle of Wight, the journey from Ryde to Ventnor, thirteen miles, being performed in less time by half an hour than by the former mode of skidding, with much greater ease to the horses, and to the satisfaction of the proprietors as shown by their testimonial.

It can be applied without regard to the pace in case of accident, and may be accomplished by a child ten years of age.

Parties may be supplied with the apparatus complete, on applying at the Office of the Proprietor, No. 22, Church St., Soho, London.

To the Proprietor of WRIGHT'S PATENT DRAG. Royal Pier Hotel, Ryde. July 25th, 1842.

Sir, -Having had your drag in use on the Rocket Coach, running daily from Newport to this place and Ventnor and back, over one of the most hilly roads in the Isle of Wight, during the last two seasons, we express our satisfaction in its usefulness, affording a great relief to the horses, and a saving of time full half an hour between Ryde and Ventnor, a distance of thirteen miles, and feel assured your drag when known will be generally adopted.

We are, Sir,
GEORGE RENDALL,
WILLIAM LAMBERT, Coachman. } Proprietors.
JOHN WHITTINGTON, Coach Builder.
All letters prepaid.

BRITANNIA LIFE ASSURANCE COMPANY, 1, Princes Street, Bank, London.

Empowered by Special Act of Parliament, IV. Vict. cap. IX.

DIRECTORS.

William Bardgett, Esq.	Robert Eglinton, Esq.
Samuel Bevington, Esq.	Erasmus Rt. Foster, Esq.
Wm. Fechney Black, Esq.	Alex. Robert Irvine, Esq.
John Brightman Esq.	Peter Morrison, Esq.
George Cohen, Esq.	H. Lewis Smale, Esq.

John Drewett, Esq.	

AUDITORS.

J. B. Bevington, Esq.—F. P. Cockerill, Esq.—J. D. Dow, Esq.

MEDICAL OFFICER.

John Clendinning, M.D., F.R.S., 16, Wimpole St., Cavendish Square.

STANDING COUNSEL.

The Hon John Ashley, New Square, Lincoln's Inn.
Mr. Serjeant Murphy, M. P., Temple.

SOLICITOR.

William Bevan, Esq., Old Jewry.

BANKERS.

Messrs. Drewett and Fowler, Princes Street, Bank.

This Institution is empowered by a Special Act of Parliament, and is so constituted as to afford the benefits of Life Assurance in their fullest extent to Policy-holders, and to present greater facilities and accommodation than are usually offered by other Companies. The decided superiority of its plan, and its claim to public preference and support, have been proved incontestably, by its extraordinary and unprecedented success.

ASSURANCES MAY EITHER BE EFFECTED BY PARTIES ON THEIR OWN LIVES, OR BY PARTIES INTERESTED THEREIN ON THE LIVES OF OTHERS.

The effect of an Assurance on a person's own life is to create at once a Property in Reversion, which can by no other means be realized. Take, for instance, the case of a person at the age of Thirty, who by the payment of £5 3s. 4d. to the Britannia Life Assurance Company, can become at once possessed of a bequeathable property, amounting to £1000, subject only to the condition of his continuing the same payment quarterly during the remainder of his life,—a condition which may be fulfilled by the mere saving of EIGHT SHILLINGS weekly in his expenditure. Thus, by the exertion of a very slight degree of economy, such, indeed, as can scarcely be felt as an inconvenience, he may at once realize a capital of £1000, which he can bequeath or dispose of in any way he may think proper.

A Board of Directors in attendance daily at 2 o'clock.

Detailed Prospectuses, and every requisite information as to the mode of effecting Assurances, may be obtained at the Office.

PETER MORRISON, Resident Director.

SILVER SUPERSEDED, and those corrosive and injurious metals, called Nickel and German Silver, supplanted by the introduction of a new, and perfectly matchless ALBATA PLATE. C. WATSON, (late Alderman,) 41 and 42, BARBICAN, and 16, NORTON FOLGATE, aided by a person of Science in the amalgamation of Metals, has succeeded in bringing to public notice the most beautiful Article ever yet offered, possessing all the richness of Silver in appearance—with all its durability and hardness—with its perfect sweetness and use—undergoing, as it does, a Chemical Process, by which all that is nauseous in mixed Metals is entirely extracted—resisting all Acids—may be cleaned as Silver, and is Manufactured into every Article for the Table and Sideboard.

Table Spoons and Forks	per doz.	16 6
Dessert Ditto	ditto	12 0
Soup Ladles		6 0
Sauce Ladles		1 0
Tea Spoons	per doz.	
Gravy Spoon		3 0

C. WATSON begs the Public will understand, that this Metal is peculiarly his own, and that Silver is not more different from Gold, than his Metal is from all others. The Public will, therefore, have no difficulty in discovering the animus which directs the virulent attacks made against him by a party who is daily suffering from the unparalleled success which has marked the progress of his New Plate since its introduction. C. W., unlike this party, courts comparison, feeling confident that the result will establish its pre-eminence. Entire Services of Plate Purchased. 41 & 42, Barbican, and at 16, Norton Folgate.

PAPER TEA TRAYS, 12s. —a full-sized set of three, Gothic Pattern, and an infinite variety of others, up to 10 guineas a set, a set of three convex japan trays, 10s., very best London made tea urn, in every variety, from 33s. to 105s.; a dozen ivory knives, 11s., a dozen dessert ditto, 10s. 8d. carvers, 4s. 6d. per pair, fenders, from 6s. to 63s.; fire irons, from 3s. 3d. to 25s., American ovens, to bake before the fire, 4s.; copper kettle, 5s. 6d.; copper coal scoop, 11s. 6d. iron saucepans, enamel inside, 1s. 6d. upwards! and every article in furnishing ironmongery unusually low. Quality is here the primary consideration,—hence its uninterrupted success for 50 years, and its present celebrity as one of the best and most extensive furnishing Warehouses in London.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, at No. 1, [illegible] Street, Strand, in the Parish of St. Clement Danes, [illegible], in the County of Middlesex.—[illegible]

THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs,

No. 181. Vol. VII. LONDON, SATURDAY, MARCH 11, 1843. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London.

ON THE IMPROVEMENTS IN MATERIA MEDICA AND PHARMACY DURING THE PAST YEAR.

By John Foote, Esq., *Fellow of the Royal College of Surgeons in London, Fellow and Secretary of the Royal Medico-Botanical Society, Corresponding Member of the Pharmaceutical Society of Portugal, and of the Societe Industrielle at Angers.*

OPIUM

Is our most valued agent in the treatment of disease, and so freely has it been used, and so largely have its therapeutic powers been made available by the medical practitioner, that it may be thought impossible to discover another ailment in which it may be found of service. Nevertheless, several medical journals at home and on the continent have recently contained papers, and details of cases of strangulated hernia, which resisted the usual measures, including the taxis, but were readily reduced when the internal administration of opium or morphia, had been had recourse to, and the sufferer was brought fully under its influence; large doses of the anodyne were required. Mr. Lyell, of Newburgh, says, the rule should be to employ the morphia in half grain hourly or half hourly doses, until the patient is fairly narcotised. He gave his patient three grains of opium, and four and a half grains of the muriate of morphia, before he was able to reduce the rupture, and he ascertained by direct experiment that the drug he employed was really good. A similar result followed the use of belladonna injections in the hands of Dr. F. Fischer of Tambach. His cases, two in number, are recorded in *Schmidt's Jahrbucher*. In one instance, symptoms of narcotism were induced. Dr. Vigier, a physician at Amfreville, speaks of a case of strangulated inguinal hernia of the right side, in which failing reduction by manipulations, he employed ether irrigations, with the effect of lessening the pain and swelling, and inducing sleep. A second application a few hours afterwards acted again as an anodyne, and when the patient awoke, the rupture was reduced. Dr. Vigier states, that he did not have recourse to the taxis, after he had tried the ether, of which about 40 scruples were used altogether.

From the increase of intercourse between European medical men and the inhabitants of the Celestial Empire, we have been enabled to gather much interesting information with respect to the effects produced by the baneful practice of opium smoking, which appears to be almost wholly confined to the male sex. Mr. Smith states, that in Penang the opium smokers are the Chinese, the Malays, and a few of other nations, chiefly the native Portuguese. It is calculated that 10 per cent. of the Chinese, two and a half of the Malays, and about one per cent. of other natives are addicted to this vice. The drug is not used as imported, but is subjected, first to a process of solution in soft water; then of evaporation, re-solution, and re-evaporation, to free it from impurities. The watery extract thus prepared is called chandoo, and is twice the strength of crude opium. The dregs of the chandoo when smoked, are collected and made into pills for the poorer classes; these are called tye-chandoo. The Benares opium is chiefly used, but the Patna is preferred, because it has a finer flavour, is stronger, and its effects are more lasting. The smoker, when he commences his daily dose, is at first rendered loquacious and animated, but as the opium takes effect, the conversation drops, and is succeeded by repeated bursts of loud laughter; the next phase presents a vacancy of countenance with pallor and shrinking of the features, followed by deep sleep, lasting from half an hour to three or four. In this state the pulse is slower, softer, and smaller than before the debauch. The effects of this poison on the system are very severe, and it appears that the habit once fixed, is very rarely overcome—loss of the mental faculties. lassitude, and early impotence are produced by it. If habitual smokers are totally and suddenly deprived of their accustomed stimulus, death speedily follows in the train of a series of horrible symptoms. The only mode to avoid a fatal result, and break the chain of diseased habit, appears to be the use, in gradually diminishing doses, of a tincture made of tye chandoo with rice spirit. This preparation is only one-fourth the strength of the chandoo. Dr. M'Pherson, in his recent work on China, gives a nearly similar account of this habit. In the Montana district, in Peru, a practice prevails, which is thus described by Dr. Smith:—It bears some resemblance to the vice of which I have just spoken, but it is not so pernicious. The coca-leaf, when moderately used, comforts the stomach of the Indian, as good tea does that of the European, and acts in a peculiarly cordial manner. It enables those who use it in moderation, to endure a great deal of cold, wet, general fatigue, and even fasting, to a surprising degree, with apparent impunity. But though it in this way fortifies and supports nervous and muscular energy, and keeps up an agreeable exhilaration of spirits, when taken in excess, as is done by many of the coca-gatherers, who repair to the Montana to indulge in it freely, it is said to excite a species of reverie, which may be looked upon as a variety of mania. Those who are thus affected are always chewing the leaves, and retire to the solitude of the thicket, finding their joy in flying from the presence of their fellow-men, and indulging in silent contemplation, or rather in vague associations and trains of ideas, without exercising any rational control of thought, or feeling an interest in the ordinary concerns and duties of life. The remedy for this state is simply to return into society, and abandon the abuse of the coca-leaf.

INDIAN HEMP.

While thus calling attention to the effects of anodynes, it may be as well to mention that Mr. Ley has found the resinous extract of the Indian hemp a very powerful remedy in allaying muscular spasm and irritation. He gave it in doses of from one to three grains. Dr. O'Shaughnessy calls it an anti-convulsive remedy of the greatest value. Mr. Ley has found it, in full doses, produce a singular sensation of terror or fright, instead of the pleasant feeling of inebriation, of the most cheerful kind, described by authors

The Indian hemp (*Cannabis Indica*) appears to be identical, in all respects, with the European variety, (*Cannabis Sativa*) with the single exception, that the former plant contains a certain amount of resin, on which its narcotic and anti-convulsive powers depend, and which seems to be almost totally absent in the European plant. Mr. Ley stated at a recent meeting of the Royal Medico-Botanical Society, that he had collected some in the Regent's Park, and had obtained from it a tincture, and an alcholic extract; but found it contained only about one-tenth the quantity of resin yielded by the Indian plant, and, as he expected, he had found it comparatively inert. The hemp in question was gathered very late in the season, and was perhaps too old. The resin of the hemp is soluble in alcohol and ether, partially soluble in alcaline, insoluble in acid solutions; when pure, of a blackish grey color—hard at 90 deg.,—softens at higher temperatures, and fuses readily—soluble in the fixed, and in several volatile oils. Its odour is fragrant and narcotic, taste slightly warm, bitterish, and acrid. The Indian plant exhales a powerful narcotic odour, and the branches are glutinous to the touch with the resinous secretion, which is collected when the seed is formed, (as the plant is then in its greatest perfection,) and is sold under the name of *churus*, or the shoots from which the resin has *not* been collected, are cut, dried, and sold as *gunjah*. The churus is in general use as an intoxicating agent, from the farthermost confines of India to Algiers. If it be swallowed, almost invariably its inebriation is of the most cheerful kind, causing the persons to sing and dance, to eat food with great relish, and to seek aphrodisiac enjoyment. The intoxication lasts about three hours, when sleep follows. No nausea, nor sickness of the stomach supervenes, nor are the bowels at all affected: next day, there is slight giddiness, and much vascularity of the eyes, but no other symptom worth recording. Dr. O'Shaughnessy stated, with regard to the character of the intoxication produced by the churus, that apathy, or insouciance, was as often present as the feelings of pleasurable excitement; but he could not recollect a single instance in which that of alarm or terror had been occasioned by it. The effects of the resin are much modified in this country, and much less marked, possibly from the length of the voyage rendering the article deteriorated in value. The resinous extract prepared at Calcutta from the fresh plant, is the most valuable of all the preparations: next to that ranks the extract made from the gunjah immediately after it has been brought to this country, while a similar preparation made from the plant after it has been a length of time in England, is comparatively inert. From this circumstance we may conclude, that some portion of the virtues of hemp depends on the essential oil it contains. Dr. O'Shaughnessy says, that the gunjah yields to alcohol twenty per cent. of resinous extract, composed of the resin, (*churus*,) and green coloring matter (*chlorophylle*.) Distilled with a large quantity of water or spirit, traces of essential oil pass over, and the distilled liquor has the powerful narcotic odour of the plant.

Mr. Ley, in his essay, read before the Royal Medico-Botanical Society, draws a comparison between the effects produced by opium and those caused by the cannabis indica, the result of which induces him to give the preference to the latter, its influence being exerted more kindly and gratefully on the system. It has proved of service in cholera and rheumatism, but it is in spasmodic and convulsive diseases that it is most eminently useful. In tetanus it has been the means of cure in the majority of cases, and it has relieved much of the severity in hydrophobia, although it did not prevent the fatal termination. It is useful in chorea, spasmodic asthma, and delirium tremens, and generally wherever opium is indicated. In India it has produced catalepsy. Mr. Ley considers further, that it will prove a direct antidote, the first of its class, to the strychnia poisons, in which opinion he is confirmed by Dr. O'Shaughnessy, who experimented with it on dogs. Having ascertained by direct experiment the poisonous dose of the nux vomica bark on animals, he administered it to 6 dogs, following it in half an hour with a full dose of the resin. The dogs who did not get the resin died with all the symptoms characteristic of poisoning by nux vomica, and the others all escaped. Dr. O'Shaughnessy observes further, that a blister to the nape of the neck, leeches to the temple, and nauseating doses of tartar emetic, with saline purgatives, have rapidly dispelled the symptoms of an over-dose of the drug. Makrizi recommends oxymel and acids as its antidotes, and next to these, emetics, cold bathing, and sleep.

BELLADONNA.

The leaves of belladonna have been tried by Dr. Avoyne, of Batignolles, externally, for the relief of anomalous nervous pains with advantage. He cites several cases in which the pains were removed by the application of the poultice; and he attributes their cessation to the relaxation of the muscular fibres adjoining the suffering nerve. Dr. Delpage has found the internal use of the powder of the same leaf, in doses of five to ten grains, relieve the nervous cough which precedes consumption, and it has been also tried with benefit

in cases of sciatica and epilepsy. Dr. Debreyne, who has published a long communication upon the treatment of epilepsy, in the *Bulletin General de Therapeutique*, says he has tried it in about two hundred cases, and there was scarcely one in which its use was not attended with advantageous results. It is, however, by no means a specific. Mr. Bulley, of Reading, has used the extract dissolved in water, in irrigation in cases of inflamed eyes, and he speaks favourably of its employment. When the liquid is first thrown on the eyes, the lids must be closed, but the patient soon gets accustomed to the shock, and the continued stream may afterwards be thrown upon the eye itself, without producing any disagreeable sensation. His essay is illustrated with cases.

IODINE

and its preparations may fairly claim the next place in our notice, from the very important therapeutic services they render to suffering humanity. In the various forms of scrofula, the iodide of potassium has long been found serviceable; more recently it has secured its reputation in the treatment of subacute and chronic rheumatism, periostitis, and secondary syphilis; and has still more lately been used with advantage in cases of dropsy after scarlatina, and in schirrus uteri. By some medical men it has been given in very large doses. Dr. Bouyer, of Marennes, has raised the quantity gradually, until he has given two drachms in the course of the day. He adds a small quantity of opium to prevent its injurious influence on the glandular system. Dr. Langevin, of Havre, has detailed several singular and interesting cases of secondary and tertiary syphilis, remarkable for the large quantities of the iodide he administered, and the rapidity with which he effected cures, even in cases of very long standing. He commenced with forty grains daily, and doubled and trebled the dose very soon, so that in the course of a fortnight after the commencement of the treatment, he gave eight scruples in the four-and-twenty hours. Chomel adds his testimony in favour of the remedy, but the doses he prescribed were more moderate. (*Bulletin general de Therapeutique.*) Dr. Ross, of Cambersmere, Sutherlandshire, has employed iodine and its compounds very freely as external applications. The tincture of iodine, undiluted, he has found serviceable in cases of obstinate ulcers, with large flabby granulations, and in ulcers of the tonsils and fauces, whether specific or non-specific. In these last named cases it is best used as a gargle. He does not speak very highly of its application over enlarged and indolent glands and buboes. He supports Mr. Martin's recommendation of the diluted tincture as an injection in hydrocele, but condemns its use in phthisis and bronchitis by inhalation, from having witnessed fearful bronchial irritation produced by it. In tinea, porrigo, impetigo, eczema, &c., he has found it very useful, after the hair has been cut close, and the head cleaned of the scabs. Dr. Graves, speaking of this application of iodine, says it will not do to apply it as is generally done with a camel's hair brush, for it must be strongly rubbed into each spot, for which purpose a small bit of sponge, covered with fine linen, and tied to the end of a quill, or slender stick, should be employed; the application should not be repeated more than once a week. Mr. Wilson recommends a liniment made with the iodide of sulphur and olive oil in cases of porrigo, in which he is supported by Dr. Davidson, of Glasgow. The iodide of zinc is advised as an application to the tonsils when enlarged, and the iodide of arsenic Dr. Ross has seen used in a case of lupus, with great success; he adds, there is not any cause to fear absorption of the arsenic. The use of the iodine injection has been extended by Velpeau to the treatment of serous cysts, which he penetrates and evacuates the contents, and then throws in a solution of iodine, which is retained for a few seconds and afterwards withdrawn. Slight inflammation comes on in a few days, and a cure is effected in five or six weeks. Very little pain is caused by the injection.

THE HYDRIODATE OF ARSENIC AND MERCURY.

Mr. Donovan, of Dublin, has introduced a mixture, holding in solution a compound salt, the hydriodate of arsenic, and mercury in the treatment of lupus, lepra, psoriasis, pytyriasis, sycosis, porrigo, impetigo, venereal eruptions, ephelis, &c. which has been tried very extensively by the profession, and has been reported on very favourably. Cases of inveterate psoriasis, in which arsenic, the iodide of potassium, sarsaparilla, mercurials, guaiacum, &c., had been directed unavailingly, yielded speedily under the administration of the iodide of arsenic and mercury. In the first case reported, that of a child nine years old, within ten days after the commencement of its use, the eruption began rapidly to decline upon the trunk, and the thick scales to loosen upon the extremities. In five weeks time all traces of the eruption, which was of two years' duration, had disappeared from the surface of the trunk, and only a few patches remained on the extremities. The mixture disagreeing now, its use was intermitted for a time, and the child sent into the country. On her return its exhibition was resumed, and in three weeks the patient was entirely cured. She was seen eight months afterwards, and had not had a relapse. This case, which was under the care of Dr. Osbrey, is one of particular interest, because the disease was of a very aggravated nature, and of considerable duration. The child had been previously under the care of several practitioners in London, but had not received any relief. The case is one of value in another respect, as it gives a warning against the unguarded and too protracted use of the salt, as emaciation, with loss of appetite and other symptoms, presented themselves while it was given, and ceased on its discontinuance. When first administered, it generally produces nausea and sickness. Dr. Osbrey has used it also in cases of button scurvy, syphilis, pytyriasis, and lichen urticatus. Messrs. Carmichael, Colles, Cusack, Sir H. Marsh, Dr. Graves, and Dr. Croker have also tried it in the cases for which it is recommended, and speak very highly of it. One drachm measure of the liquor of hydriodate of arsenic and mercury consists of one drachm of distilled water, one-eighth of a grain of arsenious acid, one-fourth of a grain of peroxide of mercury, and three-fourths of a grain of iodine in the state of hydriodic acid. It occasionally produces slight ptyalism, an effect not very astonishing when it is borne in mind that each of its three elements may cause that result. It sometimes at first causes disturbance of the stomach and bowels, and when, by continuance of its use, its effects are accumulated, it often affects the head. The dose of the mixture should be from fifteen minims to half a drachm, twice a day. Larger doses have been given, but it is not advisable. It cannot be too much impressed on prescribers that thay incur great risk of destroying its powers by mixing it with other articles, intended to modify its effects. It ought not to be conjoined with opium, nor with the salts of morphia. When opiates are necessary, they should not be administered at the same time with the arsenico-mercurial liquor, the best menstruum for which will be distilled water.

COD LIVER OIL.

The oils obtained from the livers of the cod and skate have been advised medicinally in scrofula, &c., and their virtues appear to depend on the iodine they contain. — The following method of ascertaining the presence of iodine in cod liver oil, is given in the *Journal de Chimie Medicale*. Four ounces at least of the oil to be examined are to be treated with an excess of liquor potassæ, moderately diluted. This is afterwards to be heated until the whole of the liquid is evaporated, care being taken that the temperature is not raised to the boiling point. Collect the residue of this evaporation, throw it, a small quantity at a time, into a large crucible, and proceed to carbonize it, taking the precaution, towards the end of the operation, to place a well-fitted cover over the crucible, so as to prevent the volatilization of the combination of iodine, which may be formed. The carbonized residue is now to be boiled several times with alcohol, after which, these solutions are to be mixed together, and evaporated nearly to dryness. Dissolve this product in a small quantity of distilled water, add a slight excess of sulphuric acid, and either carbonate of sulphur, or what is better, a little fresh starch, with one drop of solution of chloride of lime. In this manner the least trace of iodine may be discovered, and it will be found that the pure oil of cod's liver always contains a minute portion.

THE IODURET OF POTASSIUM.

M. Ricord, in a second communication on the effects produced by the ioduret of potassium, points out the pathogenic results from its administration in certain persons. He has found it cause eruptions of a psydraceous character, somewhat resembling the pustules of acne, but not confined to the places where that disease is located, the eruption occasionally simulating eczema, herpes, purpurea hæmorrhagica, rupia, or the varieties of erythema; gastralgia, ptyalism, diuresis, catarrho-œdematous ophthalmia, coryza, bronchitis, iodic intoxication, and blenorrhagia, have all been respectively induced by the use of the ioduret of potassium. Ricord observes, that for the removal of any of these affections thus induced, all that is required is to suspend the medicine for a time, or diminish the dose. He has as yet only met with six cases in which he was obliged finally to abandon the use of the remedy.

CLINKERS.

Mr. Conway Edwards, of Batheaston, has published an interesting communication on the medicinal use of clinkers, the refuse ot the blacksmiths' forge. It differs from common ashes and coke in its greater specific gravity, component parts, and external appearance. It appears to possess tonic, stimulant, and anthelmintic properties, and is of essential service in chlorotic and dyspeptic cases. Its use is contra-indicated where an inflammatory diathesis prevails. The quantity of metal which clinkers contain, varies considerably: the best is obtained from a blacksmith's forge, and the most ponderous, darkest, and most metallic in appearance, should be selected. The light slate-coloured clinker is inert. It is prepared for medicinal use by pulverizing it, and mixing it with treacle and honey: to every eight ounces of this mass, which should be of the consistence of stiff paste, half an ounce of magnesia, and the same quantity of ginger, must be added. The dose is a tea-spoonful twice a-day for three days; then an interval of three days, and a repetition of the medicine for the same period. The first dose is apt to cause a sensation of a great weight in the epigastric region, with a feeling of burning, followed by sickness and fainting, which is relieved by eructation of flatus. Some complain of pains in the limbs, and particularly the joints; others, of tightness across the forehead, with giddiness; while all are troubled with heat, dryness of the mouth, and great thirst. At the second dose, the symptoms are moderated; and the third is generally taken with impunity. After it has been persevered in for some time, sensations of a different character arise. These are, hunger, and a feeling of health and energy, to which, perhaps, the patient has been a stranger for years. Then the complexion, if pale, commonly receives a ruddy tint, and the muscular fibre becomes firm and enlarges. After the first dose, the fæces are like pitch—the urine generally pale and large in quantity—the bowels, if previously costive, become regular in their action—the pulse gets full, and the skin pleasantly relaxed.

CHALYBEATE SALTS.

Mr. Bullock has lately introduced the citrate, ammonio-citrate, and lactate of iron, chalybeate salts, which were first prepared by M. Béral, as useful, more scientific, and more pleasing preparations of iron than those in ordinary use. They have been employed by many members of the profession, who speak highly of them in those cases where a chalybeate is required.

PHLORIDZINE AND CINCHOVINE.

By the aid of chemistry we have obtained two vegetable alcaloids, considered to possess tonic and anti-febrifuge properties. One of these, phloridzine, is obtained from the bark of the root of the apple and wild-cherry trees, as follows:—The bark of the recent roots is boiled with water sufficient to cover them, for half an hour. This is poured off, and the same quantity is again used. The two decoctions are mingled together, and at the end of six hours they deposit the phloridzine

in the form of a deep red velvety-looking matter. M. Lebaudey, the Editor of the *Journal de Connaissances Medico-Chirurgicales*, says, its efficacy is so decided, that we cannot hesitate to class it with the most powerful febrifuges; and it has this advantage over quina, that it never induces gastralgia. The other alcaloid is the cinchovine, which has been discovered by M. Manzini, in the quinquina jaen of commerce, the white bark of Condamine, the cinchona ovata of Peru. Its preparation is precisely the same as that of quina. It exists in the form of prismatic, elongated, white, and inodorous crystals, having a bitter taste which is not at first perceptible, as is is not very soluble in water. It presents the characteristics of an alcaloid: it forms salts with dilute acids, which are very soluble in alcohol, and is precipitated from its solution by alcalies and their carbonates, the ioduret of potassium, the bi-chloride of platina, the chloruret of gold, and other metallic chlorurets. Ammonia also causes a precipitation; but if the volatile alcali be at all in excess, a portion of the cinchovine is re-dissolved. Its atomic composition is—carbon 26, hydrogen 54, nitrogen 4, oxygen 8. (*Revue Medicale.*)

QUINA.

Dr. Lugeol, of the Havannah, has signalized an interesting fact occurring from the internal exhibition of large doses of quina: it has in many cases caused deafness, which has continued for two or three days. His statement has been confirmed by other physicians, and a case of permanent deafness has never been induced by it. The sulphate has been recently tried to a very great extent, and in enormous doses in Paris in the treatment of acute rheumatism and of typhoid fever. Several cases are recorded where the patients recovered; but others again have been published, from which it is clear that the unfortunate sufferers died from the poisonous effects of the overdose of quina, of quininism in fact. Dr. Meirieu of Saint Gilles, recommends as a substitute for the simple sulphate of quinine in the treatment of disease, a mixture containing that salt in solution, and charged with an excess of carbonic acid gas. He considers that the quina is rendered more soluble, acts with greater energy, and in a smaller dose. (*Bulletin de Therapeutique*) Other compounds of the alcaloid of the cinchona have been introduced into notice by Prince Lucien Bonaparte, under the title of the lactate and valerianate, and are said to have been found serviceable in practice, but cannot come into general use on account of their high price.

ARTEMESIA ABSINTHIUM.

Dr. H. Coulton has strongly recommended certain preparations of the artemesia absinthium, the plant being a grateful bitter and tonic. It has had numerous medicinal properties attributed to it, the chief of which are antiseptic, anthelmintic, deobstruent, tonic and stomachic. An infusion made with half a drachm of the dried herb (freed from the stalk) and ten ounces of boiling water, allowed to stand for an hour, will produce an infusion of sufficient strength: the dose, an ounce and a half three times a day. The tincture is superior to any other preparation, and is made in the following manner:—Take two ounces of the dried herbs, free from the stalk, and 16 ounces of rectified spirits; macerate 12 days, and strain. This has a most beautiful green colour, but fades on keeping, and it possesses the full aroma of the plant, and the bitter flavour in a high degree: 10 or 15 minims will impart a strong flavour to two ounces of water, and form a good stomachic draught. Wormwood is an aromatic tonic, well suited to various cases of chronic disease, in which it is desirable to support the tone of the stomach. Where debility of the digestive organs has been the chief feature of the disease, its adaptation has been evident, from the happy results that have followed its administration.

NITRATE OF SILVER.

A great objection to the use of the nitrate of silver internally, for any length of time, has been the discolouration of the skin which is in general caused by it, and which has hitherto unfortunately proved to be permanent. Dr. Patterson, of the Rathkeale Infirmary, has made this a subject of inquiry, and has published his experiments. He does not believe the nitrate reaches the stomach undecomposed, but is inclined to believe that ere it enters that viscus, it is changed into the chloride; and the discolouration he attributes to the decomposition of the chloride of silver circulating in the cutaneous tissue through the chemical action of the sun's light, and the deposition there of its metallic basis in a state of extreme disaggregation. All persons are not subject to this accident, for the influence of the sun's rays can only be effective in those cases where the cutis is more than ordinarily vascular, and is clothed with transparent cuticle. To avoid this discolouration, and yet receive the full advantage of the tonic powers of the silver, Dr. Patterson advises the employment of the ioduret, which is uninfluenced by the sun-light. It is easily prepared, by adding to a solution of the nitrate, in distilled water, a solution of hydriodate of potash in atomic proportions. If 164 grains, or one proportional of ioduret of potassium, be dissolved in two or three ounces of distilled water, and 172 grains, or one proportional of nitrate of the oxide of silver, be dissolved in two or three other ounces of distilled water—on mixing the solutions, 234 grains, or one proportional of ioduret of silver, are precipitated. The whole is then to be thrown on a filter, and the ioduret of silver should be washed with repeated effusions of rain or distilled water, and then dried in the sun or before a fire. If the ioduret of silver, so formed, be in the slightest degree contaminated with any nitrate remaining undecomposed, it will be liable to discolouration. It is, therefore, best to use the ioduret of potassium in very slight excess, and, for facility of practice, equal weights of each salt may be employed. Ioduret of silver, thus prepared, is a soft, rich looking, granular powder, having the beautiful pale greenish yellow color of the canary bird. It has neither taste nor smell, and is insoluble in water; it resists the action of the diluted nitric, hydrochloric, and acetic acids, of the alcaline subcarbonates, and of hydrochlorate of soda; it is very sparingly soluble in solution of hydriodate of potash. Dr. Patterson has found the stain caused on the skin by the external application of nitrate of silver removed by a solution of the hydriodate of potash, and has further ascertained, that nascent iodine will discharge the writing of indelible marking ink, made with the nitrate, and thence concludes, somewhat too hastily, that the discoloration from the deposition of the silver in the skin may be removed by the internal and external employment of suitable preparations of iodine, forgetting the impossibility of applying his remedies directly to the rete mucosum, where the oxide or metallic silver is deposited, and also not taking into account, that although the iodine may influence the stains caused by the nitrate, it does not follow that a similar effect will be produced on the reduced metal.

STYPTIC WATER OF BROCCHIERI.

The styptic water of brocchieri, which is said to be an excellent application in cases of hæmorrhage, has been imitated by Dr. Pereira, of Bourdeaux, who distills a water from the fresh wood of the pine, possessing all the virtues of the water of brocchieri. It is prepared as follows:—Ten proportions of the fresh wood of the pine, sawn into small thin pieces, and bruised in an iron mortar, are put into a flask with twenty proportions of water, and macerated for twelve hours; the liquid is then to be distilled until ten proportions have passed over. The liquid thus obtained is to be put into a larger vessel, and allowed to remain for twenty-four hours, when the essential oil which floats on the top is to be removed. When this has been done, the vessel is to be well shaken, and the styptic water is prepared. It is somewhat opaque, and has a smell of turpentine. It ought to be well shaken before it is used.—(*Journal de Medecine et de Chirurgie Pratique*). M. Dumas, of Montpellier, has published several cases of uterine hæmorrhage occurring during pregnancy, which he has arrested by the internal exhibition of tannin, either in the form of pill, draught, or injection. (*Journal de Medicine et Chirurgie Pratique*) and Dr. Lüdiche mentions a case where it evidently acted as an antidote to strychnia.—(*Medicinische Zeitung*).—Another styptic, the South American plant *matico* has been found a useful application. Dr. Monro, of Dundee, has employed it in three cases. The feeling produced by the leaf, when applied to the bleeding surface, is one of increased heat and throbbing, continuing for about five minutes, and then ceasing. He adds that he cannot doubt but that the matico has most decided styptic qualities, and may become a very valuable addition to our materia medica. The tincture of catechu spoken of as a valuable remedy in the sore nipple of puerperal females, when the inflammatory symptoms are abated. Much contradictory evidence has been offered on the subject, but it appears from the great mass of testimony that it is most useful in sloughing from want of tone. Fissures in and about the rectum have been cured in many instances by the use of enemata, containing the extract of rhatany. Protracted or obstinate cases have been cured in a comparatively speaking very short time by this remedy.—(*Bulletin general de Therapeutique.*) Dr. Burdach of Luckau describes a case where creosote acted as an astringent and styptic, in repressing spongy granulations, and arresting hæmorrhage with the most beneficial effects. (*Medicinische Zeitung.*) It has also been recommended in sea sickness and in neuralgia. It is used in the latter disease in the form of an ointment composed of ʒj. creosote to ℥j of lard. This is to be applied three times a day to the part affected.

SECALE CORNUTUM.

M. Payan, a celebrated surgeon at Aix, has employed the secale cornutum in the treatment of paraplegia, dependant on defective action of the spinal cord, without alteration in its structure. He has published three cases in the *Journal de Pharmacie*, illustrative of its efficacy. He believes the secale cornutum acts primarily and especially on the spinal cord. Mr. Quekett attributes the presence of the spur in rye to a parasitic fungus, and he thinks that the absorption of the sporules of the fungus by the fibres of the root of the germinating grain, will be found to be the true cause of this singular production, and when they arrive at the grain, they convert it into the body known as the ergot. M. Bonjean de Chambery has discovered two principles in the secale, the one a yellowish acrid oil, soluble in cold ether and in boiling alcohol, which is highly poisonous, and the other an aqueous extract, of a brown colour, thick consistence, and musty smell, which possesses antihæmorrhagic properties. He has also found that ergot gathered the first day of its formation has not the poisonous properties it possesses on the 6th day, and further that when exposed to boiling heat, or the process of fermentation is excited, it loses its properties.—(*Journal de Chimie Medicale.*) Mr. Gore, of Limerick, recommends an aromatic ammoniacal tincture as the best mode of administering the ergot in cases of inertia uteri. Dr. Wright has used the oil obtained by means of ether in the dose of from twenty to fifty drops combined with a little aromatic tincture, and he states that he has found it particularly efficacious in all cases in which the spur itself would have been serviceable. He considers it more certain and rapid in its effects, more easy of administration, and less disagreeable than either the infusion or the substance. He has used it externally in cases of rheumatism, he recommends it as a substitute for creosote in the treatment of tooth-ache, and has employed it with success in epistaxis and other hæmorrhages. M. Blanc, of Aix-les-Bains, has used the aqueous extract in a case of abundant and obstinate hæmorrhage with excellent effect; he gave from ten grains to a scruple in the course of the day. M. Bonjean de Chambery thinks it applicable in cases of hæmorrhage whether simple or puerperal—(*Journal de Chimie Medicale.*) A singular case is recorded in the supplementary number of the *Gaz. des Hopitaux* for October last. An unmarried woman, 40 years of age, was affected with cancer uteri, attended with hæmorrhage, to arrest which her medical attendant prescribed the secale in the form of pills, giving from thirty to forty grains in the twenty-four hours. These pills were taken for several successive days, their use intermitted when the hæmorrhage diminished, and resumed on its reaugmentation. In the space of thirty-six days four drachms had been taken; the patient was

then seized with violent vomiting, and the whole of the vaginal mucous membrane appeared of a slaty, grey colour, and exhaling a characteristic odor. The membrane came away in shreds at the end of about eight days, but when the cure had proceeded thus far, a sudden attack of hæmorrhage carried off the patient.

BENZOIC ACID.

Mr. Alexander Ure, in a communication on gouty concretions, published in the last volume but one of the *Medico-Chirurgical Transactions*, states that the most unequivocal proofs have been afforded him of the efficacy of benzoic acid in correcting and removing certain disordered states of the urine in individuals prone to attacks of gravel. Dr. Walker of Huddersfield published an account of the advantage he had derived from the use of benzoic acid, combined with balsam of copaiba, in certain affections of the urinary organs. These united statements induced Mr. Soden, of Bath, to give it a trial in certain cases of irritable bladder which came under his notice, and he has every reason to be satisfied with the result. He details five cases, one occurring in private practice, and the rest in the hospital, in all of which almost immediate benefit followed. He prescribed it, combined with the balsam of copaiba, according to Dr. Walker's plan, but he says it is very desirable to ascertain the effect of the benzoic acid alone in similar cases, more particularly as the balsam is apt to disagree with delicate stomachs. This he promises to do in future cases. The most remarkable circumstance connected with the exhibition of this compound medicine is, its decided efficacy in diminishing, and in some instances, completely suppressing the muco-purulent deposition in the urine, which is so prominent a symptom in most cases of affections of the bladder. An important fact is stated by Mr. A. Ure, that during the administration of benzoic acid, the uric acid disappears from the urine, its place being supplied by hippuric acid, into which, he thinks, it is converted by the action of the benzoic acid. Mr. Garrod confirms the discovery of the hippuric acid in the urine, after the administration of benzoic acid; but he adds, that he has also found a trace of uric acid. M. Bouchardat, the principal pharmacien at the Hotel Dieu, however, gave a patient, whose urine deposited uric acid freely, a scruple of benzoic acid in eau sucrée; the sole effect of which was, that the uric acid was rendered soluble, but not changed into hippuric acid. The experiment was repeated three successive days, each time with the same result.—(*Journal des Connaissances Medicales.*)

Mr. Garrod has suggested a very ingenious theory for explaining the manner in which the benzoic acid is converted into the hippuric. According to this theory one equivalent of lactate of urea, minus two equivalents of water, give the requisite elements for the conversion of two equivalents of benzoic acid into two equivalents of hippuric acid. The following formula will express this more clearly.

Benzoic acid (2 equiv.) . .	C 28	H.10	O.6	
Lactate of urea (1 equiv.).	C. 8	H. 8	O.6	N.2
	C.36	H.18	O.12	N.2
Minus		H. 2	O. 2.2	eqv.
	C.36	H.16	O.10	N.2
= Hippuric acid (2 equiv.)	C.36	H.16	O.10	N 2

This explanation, however, Mr. Ure does not admit, and he mentions, to disprove it, that having swallowed a scruple of cinnamic acid, the presence of the hippuric acid in the urine resulted, and if we apply the arithmetical formula to this fact, substituting the cinnamic for the benzoic acid, we obtain a result wholly incompatible with this hypothesis; for two equivalents of cinnamic acid + one of lactate of urea, — two of water will give C.44 H.20 O.10 N.2, while two equivalents of hippuric acid give C.36 H.16 O10 N.2, leaving C.8 H.4 to be accounted for. Mr. Ure, as I have already said, is of opinion that the uric acid, and not the benzoic, is converted into the hippuric, but as early as 1831 Professor Wöhler believed that benzoic acid, during digestion, was probably changed into hippuric, and his opinion has been since confirmed by the experiments of M. Keller, who, having taken thirty-two grains of benzoic acid, obtained a proportionate quantity of hippuric acid from the urine, the fluid also containing its chief ingredients, urea and uric acid, apparently in the same proportion as in the normal urine. The hippuric acid existed in the fluid in combination with a base. M. Keller, speaking of the application of the benzoic acid as a remedy for the gouty and calculous concretions of uric acid concludes as a consequence of his experiments, that Mr. Ure was too hasty in advising it, and he adds that as his observations were made on a gouty patient, it may be supposed that the urine, even without the internal use of benzoic acid, would have been found not to contain any uric acid. The question, however, is still *sub judice.* (*Annalen der Chemie und Pharmacie.*) While on this subject I may mention that, to obtain benzoic acid very pure, and free from empyreumatic smell, M. Jaussens directs one part of the benzoic acid of commerce to be mixed with eight parts of distilled water, an excess of solution of ammonia added, and the solution of benzoate of ammonia thus formed, to be treated with purified animal charcoal. He then orders the solution to be filtered, and decomposed with hydrochloric acid, when the benzoic acid will be separated in beautifully white flakes. These flakes, thrown on to a filter, and washed several times with distilled water, are afterwards to be drained, and then dissolved in a sufficient quantity of alcohol. The alcoholic solution is to be filtered, and then diluted with distilled water, so as to precipitate the benzoic acid, which is but sparingly soluble in that liquid. By this means, the essential oil, to the presence of which in the ordinary flowers of benzoin, their peculiar smell is due, is retained in solution in the alcoholic liquor. It only remains to crystallize or sublime the precipitated acid, to obtain it in a state of great purity and beauty. (*Archives de Medicine Belges*).

CUBEBS.

On giving cubebs internally, we remark that shortly after its reception in the stomach, the urine becomes impregnated with a very marked odour of the volatile oil, showing that the essential oil contained in the piper passes rapidly through the digestive tube into the urine. The knowledge of this fact led M. Piorry to think that this medicine acted locally in the treatment of gonorrhea, by exercising through the medium of the urine a topical action upon the canal, and that consequently the best mode of administering the cubebs will be that which keeps the urine constantly charged therewith. Acting upon this opinion, M. Piorry gives his patients a bolus containing a scruple of cubebs every hour, or about an ounce in the course of the day. He has thus cured several cases in four or five days, and in one instance, where the complaint was of two months' standing, it was removed in forty-eight hours. The plan pursued for women consists in throwing an injection, made by infusing half an ounce of cubebs in a pint of water, into the vagina every hour.

Two very interesting cases of poisoning by cubebs, one of which terminated fatally, have been recently placed on record. They occurred at Valparaiso, and it seems that the patients in both cases, after taking cubebs for some time, changed their druggists, and obtained the drug from another party, both sending to the same house. The dose taken was half an ounce at bed time, and the next day they were found in a state of complete asphyxia. The symptoms presented in the case that terminated fatally were as follows:—the body in a state of supination; all the senses extinguished, without hearing, speech, or movement; the eyelids fallen, and when raised, the eyes look cloudy and fixed; the pupils dilated; extremities flexible; heat natural and equally diffused; face red; pulse slow, feeble, and very irregular, respiration hardly perceptible. On examination of the body after death, the viscera were found congested with black fluid blood, the entire venous system being quite gorged therewith; nowhere was there found any red or coagulated blood. The only explanation that can be given of such an occurrence, is that some poison was mixed with the cubebs, but it is said that they have been examined by two pharmaceutical chemists, who could not detect anything deleterious.

GURJUN BALSAM.

Dr. O'Shaughnessy, a gentleman of high chemical knowledge, to whom was entrusted the editing the Bengal Dispensatory, has introduced to our notice some indigenous remedies as substitutes for drugs in general use, which are only to be obtained from foreign countries. Among these is the gurjun balsam, the essential oil of which has been found to be nearly equal to the balsam of copaiba in the treatment of gonorrhea. Some obstinate cases of chronic gonorrhea and gleet, which had long resisted copaiba and cubebs, have been cured by this remedy. The balsam itself varies in consistence from that of thick honey to a light oily liquid. As found in the bazaar, it generally occurs as a brown oily, semi-transparent liquid, possessing a sp. grav. 0,962. It is totally insoluble in water, freely in warm alcohol, and with difficulty in ether. By distillation, from thirty-five to forty parts per hundred of essential oil are obtained, and a thick resin remains in the retort. The pure essential oil is transparent, and nearly colourless, of sp. grav. 0,934: it is soluble in alcohol, ether, naphtha, and the essential and fixed oils. It dissolves caoutchouc, copal, vateria resin, and solid gluten. Its savour is acrid, sweetish, and heavy, and its odour closely resembles that of the essential oil of copaiba. It is administered in the dose of 10 to 30 drops, three or more times in the day. It generally causes a sensation of warmth at the epigastrium, eructations, and sometimes slight purging, and it communicates a strong smell of turpentine to the urine, which it increases remarkably in quantity.

STORAX.

In France purified storax has been again tried on the plan of L'Heritier, as a substitute for copaiba. M. Lepage, of Gisors, recommends the following plan for purifying the storax. Liquid storax is insoluble in cold, but soluble in boiling alcohol. By introducing it into a retort with from two to two and a half parts of alcohol at 34 deg. and heating the mixture in the sand-bath until it boils, a turbid solution will be obtained, which, filtered rapidly, will deposit on cooling, a greenish fluid resin, almost transparent, and of a very powerful odour. If the operation be carried on speedily, and the liquid be divided so as to be filtered through different apparatus at the same time, the only residuum in the filter will be impurities without any resin; but if any turbid solution remain, it may be heated again with a little alcohol, and filtered while boiling. When the resin has been entirely separated, which requires about 12 hours, the alcohol may be recovered by distillation, and the storax must be heated in a sand-bath, to drive off the alcohol which may be combined with it. Thus purified, storax presents itself in the form of a greenish semi-transparent resin, of an agreeable odour, and the consistence of turpentine; it is soluble in ether in almost any proportion; alcohol at 40 deg. dissolves it rapidly, but it is little soluble in alcohol at 33 deg.: its alcoholic solution reddens test paper. It must be preserved in well stoppered bottles, kept full as much as possible, without which a superficial crystalline layer forms on the surface, the thickness of which augments gradually. For internal administration, it may be mixed with calcined magnesia and made into pills, or dissolved in alcohol, and then made into syrup with sugar and gum arabic, or else given in the form of mixture, rubbed down with the yolk of eggs.—(*Journal de Chemie Medicale*).

CRINUM ASIATICUM.

As a substitute for ipecacuanha, the fresh bulbs of the crinum asiaticum, a plant common in Bengal, and often cultivated in the gardens, have been found serviceable; indeed, it is said to be the only indigenous emetic plant met with abundantly, which does not produce griping, purging, or other distressing symptoms. From two to four drachms of the fresh root, bruised into a paste, and squeezed, will furnish a juice, which becomes emetic after a few minutes, and in smaller doses nauseant and diaphoretic. The dried sliced roots are efficient, but the dose must be doubled; the extract, whether aqueous or alcoholic, is uncertain in its se-

tion. The powdered seeds of the ipomæa cærulea in the dose of from 30 to 40 grains, act as a quick, safe, and pleasant cathartic. The alcoholic extract, which consists of resin and oil, is deep brown, ductile, of excellent pillular consistence, and keeps for several months. In ten grain doses it produces the effects of jalap with certainty and speed; the taste is scarcely perceptible.—(*Bengal Dispensatory.*)

OX-GALL.

Ox-gall has been introduced by Dr. Clay, the eminent surgeon of Manchester, as a valuable aperient, acting without causing any uneasiness, and giving a free and full pulpy motion. He thinks it directly dissolves the hardened fæces, and by that action alone renders them easier of propulsion, while, by the addition of bile, the constipation is directly overcome, and by charging the system with an extra quantity of healthy bilious secretion, its recurrence is prevented, giving time for improving the secreting powers of the liver, by other remedial measures. When it is necessary to employ opium, and it is wished to avoid the peculiar tendency of the drug to constipate the bowels, the effect is obtained by combining the inspissated ox-gall with it, which, at the same time, in no way impedes the action of the opium. The gall bladder of a moderately sized ox will afford as much extract as will make 100 pills of four grains each. It is an article both cheap and easy to procure, and deserves to be generally tried.

TALLICOONAH OIL.

Mr. Clarke the senior assistant surgeon to the colony of Sierra Leone, has published a communication on the Tallicoonah or Kenduh oil, which is used by the liberated Africans as an anthelmintic and cathartic. The best specimens are liquid, but it is more generally found concrete. The dose is from one to two ounces, thrown up as an enema. In over-doses, it produces the most violent hypercatharsis, cold sweats, and vomiting, succeeded by collapse; and, if remedial means are not promptly employed, even by death. Mr. Clarke says it is injurious in persons of a weak habit of body: but, to others, he can confidently recommend it as a safe and powerful anthelmintic.

BISULPHURET OF CARBON.

The bisulphuret of carbon has been employed in the treatment of diseases of the eye, by Dr. Turnbull. He says it is so volatile that the application of it to the eye, when the bottle is held in a warm hand for a few seconds, is as much as can be borne, in consequence of the intense pricking heat and flow of tears it occasions. He, therefore, directs the patient to close the eyelids during its use, deriving, he says, the same beneficial effect to the eye, without inconvenience to the patient. It generally contracts the pupil, and very seldom dilates it. He has used it in enlarged, indurated, lymphatic glands, and in deafness depending on a want of nervous energy, and deficiency of wax. The value of this remedy remains, however, to be ascertained, for, unfortunately, the authority on which it is brought forward is so slight, the reasoning so inconsequent, and the communication itself so imperfect in its details, that no reliance can be placed on the statement.

PRUSSIC ACID.

The vapour of prussic acid has been recommended by the same person, for the treatment of certain diseases of the eye, among which staphyloma has been especially particularized, without regard to the obvious fact, that as it consists essentially in a change of structure, it is physically impossible to effect a cure by any remedies, so as to restore the organ to its primitive condition. The statements that were made in recommending a remedy for such a purpose, would serve only to excite the ridicule of the profession, were they not promulgated by the non-medical portion of the press, which has unfortunately given them an injurious notoriety.

NEW REMEDIES FOR SKIN DISEASES.

I cannot conclude this summary without noticing cases. In two—one of psoriasis gyrata, and the other of lepra vulgaris—it failed. The remaining twelve were cured. Two were instances of lepra vulgaris the others of psoriasis. The remedy was applied in the form of ointment, made with two scruples of naphthaline to thirty of lard. When applied too strong, it causes a burning heat, which is soon removed by baths and poultices. It is apt to cause erysipelas, if not carefully watched. (*Bulletin Generale de Therapeutique.*)

Compounds of charcoal and potass, and of soot and potass, with or without sulphur, were introduced above two years since by Dr. Polya, under the barbarous, but significant, names of anthrokokali and fuligokali. He says, he has tried them with great success in cases of dartres, scrofula, chronic rheumatism, rheumatic enlargements of the joints, gouty concretions, and hydrarthosis. He administers two grains three or four times a day, mixed with liquorice powder, or the carbonate of magnesia. M. Gibert found them most useful as external applications. He tried them in eighty cases, all of which improved under the treatment, and several were cured. They possess discutient, detersive, and slightly stimulant properties.—(*Gazette des Hospitaux.*)

The chloride of zinc, introduced by M. Canquoin, and afterwards brought before the medical profession in England by Dr. Rioffrey and Mr. Ure, has been extensively tried by Dr. Byron, of the County of Meath Infirmary, in cases of lupus exidens, or cutaneous cancer. He prefers it to any other remedy but applies it differently to M. Canquoin, who directed it to be made into a paste with flour, lime, or some other substance. Dr. Byron uses it in substance directly, because, 1st., it is at once, and in the full enjoyment of its escharotic powers, brought into immediate contact with the diseased surface; 2nd, its re-application is regulated by existing circumstances; and, 3rd, no parts are subjected to its use, but those which seem to require it. Its power in speedily removing the painful corroding sensation experienced in the site of the ulcer is very remarkable. The sloughing condition of the sore also is soon changed into a more healthy state, and florid firm granulations spring up under its use. The pain occasioned by its application is exceedingly severe, and all the symptoms produced by it should be allowed to pass by, before it is re-applied. Some precaution is necessary in using this escharotic to the skin of the head and face in young subjects, for whom it should be employed in a diluted state

RECENT DISCOVERIES IN SCIENCE.

VENTILATION OF HOUSES.

Mr. A. Liddell, of Glasgow, read to the British Association, a paper on the Ventilation of Houses, which consists in drawing off the foul air from each room by a pipe leading to the chimney of a steam-engine, which has been attended with the most beneficial results as regards the health of the inmates, and particularly by a great diminution in the number of fever cases. The plan has been tried in the Glasgow Fever Hospital, in which the beds for fever patients, &c., were fitted up with the tubes for carrying away noxious effluvia. A similar plan for the ventilation of ships and steamers has been introduced by Dr. Reid, by leading tubes from the berths into a stove on deck, or in steamers, into the chimney. Mr. Liddell stated that the expense for a house of 60,000 cubic feet was only 40 lbs. of coal in twenty-four hours. Sir John Robison observed, that it was highly satisfactory to find sound principles in regard to ventilation making their way amongst the people of this country; but it was at the same time to be regretted that ineffective plans should be resorted to, when the very best plans had been many years before the public. The mode of ventilating the Derby Infirmary, devised by

DR. PAYERNE'S SECRET.

The Editor of the *Mechanic's Magazine* observes, "It is only to take down with you something that will absorb the carbonic acid gas as fast as you generate it, and something else (with a lucifer match or two to heat it,) from which you may set free oxygen enough to keep you alive. Doubtless, these are the main conditions of the experiment—and there are several well-known substances which do possess these two requisites. Pure potassa, for example, will absorb nearly half its weight, of carbonic acid gas; and chlorate of potass gives out, when heated, 39·15 parts per 100 of oxygen."

THE BUDE LIGHT IN MANCHESTER.

The Bazaar at Deansgate, Manchester, has lately been illuminated with Mr. Goldsworthy Gurney's patent Bude Light. The shop is 1280 feet in length and 48 feet wide, and contained formerly no fewer than 73 gas-lights, (12 of them argand burners), which have been displaced by *four* Bude Lights. Not only is this new light more intense and beautiful than that of ordinary gas, but it is so pure and white that it does not cast a false glare on colours. Thus, by it greens may be distinguished from blues at a considerable distance; and any small print can be more readily read by the Bude Light at a distance, than by the common gas light placed just above it. Each of the lights proceeds from three concentric rings of tubing, with numerous perforations, in which is burnt the gas supplied from the Manchester gas works; Mr. Gurney's patent consisting in an apparatus, attached to the meter, for purifying the gas by passing it through a chemical mixture; and iron tubing being substituted for that of lead. The consumption of the purified gas by the large centre light in the bazaar is 80 cubic feet per hour; each of the smaller ones consumes 45 cubic feet in the same time. —*Abridged from the Shrewsbury Chronicle.*

THE BOCCIUS LIGHT.

This invention, named after the patentee, Gottlieb Boccius, was first exhibited opposite Northumberland House, in the Strand, when its brilliancy excited considerable interest as to the means of its production.

In the specification, this new light is described as "certain improvements in the combustion of gas." The gas is supplied from a number of concentric rings, perforated with a vast number of small holes on their upper surfaces; that is, precisely the plan adopted by Mr. Gurney, in his Bude Light. Instead, however, of one chimney, as usual, Mr. Boccius applies, above the jet-holes of the burners, two or more concentric chimneys, or cylinders, in addition to and within the usual chimney of glass. The body of the burners may be of any suitable metal: but, for the upper surface, through which the jet-holes are pierced, the patentee uses the German silver soldered into it, "on account of the high temperature required for its fusion."—In constructing burners of two or more concentric rings, the patentee places the inner ring at a certain height above the outer one, or that next to it; thus to provide for the greater equality of the height of the several cylinders of flame in such burners, so that they shall terminate as exactly as possible at one and the same level, and all enter the central chimney altogether. He finds by this arrangement that the economy or luminous effect arising from the combustion of a given quantity of gas, is much increased; an effect which he attributes in great measure to the circumstance that nearly equal luminosity is obtained in the flames from each

lame, should be such that its top is just received within the lower edge of the innermost central chimney. "When this is the case the combustion will be found very perfect, and the light brilliantly white. No carbon will be deposited within any of the chimneys, and the light will be perfectly steady; the lower edge of the central chimneys defining the upper part of the light, so that the jagged or irregular edges and flickering so unpleasant to the eye in common gas-burners, does not exist, but the light appears of a permanent form, as a truncated section of a luminous cone."

The merit of this light has been much questioned. The Editor of the *Mechanics Magazine* observes: "Its novelty is of a strange sort: —whereas it has been generally considered advisable that the chimney of a lamp should cast as little shadow as possible, the second chimney of the Boccius lamp is made of solid metal, and casts a darker and deeper shadow than any we ever saw. Our present impression of this new wonder of the day is—that what is good in it is not new, and what is new is not good."—Dr. Ure, too, has pronounced the Boccius Light to to be a palpable imitation of the Bude Light.

THE NEW FRENCH LIGHT.

A French chemist of note has patented this improvement, both in France and England, through M. Charlieu, of Paris. Its main feature (which forms the subject of the latter part of the patent) consists in affixing to the centre of the burner an upright stem, or one stem to each hole of the burner. The liquid is conducted up to the burner by cotton yarn, and the flame keeps the stem hot; thus the liquid, as it comes up towards the burner, is volatilized, and the vapour to be consumed passes through the holes in the burner in a similar manner to gas. To light these burners, a hoop, surrounded with cotton or other fibrous substance, and provided with a stem, is employed. The hoop is dipped into some of the liquid and ignited, and then passed down over the burner below the upper part of the cotton yarn; by this means, vapour is quickly produced in the burner, and passing through the holes in the same, becomes ignited; the hoop is then removed, and the heat of the flame maintains the requisite supply of vapour.

This light combines all the advantages of gas, and also those of oil or tallow; for while, like the former, a constant and brilliant light is produced, and all difficulty and trouble of cleaning and trimming lamps are avoided, so, at the same time, all the advantages of portability and smallness of compass of the latter are retained. But one great feature of its superiority over both consists in an almost entire absence of smoke.

The liquid consists chiefly in distilling a mixture of some spirit, (naptha, for instance) and of some essential oil in certain proportions according to circumstances; generally of about twenty-three parts of essential oil, combined with seventy-seven parts of spirit of the strength of ninety-five degrees.—*Polytechnic Journal.*

UNFAIR GAS-METERS.

Mr. Flower, in a pamphlet on the gas-meter, proves in what manner it may be affected so as to show a false register of the quantity of gas consumed, to the great loss of the consumer, Thus:

"An undue quantity of water in a meter will make a difference of about twenty per cent. in the amount registered over the quantity actually consumed; but let the water in a meter consumer and to the companies, but more especial to the latter, who take good heed that the meter shall not and cannot give more than a nominal 1000 feet for the 1000 feet registered, which my experience shows to be not 900 for the 1000; but they leave their tenants to run the risk of defrauding themselves out of from one to twenty per cent. of gas as well. If, as the companies construct their meters, that too little water in them will occasion an impossibility of obtaining a supply of gas, why should they not be so guaged as to declare to the consumer, that if he has above a certain quantity of water in his meter he is registering water as well as gas?"

FEATS OF STRENGTH.

The following extraordinary Feats of Human Strength and Endurance are related in the *New York Courier and Inquirer*, to have been exhibited at the Bowery Theatre. It was announced in the bills that M. Paul was to resist the power of two of the strongest horses to be found in New York, for a wager of 1000 dollars. The animals selected to pull against him were a pair of large-sized Pensylvania-bred horses, which are in the daily habit of drawing from two to three tons of granite at a load, on an enormous truck. Paul, after firing a cannon weighing 400 lbs. from his shoulders, and ascending the fireman's rope, feet uppermost to the flies, by means of his hands alone, and performing other Herculean feats, placed himself horizontally upon a strong oak ladder, in order to make the grand effort. The horses were led on by their regular driver, and harnessed to a rope fastened to Paul's feet. To this rope were attached three broad ribands or girths, one of which was drawn tightly over his loins, and the others over his shoulders. The brace afforded by his feet against the step of the ladder, the power of the girths, and his hold with both hands upon the upper part of the ladder, constituted his only resistance to the immense power he had to contend against. Paul's body when thus disposed, resembled that of a malefactor upon the rack, preparatory to being torn to pieces. When the colossal horses were brought upon the stage, and attached to the feet of the intrepid performer, a sensation of horror seemed to pervade every part of the house. The word was given—the harness straightened—the ladder creaked and strained—the two ropes by which one end of it was secured to the stage stretched and threatened to break: the horses aided by a platform upon the stage, with cleets to brace their feet, strained every muscle and vein—the well known voice of the driver—the lash repeated again and again—all failed to force the enduring champion from his hold. The shouts of the audience, and the withdrawal of the horses, proclaimed his triumph! M. Paul attained his 18th year in March last.

THE IMPILIA BOOTS.

In the specification of the patentee (Mr. W. Baker, surgeon, of Grosvenor-street), the invention is stated to consist in a layer of horse or other strong curled hair (felt or matted together, with or without a layer of caoutchouc) between the inner and outer soles of shoes and boots. When a sole is to be composed of more than two thicknesses of leather, the patentee prefers that the layer of felted or matted hair should lie between the two upper pieces of leather. In some cases, in addition to the use of the layer of matted or felted hair, he applies a thin sheet of India rubber (caoutchouc) on the under surface of the matted hair, either by applying the solution of India rubber after it, or by placing a thin sheet of India

WARMTH OF THE SNOW BLANKET.

At the French Academy of Sciences (March 14) M. Arago read a communication on the warmth imparted to the earth by a covering of snow, and respecting which there has hitherto been much scepticism. M. Arago stated that M. Boussingault had ascertained the truth of the theory beyond the possibility of doubt, during the past winter. He found that a thermometer plunged in snow in the depth of a decimitre (about 4 inches) sometimes marked 9 degrees of heat greater than at the surface.

CREAM AND BUTTER.

The Viscount de Romanet, in treating on the phenomena presented in the transformation of cream into butter, states, from microscopic observation, that the cream consists of the globules of the milk, which rise to the surface from their lightness, and which contain the butter in the form of pulp, enveloped in a white, thin, and elastic pellicle. The action of the churn is, he says, nothing more than the rupture of the pellicle, and it is the fragments o this pellicle which whiten the liquid called butter-milk; the acidity which manifests itself in this liquid, at the instant when the butter is formed, is due to the immediate contact of the butter with the acid principles of the milk.

ELECTRIC GILDING.

Prince Louis Bonaparte has exhibited to the Scientific Congress at Florence (in 1841), some platina gilt by De la Rive's process, and observes that this metal takes the gilding better than silver. He explains this, on the one hand, by the greater density of the platina; and on the other, by the insoluble layer of chloride of silver, which must withstand the perfect gilding of silver.

THE TORPEDO.—GLOW WORM.

M. Zantedeschi has confirmed the experiments of M. Mattencei on the torpedo: he thinks that the nerves come from the dilatation of the medulla oblongata, which forms the fourth lobe with the grey matter covering it.—Mr. Morren has found phosphorus in glow-worms, as well as a system of prisms or transparent lenses above the luminous matter.

PROPERTIES OF GELATINE.

There has lately occurred in Paris a controversy on the use of the gelatine of bones for hospital soup, as recommended by D'Arcet; and the most contradictory opinions as to its qualities are daily published. Professor Liebig has, we think, decided this question. He has shown that gelatine cannot yield blood, and that by itself, therefore, it cannot support life. But he supposes that it is dissolved in the stomach, and being conveyed in the blood to every part of the body, acts as nutriment to the gelatinous membranes and bones alone. This ingenious idea explains both how gelatine mixed with other animal matter form a good diet, and how it is peculiarly adapted fo the sick and convalescent, in whom it acts by giving nutrition to the gelatinous tissues, an so sparing much of the energy of the en feebled digestive system, which is thus no consumed in producing gelatine for thes tissues, but is expended in the digestion o sanguiferous nourishment. We can now readil credit the statement of D'Arcet, who has show that in all the hospitals where the gelatine h been used as a principal but not the only article animal food, the patients relish it, the succe of the treatment has been much increased, a the period of convalescence on the avera much diminished. Now that we possess wh appears to be the true theory of the action

country against its use may be overcome; and that our hospitals mayparticipate in the benefits of D'Arcet's benevolent system, which, when successfully conducted, has likewise the advantage of superior economy.

PRESERVATION OF ANIMAL AND VEGETABLE BODIES.

Mr. Babington has reported to the British Association the results of experiments for the above purpose commenced in June, 1838, and continued four years. They were made by placing in small jars (5 inches by 2) solutions in water of the different substances unmixed but tried in three proportions: viz., 1, a saturated solution; 2, a solution diluted with an equal quantity of water; and 3, with a double quantity. The following is a list of them, arranged according to their value as preservatives of animal substances:

1. Good preservatives: napthha employed in the proportion of 1 part to 7 of water.

2. Moderately good, but the specimens soft: sulphate of magnesia, arseniate of potash.

3. Moderately good when examined in 1840, but the specimens decomposed in 1842: alum, muriate of ammonia, muriate of magnesia, nitre, sulphate of zinc, bicarbonate of potash, arsenious acid.

4. Quite useless for the purpose of preservation: sulphate of iron, sulphate of copper, sulphate of soda, sulphate of potash, carbonate of ammonia, nitrate of barytes, nitrate of strontian, nitrate of soda, muriate of barytes, muriate of lime, phosphate of soda, chloride of potash, oxalic acid, and rough pyroligneous acid.

A few drops of kreosote in water is a good preservative, but stains the specimens brown. Corrosive sublimate preserves perfectly, but hardens the substances too much. Concentrated acetic acid decomposes the skin, bones, and cellular membrane, but leaves the vessels untouched, i.e. preserved.

The vegetable substances are well preserved in oxalic acid, concentrated acetic acid, napthha, and kreosote; moderately well in muriate of ammonia, and corrosive sublimate. None of the others appear to have succeeded: nor, indeed, is the colour of the vegetables well preserved in any case; and, on the whole, the experiments with them are far from satisfactory.

ON THE ANALYSIS OF URINARY CALCULI.

By Mons. E. Marchand, (with Notes by Mr. Ure.*)

When a urinary calculus is to be examined, it ought to be sawn in two, in the direction of its greatest diameter, so as to enable us to ascertain the different layers of which it is formed. These layers are sometimes very different in their nature, and merit very great attention on the part of the inquirer.

The first thing to be done in the treatment of a calculus, is to incinerate a small quantity in a platinum capsule, in order to know whether it be composed in whole or in part of substances which are volatile by heat. In the first case, it may be formed entirely of uric acid, or of urate of ammonia; in the second, it may contain the phosphates oxalate of lime, urate of soda or of lime, &c. When the residue fuses by the agency of heat, it may be inferred to contain the ammonio-magnesian phosphate. If, on the other hand, it effervesce on the addition of muriatic acid, we may conclude, that urate or oxalate of lime had been present in the calculus, more especially if it afford the characters of the salts of lime, when subjected to the proper tests.

Where the calculus is destroyed, in whole or in part, by the action of heat, we must then look for uric acid. For that purpose, we pour a drop or two of nitric acid upon a small portion of the pulverized calculus, and expose it to a gentle heat, until perfect desiccation. Should it contain uric acid, that treated by the nitric acid, assumes a fine red color; of which the intensity may be increased by adding a few drops of water, and drying at a moderate heat. To succeed well in this operation, care must be taken not to employ too much nitric acid, otherwise we transform the uric into oxalic acid, and no longer obtain the desired result—namely, the formation of purpuric acid.

I may remark in passing, that M. Berzelius commits an error, when, in speaking of the action of nitric acid upon uric acid, he says, that the red matter arising from that re-action, and which accompanies the purpuric acid, does not colour the water in which it is dissolved. The fact is, I have always seen the liquor acquire a beautiful crimson tint at the moment of solution, which disappeared by an elevation of temperature but re-appeared in the residue of evaporation. In the cold the decoloration still occurs, though after a lapse of some hours, and there is deposited a powder of a reddish yellow hue. [On treating five grains of pure uric acid with a little nitric acid of sp. gr. 1.280, diluted with five waters, and gently evaporating, the interior of the porcelain capsule, which had been used, exhibited the characteristic purple coating. Distilled water being added, immediately became a deep carmine colour; which, in the cold, as above stated, got gradually fainter and fainter, and, after six hours wholly vanished.]

By this procedure we demonstrate, it is true, the presence of uric acid; but it is necessary to determine whether the acid be pure or mixed, or combined with other substances. For this end, a portion of the calculus, previously pulverized, is to be treated with a solution of caustic potash. If, during the process of solution, an ammoniacal smell be developed, other than that of lye, which is peculiar to uric acid, we may be sure, that it is united in totality, or in part only, with ammonia. When the calculus dissolves altogether in potash, it is composed entirely of uric acid or of urate of ammonia. Should it not dissolve completely, we must ascertain the nature of the substances which enter as constituent parts into its composition, and which are mingled or combined with uric acid.

When a calculus consists at the same time of uric acid and of urate of ammonia, we can easily recognize if the uric acid be wholly combined with ammonia, or if only a part be associated with that base. With this view, we must boil a portion of the pounded calculus for some instants in distilled water, and then filter. The urate of ammonia alone dissolves, sometimes in the state of biurate, while the free uric acid remains at the bottom of the tube, as can be verified by treating the remainder with potash, which no longer disengages any ammonia.

It has been stated above, that all calculi are not destroyed by the action of heat. To discover the nature of the substances which withstand fire, we must try whether they are alkaline or not after incineration, and whether they effervesce or not with muriatic acid. When the ashy residuum is alkaline and effervesces with acids, it is from the decomposition of a urate or an oxalate, frequently with lime for its base. To learn which of those acids exists in the calculus, we must boil a very small quantity of the last in water acidulated with nitric acid, then filter the liquor and saturate with ammonia. If a white precipitate be obtained, we may thence infer the presence of oxalate of lime; if, on the contrary, ammonia give no precipitate, we may conclude that the residuum is merely the product of the decomposition of a calcareous urate. These two re-actions are readily explained:—Under the influence of the nitric acid, the oxalate, as well as the urate of lime, is dissolved in water, but the former without changing its nature, and it is simply requisite to saturate the nitric acid, by means of ammonia, to make it re-appear. The urate of lime, on the other hand, undergoes decomposition when dissolved in water acidulated with nitric acid, nitrate of lime being formed which the ammonia does not affect.

When the residuum is alkaline and does not effervesce with acids, it usually consists of phosphate of lime, as ascertained by triturating it along with a few drops of a solution of nitrate of silver. If it acquire a yellowish tint, we are sure that it contains phosporic acid; by heating another portion with water acidulated with nitric acid, we obtain a liquor which, provided the residuum consisted of phosphate of lime, affords, by means of tests, all the characters of salts, and which, moreover, is precipitated by ammonia.

When the residuum is not alkaline and does not effervesce with acids, it is ordinarily formed of the ammonia-magnesian phosphate, fusible below the blow-pipe, emitting an odour of ammonia when treated by caustic potash, and assuming likewise a yellow tint when put in contact with nitrate of silver.

When the calculus does not experience any sensible loss by the action of heat, or exhibit the characters of uric acid when treated with nitric acid, it consists of oxalate of lime, of ammonia-magnesian phosphate, of phosphate of lime, of silica, of sulphate of lime, &c.; sometimes of a mixture of two or more of these substances.

To arrive at a knowledge of the constitution of these kinds of calculous concretions, we commence by calcining a small quantity in a platinum spoon, over the flame of a spirit lamp. We next pour some drops of water upon the ashes and see whether they are alkaline and effervesce with acids; if so, oxalate of lime forms a component part; if not, we must search for phosphate of lime, phosphate of ammonia and magnesia, silica, or sulphate of lime. For this purpose a drop or two of nitrate of silver is to be poured upon a portion of the calculus, and they are to be well triturated together. If the mixture assumes a yellow tinge, it is a proof of the presence of phosphoric acid in the calculus. In treating a particle of the calculus with caustic potash, we can tell whether or not the acid is combined with ammonia. In the first case it will evolve an ammoniacal odour. However, we must still submit to the flame of the blow-pipe what remains after calcination, to see if it fuse into a glass bead a character of the double phosphate of ammonia and magnesia. By its greater or less fusibility we may soon, with a little practice, determine whether the calculus be formed or not of a mixture of phosphate of lime and phosphate of ammonia and magnesia. Further information will be obtained by dissolving a small quantity of the ash in water acidulated with nitric acid, and treating the filtered liquor with oxalate of ammonia, which occasions in the solution of the calcareous phosphate, only, a white precipitate of oxalate of lime.

Siliceous concretions are recognised by their insolubility in acids, and by affording on fusion with alkalis a colourless glass, which will dissolve in water provided there be a sufficient excess of alkali.

In the collection of Mons. E. Barruel is the fragment of a vesical calculus, weighing nearly sixty *grammes*, and formed almost entirely of sulphate of lime. This fragment, which is concave, (the internal portion having gone astray) is in brilliant lamellar crystals, of a reddish colour. Calcined, in a platinum crucible, it exhales an odour of burnt milk, and takes a greyish hue. Heated before the blow-pipe it does not fuse, but becomes, on the contrary, very friable. It is not attacked by a solution of caustic potash, or sensibly by nitric acid. Treated with distilled water, it furnishes a liquid in which the presence of both lime and sulphuric acid can be unequivocally detected. Hence, it will be proper in future to test calculi for sulphate of lime.

When a few drops of solution of chloride of barium are poured into a solution of uric acid, saturated by the aid of heat, and allowed to cool, a white precipitate ensues, only partially removed upon adding nitric acid. The portion which does not dissolve in that acid, and which an excess of water will not take up, presents completely the pearly aspect of sulphate of barytes, recently precipitated, and diffused through a quantity of water. However, it must be admitted, that when the barytic chloride is poured into a saturated and boiling solution of uric acid, or urate of ammonia, a precipitate is thrown down, which readily dis-

* The Notes are inserted between brackets.

appears when treated, first, with concentrated nitric acid, and next with distilled water.

This property of the urate of barytes ought to be considered, as regards the determination of sulphuric acid in urinary concretions. The sulphate of lime being indecomposable by heat, the calculus should always be calcined before any researches are instituted for discovering its presence.—[Entertaining some doubts upon the above point, inconsequence of the very sparing solubility of uric acid in water, I was induced to repeat the experiment. I accordingly boiled some pure uric acid in a quantity of distilled water, and allowed the whole to cool. On pouring off the clear liquid, and adding to it a few drops of solution of chloride of barium, no precipitate whatever ensued. Probably the fallacy in the French experiment was owing to the accidental presence of sulphate of lime.]

Oxide of iron is another substance we may look for in the analysis of urinary calculi. Some time back, M. E. Barruel met with gravel almost entirely composed of it, although the patient, who voided it, had never been submitted to a ferruginous treatment.—[A remarkable calculus of this kind was sent from Bogota, by Dr. Roulin, to M. Boussingault; it weighed rather more than a *gramme* [15.4 grains.) was about the size of a nut, and considerably resembled certain mineral states of iron sand; it consisted, by analysis, of peroxide of iron, 38.81; alumina, 23.00; silica, 17.25; lime, 8.02; water, 10.89; loss, 2.03, in 100 parts. Several other calculi, of similar composition and appearance were afterwards passed by the same person.—See *Bull. Univ., c. x., p. 128, in Quart. Journ. of Science for* 1827.]

In order to save complexity, the methods of distinguishing the xanthic and cystic oxides have not been indicated, because these kinds of calculi are extremely rare, and, besides, easily recognised by the characters assigned to them in works on Medical Chemistry.—[*Xanthic oxide* dissolves in nitric acid without any gaseous evolution; and there remains after evaporation a bright citron yellow mass of which the solution in water is of a light, and that in potash of a deep reddish-yellow hue. Salammoniac throws down the substance again with its yellow colour from the alkaline solution. *Cystic oxide* or *cystine* dissolved in caustic potash, and the solution decomposed while boiling hot with excess of acetic acid, crystallizes by slow cooling in hexagonal spangles. It is soluble in diluted acids, as oxalic and muriatic, in which respects it differs from the zanthic oxide.]—*Pharmaceutical Journal.*

INGREDIENTS OF STAMPED AND PATENT MEDICINES.

(*According to Dr. Paris and other Authorities.*)

Dry Vomit of Marriott.—This once-celebrated vomit, called dry from its being exhibited without drink, consisted of equal proportions of tartarized antimony and sulphate of copper.

Madame Nouffleur's Receipt for Tape-worms.—Three drachms of the root of the *male fern*, reduced to a fine powder, and mixed with water; this constitutes one dose. Two hours after taking the powder, a bolus of calomel, scammony, and gamboge, is to be administered.

Duke of Portland's Powder for the Gout.—Equal quantities of the roots of gentian and birthwort (aristolochia rotunda), the tops and leaves of germander (chamædrys), ground pine (chamæpitys), and lesser centaury (chironea centaurium), powdered and mixed together.—As this is a combination of bitters, it might without doubt, be serviceable in certain cases of gout.

Keyser's Anti-Venereal Pills consist of the Acetate of Mercury, triturated with manna.

Arquebusade, ("Aqua Vulneraria,") a lotion, deriving its name from having been originally applied to wounds inflicted by the arquebuss, is composed of vinegar, sulphuric acid, honey, and alcohol, impregnated with various aromatics.

Aromatic Vinegar is an acetic solution of camphor, oil of cloves, of lavender, and of rosemary. The acetic acid used for this purpose is of about 145 degs. of the acetometer, containing 68·5 per cent. of real acid. A preparation of this kind may be extemporaneously made by putting ʒj. of Acetate of Potass into a phial with a few drops of some fragrant oil, and mxx. of Sulphuric Acid.

Thieves' Vinegar, or *Marseilles Vinegar*, is a pleasant solution of essential oils and camphor, in vinegar; the Edinburgh Pharmacopœia has given a formula for its preparation under the title of "Acetum Aromaticum." The repute of this preparation as a prophylactic in contagious fevers is said to have arisen from the confession of four thieves, who, during the plague of Marseilles, plundered the dead bodies with perfect security, and, upon being arrested, stated, on condition of their lives being spared, that the use of the Aromatic Vinegar had preserved them from the influnece of contagion. It is on this account sometimes called "Le Vinaigre des quatre voleurs." It was, however, the constant custom of Cardinal Wolsey to carry in his hand an orange, deprived of its contents, and filled with a sponge which had been soaked in vinegar impregnated with various spices, in order to preserve himself from infection, when passing through the crowds which his splendour or office attracted.

Elixir of Vitriol.—The preparation sold under this name is the Acid. Sulph. Aromat. E., and is imperfectly æthcrial in its nature.

Dr. Smellome's Ointment for the Eyes consists of half a drachm of Verdigris finely powdered and rubbed with oil, and then mixed with an ounce of yellow Basilicon, (Ceratum Resinæ.)

Taylor's Remedy for Deafness.—Garlic infused in oil of almonds, and coloured by alkanet root. It is an imitation of the "Acoustic Balsam" (Saint Marie) or the "Acoustic Oil" (Spielmann) Garlic is also an ingredient of the different aromatic vinegars recommended by various foreign authors as antidotes to contagion.

Anderson's Pills consist of the Barbadoes Aloes, with a proportion of Jalap, and Oil of Aniseed.

Hooper's Pills.—Pill Aloes cum Myrrha, (Pil. Rufi) Sulphate of Iron, and Canella Bark, to which is added a portion of Ivory Black.

Dixon's Antibilious Pills.—Aloes, Scammony, Rhubarb, and Tartarized Antimony.

Speediman's Pills.—Aloes, Myrrh, Rhubarb, Extract of Chamomile, and some Essential Oil of Chamomile.

Dinner Pills.—Lady Webster's, or Lady Crespigny' Pill.—These popular pills are the "Pilulæ Stomachicæ," vulgo, "Pilulæ ante cibum" of the Codex Medicamentarius Parisiensis. Editio Quinta, A.D. 1758, viz. R. Aloes optimæ ʒvj. Mastiches, et Rosarum rubrarum āā. ʒij. Syrupi de Absinthio q. s. ut fiat massa, the mass is divided into pills of three grains each. The operation of this pill is to produce a copious and bulky evacuation, and in this respect experience has fully established its value. It is difficult to explain the modus operandi of the Mastiche, unless we suppose that it depends upon its dividing the particles of the aloes, and thereby modifying its solubility. Similar to these pills are the "*Grains de vie de Mesue*" and the "*Grains de Sante de Frank*," although the latter are more purgative, containing, besides Aloes, Ox Gall, and Tartarized Antimony.

Fothergill's Pills.—Aloes, Scammony, Colocynth, and Oxide of Antimony.

Peter's Pills.—Aloes, Jalap, Scammony, and Gamboge, equal part ʒij.—Calomel ʒi.

Radcliffe's Elixir.—R. Aloes Socot. ʒvi. Cort.—Cinnamon et Rad Zedoar. āā. ʒss.—Rad. Rhei ʒi.—Coccinel. ʒss.—Syrup. Rhamni f℥ij.—Spirit. Tenuior. oj.—Aquæ Puræ f℥v.

The Elixir of Longevity, of Dr. Jernits, of Sweden, is an aromatic tincture, with Aloes.

The Anti-Arthritic Elixir, of Cadet de Gassicourt, consists of a mixture of the three tinctures of Aloes, Guaiacum, and Myrrh, and it is recommended also as an antidote to the effects of poisonous fungi. "*Remede contre les accidens occasionees par les champignons malfaisans.*"

Godfrey's Smelling Salts.—This highly pungent preparation is obtained by resubliming the common subcarbonate of ammonia with pearlash and a proportion of rectified spirit. The subcarbonate of potass in this case abstracts a fresh portion of carbonic acid from the ammoniacal salt. Its atomic composition has not yet been ascertained, but it will probably be found to consist of equal atoms of carbonic acid and ammonia, and must, therefore, be a true carbonate.

Noyau (Creme de Noyau).—Bitter almonds blanched 1 oz, proof spirit half a pint, sugar 4 oz. It is sometimes coloured with cochineal. The foreign Noyau, although differently prepared, is indebted to the same principle for its qualities. It is a liquor of a fascinating nature, and cannot be taken to any considerable extent without danger: the late Duke Charles of Lorraine nearly lost his life from swallowing some "Eau de Noyau," (water distilled from peach kernels too strongly impregnated)

Almond Paste.—This cosmetic for softening the skin, and preventing chaps, is made as follows: bitter almonds blanched 1 oz., the white of an egg, rose water and rectified spirit equal parts, as much as is sufficient.

Norris's Drops.—A solution of tartarized antimony, in rectified spirit, disguised by the addition of some vegetable colouring matter. I am credibly informed, says Dr. Paris, that the original recipe contained opium, but that which I have examined, and which was procured from a respectable agent, yielded no indications of its presence.

Composition of the Muscular Flesh of Different Animals.—Dr. Schlossberger examined the flesh of the ox, the calf, the hog, the sheep, the buck (of 3½ weeks old), the roe, the hen, a young pigeon, a very young duck, the barbel, the trout, and the crayfish. All contained fibrine, cellular tissue, liquid albumen, animal matters soluble in alcohol, extractive matter soluble in water only, salts, and, while fresh, more or less free lactic acid. The albuminous coagulum varied according to the quantity of intermixed blood; in the younger animals being less coloured. It was formed more speedily in the flesh of the fish and the crayfish, and invariably yielded, by incineration, phosphorus, sulphur, and iron. The pigment was entirely absent in most fishes and had a more fatty or resinous character in the crayfish. The hæmatosine, whenever found was always the same. The quantity of contained blood increased with the age, and appeared to be in inverse ratio with the water, but in direct ratio with the contained fibrine. All the kinds of flesh contained osmazome. This was a brownish yellow, non-gelatinous extractive matter, having an aromatic odour and an acrid taste, and being soluble in water and alcohol. It increased with the age and with the height of the animal in the scale of organization. The fibrine was every where th same.

ARTIFICIAL MINERAL WATERS.

(From the French Pharmacopœia.)

Natural Mineral Waters constitute an important art of the agents for removing disease. The difficulty which exists of procuring them, and the changes to which they are subject in the depots where they are preserved, have given rise to the idea of making artificial waters, but the actual state of science does not enable us to imitate accurately the waters of the majority of the springs; whether it is that chemical analysis leaves a doubt as to the nature of their component parts, or as to the mode in which they are combined, or that these waters contain principles which art has not yet been able to produce. As, however, these artificial waters form part of the kingdom of materia medica, and they are of great use in curing disease, it may not be unadvisable to give certain formulæ for their preparation, some of which have been already consecrated by use, and in the others are comprised the principal varieties of the most ordinary mineralizers of springs. By acting in accordance with their chemical analyses, imitations of the waters of other natural mineral springs, more or less accurate, may be obtained.

Mineral waters are called *saline*, when they hold a strong proportion of salts in solution; *acidulated*, when they are charged with carbonic acid gas: *ferruginous, iodurettled*, when iron or iodine is contained in them in sufficient quantity to give them a marked character; *sulphureous*, when they are mineralized by sulphuretted hydrogen or an alcaline sulphuret.

The preparation of saline waters consists in a simple solution of the salts in water: acidulated waters are made with carbonic acid gas, which has been carefully washed to remove any traces of any other acid; and as the water must contain a larger proportion of the gas than is soluble in it under ordinary circumstances, a proper apparatus must be employed for the purpose. When it is requisite to combine the saline and acidulous waters, it may be done either by dissolving the salts in water, and then charging it with the gas, or by making a concentrated saline solution, and putting it into a bottle, which is afterwards to be filled up with the water charged with gas. When insoluble carbonates are required in a mineral water, they must be used in the gelatinous state in which they are found on their production by double decomposition in water, as carbonic acid gas will more readily act on them. If by a double exchange of acids and bases, the salts directed in the formula can be all theoretically transformed into soluble salts, this substitution should be effected; then, at the moment of mixing the different saline solutions, the primitive formula is realized; the insoluble carbonates are produced and precipitated, and re-dissolved at a later period by the carbonic acid gas. An example of this kind will be found in the saline acidulated water, used to replace the natural Eau de Seltz. In the preparation of ferruginous mineral waters, water deprived of air must be employed; it may be obtained by boiling water for a quarter of an hour, and letting it cool, without being exposed to the air. The presence of oxygen in the water would cause the iron to pass to the state of peroxide, which would be precipitated in a great measure, either as an hydrate, or an insoluble salt. Sulphur is introduced in mineral waters, either as a soluble sulphuret, generally of sodium, or combined with hydrogen. In preparing this latter, a saturated solution of gas should be employed; in this state it is much too concentrated, and should be diluted with water, for the preparation of artificial sulphurous waters. As the alcaline sulphurets are exceedingly soluble, their introduction in mineral waters does not offer any difficulty.

Aqua Acidula Simplicior.—℞ aquæ puræ 1 vol.; acidi carbonici 5 vol. Charge the water with the gas by means of a proper apparatus, and fill bottles with it, each containing about 20oz.: they must be very accurately corked, and kept lying down in a cool place. By adding two ounces of syrup of lemons to each bottle before the gazeous water be added, a very agreeable drink may be obtained, called gazeous lemonade. By changing the syrup, a great number of acidulated and saccharine drinks may be procured.

Artificial Eau de Seltz.—℞ Chlorureti calcii gr. vj.; chlorureti magnesii gr.v.; chlor. sodii gr. xx.; carb. sodæ cryst. gr. xvj: phosph. sodæ cryst. gr. $1\frac{1}{3}$; sulph sodæ cryst. gr. j.: aquæ puræ ℥xx.; acidi carbonici 5 vol. Dissolve the sodaic salts in one proportion of water, and the earthy chlorurets in another, mix the liquors, and charge them with gas; the gazeous saline water which is the result, should be poured directly into bottles, and well stoppered. It is intended to replace the natural Eau de Seltz; it contains more carbonic acid, and is therefore often preferable.

Aqua Acidula Cum Bicarb. Potassæ.—℞ Bicarb. potassæ ℈iv.; aquæ puræ ℥xx.; acidi carbonici 5 vol. Dissolve the salt in water, charge with the gas, and bottle. Each ounce will contain about four grains in solution.

Soda Water.—℞ Bicarb. sodæ gr. xx.; aquæ puræ ℥xx.; acidi carbonici 5 vol. Prepare as the preceding one.

Artificial Eau de Vichy.—℞ Carb. sodæ cryst. ʒij. gr. vj.; chlor. sodii gr. $\frac{1}{3}$; chlor. calcii cryst. gr. xi.; sulph. sodæ cryst. gr. vj.; sulph. magnes. cryst. gr. iij.; sulph. ferri. cryst. gr. $\frac{1}{3}$; aquæ aere orbatæ ℥xx.; acidi carbonici $3\frac{1}{2}$ vol. Make a solution of the sodaic salts, another of the sulphate of magnesia, and a third of the chloruret of calcium; mix, and charge with the gas; then pour into bottles, in which the sulphate of iron dissolved in a little water has been previously introduced. This water differs essentially from the natural Eau de Vichy in the absence of organic matters.

Artificial Eau de Mont D'or.—℞ Carb. sodæ cryst. ʒij. gr. xxiv.; chlor. calcii cryst. gr. viij.; chlor. magnesii cryst. gr. $1\frac{1}{2}$; chlor. sodii gr. $1\frac{1}{3}$; sulph. ferri cryst. gr. ij.; sulph. sodæ cryst. gr. $1\frac{1}{3}$; aqua aere orbatæ ℥xx.; acidi carbonici 5 vol. Dissolve the carbonate of soda and the marine salt in water, and charge the solution with gas; make another solution of the earthy chlorurets and of the sulphate of iron, and mix; introduce into bottles, and fill them with the gaseous saline water. Stopper quickly.

Eau de Bourbonne.—℞ Bromuretti potassi gr.$\frac{2}{3}$; chloruret sodii gr. liv.; chlor. calcii cryst. gr.xxxviij.; sulph. sodæ cryst; gr. xxij.: bicarb. sodæ cryst. gr. vj.; aquæ puræ ℥xx.; acidi carbonici 5 vol.

Magnesian Water.—℞ Sulph. magnes. cryst. ʒviij. gr. xxiv.: carb. sodæ cryst. ʒx. gr. xlviij.; aquæ puræ ℥xx.; acidi carbonici 6 vol. Dissolve each of the salts separately in water, mix and boil the solution, keeping them boiling until gas is no longer disengaged; let them precipitate, decant, and wash the precipitate carefully, and let it drain; mix it with a sufficient quantity of water, and charge with the gas. It should not be bottled until several hours after the introduction of the gas, and during that time, should be occasionally shaken to favour the solution of the carbonate of magnesia. Each bottle will contain two drachms twenty-four grains of white magnesia in the state of bicarbonate, with a slight excess of carbonic acid.

Gazeous Magnesian Water.—℞ Sulph. magn. cryst, ʒiv. gr. xij.; carb. sodæ cryst. ʒiv. gr. liv.; aquæ puræ ℥xx.; acidi carbonici 6 vol. Proceed as for the simple magnesian water. Each bottle of 20 ounces will contain one drachm gr. xij of white magnesia in the state of bicarbonate, with an excess of carbonic acid.

Artificial Eau de Seidlitz.—℞ Magn. sulph. cryst. ʒij. gr. xxiv.; aquæ puræ ℥xx.; acidi carbonici 3 vol. Dissolve the sulphate of magnesia in water, charge with the gas, and bottle. The Eau de Seidlitz may be prepared with a larger quantity of the salt, each bottle to contain either twice, thrice, or four times as much.

Artificial Eau de Spa.—℞ Carb. Sodæ cryst. gr. iij.; carb. calcis gr. 3-5ths; magn. carb. $\frac{1}{4}$ gr.; proto-chlor. ferri gr. $\frac{2}{3}$; Aluminis cryst. gr. 1-7; aquæ aere orbatæ ℥xx.: acidi carbonici 5 vol. Dissolve the carbonate of soda in a small quantity of water, and mix the carbonates of lime and magnesia with the solution; dissolve the alum and chloruret of iron in another portion of water, and mix the two solutions. Pass into bottles, and fill with the simple gazeous water. This preparation resembles the Spa waters, and also in some degree those of Bussang, Forges, Pyrmont, Vals, &c.

Eau Sulfuree.—℞ Sulphureti sodii cryst. gr. ij. $\frac{1}{2}$; carb. sodæ cryst. gr. ij. $\frac{1}{2}$; chlorureti sodii gr. ij. $\frac{1}{2}$; aquæ aere orbatæ ℥xx. Dissolve and keep in well-corked-bottles. This mineral water is used to replace those charged with the sulphuret of sodium, and is often used in lieu of the sulphureous waters of the Pyrenees, of which, however, it is but an imperfect imitation. It is employed indifferently under the names of *Eau Minérale Artificielle de Barèges, de Cauterets, de Bagnères, de Luchon, de Bonnes, de Saint Sauveur*, or of any other sulphureous water of the eastern Pyrenees.

Solution for the Artificial Bain de Bereges.—℞ Sulphureti, sodii cryst.; carb. sodæ cryst.; chlorureti sodii; ana ℥ij. ʒiij. gr. vj.; aquæ puræ ℥x. Dissolve the salts in water, bottling quickly, and corking carefully. It is to be mixed with the water in the bath when required. The quantity above indicated is sufficient for a bath containing 300 quarts. It gives a colorless bath, having a slight hydro-sulphurous odor, differing in every respect from the ordinary sulphureous bath prepared with the sulphuret of potassium obtained from sulphur and potass.

PHARMACEUTICAL VARIETIES.

Non-nitrogenised Foods.—It cannot be a matter of doubt, (says Dr. Pereira, in the *Pharmaceutical Journal*) that non-nitrogenised substances are intended by nature to constitute part of the food of man and other animals, but especially of the herbivora. We find fixed oil in the yolk of the egg, and in milk (in which it is called butter), two substances supplied by nature for the food of young animals. Milk contains a second non-nitrogenised alimentary principle, namely sugar. If we further add the fondness of animals for non-nitrogenised substances, the craving, nay, almost insatiable desire for them, manifested by individuals who are deprived of them, and the fact before mentioned, that nitrogenised food alone cannot support life, not a doubt can remain in our minds that these principles are essential to health and life.

In commencing our enquiry then into the particular purpose they serve in the animal economy, I would observe, in the first place, that with the exception of fat, none of them are constituents of the animal system; nor in a state of health are they found in the excretions. It is obvious, therefore, that they must suffer some change or transformation in the organisms. Now they all consist of carbon, hydrogen, and oxygen. In starch, sugar, and gum, the hydrogen and oxygen are exactly in the ratio to form water. Do they, therefore, contribute carbon, or in some cases, carbon and hydrogen, to assist in the formation of blood? Liebig asserts they do not, for he observes that as the nitrogenised principles used as food contain exactly the "amount of carbon [and hydrogen] which is required for the production of fibrine and albumen," it follows that the carbon of gum, sugar and starch, and the carbon of hydrogen and butter and other fats cannot "be employed in the production of blood." If the nitrogenised principles contained less carbon than albumen and fibrine, then starch, sugar gum, and fat, might give up some carbon to compensate the difference. He, therefore, concludes, that these bodies yield their carbon, and, when their hydrogen is in excess to their oxygen, part of their hydrogen also, to form with atmospheric oxygen, carbonic acid and water, and, therefore, to develope heat. They serve to protect the organism from the action of the oxygen, which, in the absence of food, consumes the tissues. "If," says Liebig, "we observe a man or other animal in sickness, or at any time when the body is not supplied with nourishment to compensate for the continual loss, we find him become lean; the fat is the first to disappear, it vanishes through the skin and lungs in the form of carbonic acid and water as none of it can be found in the fæces or urine; it resists the action of the atmosphere on the body, and is a protection to the organs. But the action of the atmosphere does not end with the loss of fat; every soluble substance of the body enter

into combination with the oxygen of the air. The influence of the oxygen of the atmosphere is the cause of death in most chronic diseases, from want of carbon to resist its action, that of the nerves and brain is used. In a normal state of health and nutrition, the carbon of the carbonic acid must have another source."

You will now understand why Liebig calls the non-nitrogenised foods *elements of respiration*; and will comprehend in what way *alcohol* taken dietetically contributes to the production of animal heat. The *Temperance* and *Tea-total Societies* have quite overlooked this use of spirit. It certainly cannot alone form organised tissues, since it is deficient in some of the essential ingredients—nitrogen, sulphur, and phosphorus. But it cannot be doubted that it undergoes some change in the animal economy, and probably may be made some use of. It is not found in the excretions; traces of it, indeed, are recognisable in the breath, but the quantity in this way thrown out of the system is inconsiderable, and scarcely worthy of consideration. It, therefore, must be got rid of in the form of carbonic acid and water, and to convert it into these substances it requires merely atmospheric oxygen.

Alcohol . .	$C^4\ H^6\ O^2$	Carbonic Acid	C^4 — O^8
Oxygen . .	— — O^{12}	Water	— $H^6\ O^6$
	$C^4\ H^6\ O^{14}$		$C^4\ H^6\ O^{14}$

Now, the formation of carbonic acid and water must be attended with the development of heat; and, therefore, alcohol is a fuel in the animal economy, by the combustion of which, caloric is evolved. Common experience favours this view. Coachmen and others take it in cold weather to keep them warm, and it is familiarly used to prevent what is called "catching cold." In cases of extreme suffering and exhaustion from excessive exertion and privation of food, the cautious and moderate dietetical use of spirit has, on many occasions, proved invaluable. In Captain Bligh's account* of the sufferings of himself and companions, in consequence of the mutiny of the crew of the Bounty, he observes, "The little rum we had was of great service; when our nights were particularly distressing. I generally served a teaspoonful or two to each person: and it was joyful tidings when they heard of my intentions." It is said, that the inhabitants of colder climates take more spirit than others and with less injury. Liebig accounts for this by saying that they inhale a more condensed air, that is, they take in more oxygen at every inspiration; combustion is more rapid in them, and thus the elements of the alcohol are more speedily got rid of.†

I trust that in offering these remarks on the effects of alcohol, I may not be misunderstood. I do not wish to cast any reflections on the Societies before referred to, whose motives I highly esteem, and whose objects I would gladly promote. It is my duty, however, to lay before you, on this matter, what I believe to be the truth. If I had to point out the injurious qualities of alcohol, I think I could soon prove that though it evolves heat in burning, it is an obnoxious and most expensive fuel. Consider its volatility, the facility with which it permeates membranes and tissues, and its injurious operation, before it is burnt in the lungs, on the stomach, the brain, and the liver.‡ Remember that though spirit burns and evolves heat, there are, under ordinary circumstances, other better, safer, and cheaper combustibles to be burned in the vital lamp.

* *Voyage to the South Seas* in 1787-9, p. 190, Lond. 1792.

† The Highlanders, who it is well known are immoderate drinkers, pretend that spirit does not intoxicate in the Hills as it would do in the Low Country. (See *Letters from a Gentleman in the North of Scotland to his friend in London*, vol. 2, p. 161, 5th Ed., Lond. 1818).

‡ The effect of alcohol on the stomach may be ascribed to its topical chemical action. But in connection with its well-known action on the brain, and its tendency to produce granulated liver (the *drunkard's* or *gin liver*), it deserves to be noticed, that alcohol has been detected in the brain and liver of those who have died under its influence. (See Pereira's *Elements of Materia Medica*, vol. 1, p. 359, 2d edit.)

Some of these non-nitrogenised foods serve another purpose in the animal economy—*they contribute to the formation of fat*. When the quantity of these foods taken into the stomach is great, that is, out of proportion to the quantity of oxygen absorbed by the lungs, fat is, under some circumstances, formed. Sugar, starch, and gum become, by the loss of part of their oxygen, fat; for the relative proportion of their carbon and hydrogen is almost identical with that of fat.

Starch contains	79 carbon	to	10.09 hydrogen	
Sugar	79	—	" 11.80	—
Gum	79	—	" 11.80	—
Mutton fat	79	—	" 11.1	—
Human fat	79	—	" 11.4	—
Hog's lard	79	—	" 11.7	—

Some facts adduced by Liebig are almost conclusive that starch and sugar may become converted into fat in the animal economy. A lean goose, weighing 4lbs. gained, in thirty-six days, during which it was fed with 24lbs. of maize, 5lbs in weight, and yielded 3½lbs. of fat. Now this fat could not have been contained in the food ready formed, because maize does not contain the thousandth part of its weight of fat, or of any substances resembling fat. A certain number of bees, the weight of which were exactly known, were fed with pure honey devoid of wax. They yielded one part of wax for every twenty parts of honey consumed, without any change being perceptible in their health or in their weight. I agree with Liebig, that with these facts before us, "it is impossible any longer to entertain doubt as to the formation of fat from sugar in the animal body*."

But alcohol is an element of respiration. Does it form fat? I think not. In the first place, its carbon and hydrogen are not in the ratio of those of fat, for it contains 69 parts of carbon to 19.74 of hydrogen. Secondly, we do not find that spirit drinkers are fat; but, on the contrary, emaciated. Hogarth, in his *Beer Alley* and *Gin Lane*, has ludicrously though faithfully represented the differences in the appearance of beer topers and spirit tipplers. The first are plump, rubicund, and bloated; the latter are pale, tottering, emaciated, and miserable.

Phosphorus.—This, says Dr. Pereira, is a constituent of both animals and vegetables. It is an essential ingredient of albumen and fibrine, and of all tissues composed of those principles. Nervous matter also contains it. Its existence in the brain has been long known. In 1834, Couerbe † advanced an absurd notion, that the healthy or morbid conditions of the mental faculties were connected with variations in the amount of this substance in cerebral matter. "In the brains of sane men," says he, "I have found from 2 to 2.5 per cent. of phosphorus, in those of idiots only 1 or 1.5, while in those of madmen there are from 3 to 4.5 per cent.!" It is scarcely necessary to say, that the accuracy of this assertion has been disproved; and Lassaigne ‡ fixes the amount of phosphorus in the brains of madmen at from 1.93 to 1.97 per cent. The bones also contain phosphorus, which exists in them in combination with oxygen and lime principally, constituting a sub-phosphate of lime (*bone ash*). As phosphorus, therefore, is an essential ingredient of the animal body, it must of course be a constituent of the food. The yolk of egg and milk, both aliments for young animals, contain it; in the latter of these foods it exists as subphosphate of lime. It is a constituent of the bones and flesh of animals, and of many vegetable substances on which we feed. Fruits and seeds, especially of the grasses, abound in the earthy phosphates: and horses are in consequence subject to the formation of a large intestinal concretion (*hippolithus*) composed of ammoniacal phosphate of magnesia derived from the husk of the oats on which they are fed. Dr. Pereira has two specimens of this concretion, each of them as large as a child's head, and weighing several pounds. Fishes are especially rich in phosphoric matter,—a fact which explains the circumstance related by Dumas, * of the evolution of phosphuretted hydrogen in the purification of spirit which had been used for preserving fish.

* The mode of promoting obesity, practised in certain parts of the world, lends support to the above statements. If "we can trust to the reports of physicians who have resided in the East," says Liebig, "the Turkish women, in their diet of rice, and in the frequent use of enemata of strong soup, have united the conditions necessary for the formation both of cellular tissue and fat." M. Caullet de Vaumoral quoted by Mrs. Walker, (*Female Beauty*, p. 171, Lond. 1837), states that in the Bey's Seraglio at Tripoli, women are fattened against a certain day by means of repose and baths, assisted by a diet of Turkish flour, mixed with honey. Fifteen days, he says, were sufficient for the purpose.

† *Ann. de Chim. et de Physique*, p. 190, 1834.

‡ *Journ. de Chim. Med* t. 1er II. Serie p. 344, 1835.

The following table shows the quantity of phosphorus, phosphoric acid, or earthy phosphates, contained in some alimentary substances.

TABLE OF THE QUANTITY OF PHOSPHORUS, &c., IN ALIMENTARY SUBSTANCES.

1000 Parts,	Quantity of Phorphorus	
Fibrine (dried)	4.3 to 3.2	Mulder.†
Albumen of eggs (dried)		
Albumem of serum of blood (dried)	3.3	Mulder.
Vegetable fibrine	as animal fibrine and albumen.	Liebig.
——— albumem		
Cerebric acid (in brain)	9	Fremy. ‡
Oleophosphoric acid (in brain)	12 to 19	Ditto.
1000 Parts.	Quantity of Phosphoric Acid.	
Potatoes (dried)	5.631	Einhoff. §
1000 Parts.	Quantity of Earthy Phosphates.	
Wheat	from 3.6 to 9	Hermbstaedt.‖
Rye	6 to 41.8	
Barley	1 to 6	
Oats	1.6 to 6	
Rice	1.3 to 4	
Garlic	11	
Caseine	60	Berzelius.¶
Bones of sheeps' feet	1242	French Commission.**
——— Ox's head	327.7	Ditto.
Milk	2.55	Berzelius.
Blood (average)	0.6	Denis. ††

These are only some of the substances used as food in which phosphorus has been detected. But most organised substances contain it, usually in the form of phosphate of lime. Thus, in the ashes of almost every plant a phosphate is found. The crust, which is deposited in the boilers used for refining sugar, contains, according to Avequin,‡‡ no less than 92.43 per cent. of sub-phosphate of lime; so that it is obvious that unrefined sugar must contain phosphorus.

These observations fully establish the correctness of Liebig's remark, that when flesh, bread, fruit, and husks of grain are used for food, more phosphorus is afforded to the body than it requires, and the excess is eliminated in the urine and excrement.

Sulphur.—Sulphur, says Dr. Pereira, is a constituent of both animals and vegetables. Fibrine and albumen, and all tissues composed of these substances, contain it. If hydrochloric acid be added to a solution of flesh in liquor potassæ, some sulphuretted hydrogen is evolved and is detected by its staining paper, moistened with a solution of sugar of lead. The discolouration which a silver spoon suffers by being used in eating eggs, depends on the formation of sulphuret of silver. If some white of egg, boiled hard, be decomposed by heat, it evolves hydrosulphuret of ammonia, which discolours paper moistened with sugar of lead. Caseine also contains sulphur, as does also hair and bone. The efficacy of a mixture of finely powdered litharge and lime (*hair dye*) in staining the hair, depends on the formation of the black sulphuret of lead. The lime serves to form, in the first place, a sulphuret of calcium with the sulphur of the hair. Animal charcoal (*bone black*) evolves sulphuretted hydrogen, when treated with hydrochlo-

ric acid, showing that sulphur is a constituent of bones.

The existence of sulphur in so many animal substances, serves to explain the evolution of sulphuretted hydrogen and hydrosulphuret of ammonia, by putrifying animal substances; excrement for example. Indeed, so much sulphur is obtained in this way, that some geologists have considered it to be a source of at least part of the native sulphur of the mineral kingdom.* That sulphuretted hydrogen is evolved in privies is proved by its darkening the white paint, and by its blackening silver articles (watches, coin, spoons, &c.) which have accidentally fallen into the night soil.

The sulphur of the metamorphosed tissues is thrown out of the animal system, principally in the form of sulphuric acid. The urine contains sulphates in part formed by the action of the oxygen of the arterial blood on the sulphur of the tissues. If the hollow of a tooth be filled with an amalgam of silver, a black crust of metallic sulphuret is speedily formed on it. Moreover, the leaden blue line, which borders the edges of the gums attached to the neck of the teeth, in persons whose constitutions are under the influence of lead,† is probably sulphuret of lead.

The system derives its sulphur from animal, vegetable, and mineral substances, used as food. Thus flesh, eggs, and milk contain it. Vegetable fibrine (as of corn), vegetable albumen (as of almond, nuts, cauliflowers, asparagus, and turnips), and vegetable caseine (as of pease and beans) contain it. Lastly, sulphur, in the form of sulphate of lime, is a constituent of common and spring water.

TABLE OF THE QUANTITY OF SULPHUR IN SOME ALIMENTARY SUBSTANCES.

1000 Parts of	Quantity of Sulphur.	
Fibrine	From 3.6 to 3.8	Mulder
Albumen of eggs		
Albumen of blood	6.8	Ditto.
Caseine	3.6	Ditto.
Vegetable fibrine	as animal fibrine, albumen, and caseine.	Liebig.
——— albumen		
——— caseine		
Volatile oil of black mustard	204.8	
Sulphosinapisine (in white mustard)	96.57	

Celery, rice, hops, ginger, and many other vegetable substances contain sulphur. Assafœtida, which Dr. Ure says contains two per cent. of sulphur, is considered by some oriental nations as "*food for the gods.*"

An infusion of *white* mustard strikes a blood red colour with the persalts of iron, owing to the presence of sulphosinapisine. Both black and white mustard flour charred in a tube, evolve a sulphuretted vapour, which blackens paper moistened with a solution of acetate of lead. In the same way sulphur may be detected in cabbage, potatoes, and many other vegetable foods. If pease or almonds be boiled in a solution of caustic potash, and then hydrochloric acid be added, the evolved vapour blackens paper moistened with a solution of lead, thus showing that these seeds contain sulphur.

Iron.—The ashes of most animals and vegetables yield traces of iron.

This metal is an essential constituent of the blood discs. From 10,000 parts of blood we can obtain about eight parts of peroxide of iron—equal to 5,6-10 parts of the pure metal. The hair also contains iron—the black the most, the white the least. Braconnot likewise found it in the gastric juice.

Liebig regards the compound of iron in the blood as an oxidized one. In the arterial blood, it is saturated with oxygen (*hydrated sesquioxide*); but during its passage through the capillaries, it loses part of its oxygen,‡ and becomes protoxide of iron, which combines with carbonic acid, one of the products of the oxidation of the metamorphosed tissues, and forms *carbonate of the protoxide of iron*, which exists in venous blood. This, in the lungs, absorbs the same amount of oxygen it had lost, and gives out its acquired carbonic acid.

Whether this be the true theory of respiration or not I shall not stop to inquire, though the fact, that for every volume of oxygen absorbed by carbonate of the protoxide of iron no less than four volumes of carbonic acid are evolved, appears to me to present some difficulties to its admission, since we know that in the process of respiration, the quantity, by volume, of carbonic acid expired, is not quite equal to that of the oxygen which has disappeared.

Iron is found in the yolk of the egg and in milk, foods intended by nature for the nourishment of young animals. In the milk it exists, according to Berzelius, as phosphate of iron. The flesh on which we feed, as well as most vegetables (mustard, cabbage, potatoes, pease, cucumbers, &c.,) supply us with iron.

Chlorine.—This element, continues Dr. Pereira, is a constituent of the blood, and of the gastric juice; and it is found in several of the excretions, as the urine, saliva, tears, and fæces. In the blood it exists in combination with sodium.

As the chloride of sodium of the blood is constantly being consumed in the formation of the gastric juice and other secretions, this salt becomes an indispensable article of food. To the embryo chick, nature has supplied it in both the white and yolk of the egg, while the young mammal finds it in his mother's milk. The appetite which all animals evince for salt, shows that it is an agent indispensable for their health. The common salt, therefore, which we consume at our tables is not to be regarded as a mere exciter of the palate; it is an essential article of food. It contains 60 per cent. of chlorine. It is probable, that besides furnishing the secretions with salt and its constituents, the salt of the blood performs some important function in relation to the blood discs. Every one well knows that in cholera, and some other maladies, the blood, which is deficient in its saline parts, has a very dark or black appearance.

But one of the most important uses of chloride of sodium (common salt) is the formation of hydrochloric acid, an essential ingredient of the gastric juice. By what particular agency, whether by electricity or affinity, this decomposition is effected, we are unable to determine precisely, but that the hydrochloric acid of the gastric juice derives its chlorine from the chloride of sodium, can scarcely be doubted. Its hydrogen is probably derived from water, the oxygen of which at the same time unites with sodium to form soda.

The gastric juice consists essentially of *water*, *gastric mucus*, and *hydrochloric acid*. As mucus is a fluid secretion of all the mucous membranes, while the mucus of the gastric membrane alone yields with water and hydrochloric acid a digestive liquor, it is probable, that the mucus of the stomach contains some peculiar organic principle, not hitherto isolated, on which its peculiar properties depend. To this principle, the term *pepsin* (from πεπτω, *I digest*) has been applied. An artificial digestive liquor is readily prepared by macerating the lining membrane of the fourth stomach of the calf in water, to which a few drops of hydrochloric acid have been added. If small cubes of white of egg, boiled hard, be macerated in this liquor, their more superficial parts become translucent, and their edges and angles rounded. Very gradually they are dissolved, presenting during the process, the appearance of a cube of soap, dissolving in water, and having a gelatiniform character. The yolk of egg yields a turbid liquor, owing to the presence of fat globules. A piece of cooked beef-steak becomes pulpy at the surface, and gradually dissolves.

These changes are produced neither by an infusion of the stomach, nor by diluted hydrochloric acid employed separately; but by the two conjointly they are readily effected.

Now Liebig asserts "that the substance which is present in the gastric juice in a state of change, is a product of the transformation of the stomach itself;" and he goes on to state that "the fresh lining membrane of the stomach of a calf, digested with weak muriatic acid, gives to this fluid no power of dissolving boiled flesh or coagulated white of egg; but if previously allowed to dry, or if left for a time in water, it then yields to water, acidulated with muriatic acid, a substance in minute quantity, the decomposition of which is already commenced, and is completed in the solution."

But several circumstances appear to me to be opposed to this view. The fact ascertained by Schwann, that the solvent principle of the digestive fluid can be precipitated from its neutral solution by acetate of lead, and be obtained again in an active state from the precipitate by means of sulphuretted hydrogen, is apparently inconsistent with Liebig's idea, that this principle is matter in a state of decomposition or transformation. Moreover, if the essential part of the gastric juice—that by which digestion is effected—be a mere transformation of the stomach, how is it that other parts of analogous structure and composition do not suffer the same transformation? I have tried to obtain a digestive liquor from the second stomach of the calf, and from the bladder, but in vain. How is it that this fancied transformation goes on, during life, only when solicited to do so by the presence of aliment or by mechanical irritation? Dr. Beaumont ascertained that pure gastric juice will keep for many months without becoming fetid: a fact scarcely explicable on the hypothesis that its activity depends on a principle in a state of decomposition. I find that while acidulated infusions of the second stomach of the calf and of the bladder soon become putrid and fetid, that of the fourth stomach remains remarkably free from unpleasant smell for several weeks. Lastly, I find, contrary to Liebig's statement, that a digestive liquor can be prepared from the fresh undried fourth stomach of a calf.

I cannot agree with Liebig, that digestion is a process analogous to fermentation; that, in fact, it is nothing more than the transformation of food, effected by the contact of matter in a state of decomposition. If it were, a small quantity of the gastric juice ought to be capable of effecting the digestion of an unlimited quantity of food. Now, the experiments of Dr. Beaumont on the natural gastric juice, and of Schwann on the artificial digestive liquor, prove that this is not the case. Both found that only a certain amount of food could be digested with a given quantity of gastric juice; and Dr. Beaumont observes, that "when the juice becomes saturated it refuses to dissolve more; and if an excess of food have been taken, the residue remains in the stomach, or passes into the bowels in a crude state."

Sodium.—The observations on chlorine apply in part to sodium, since these two elementary substances are usually taken into the system together, in the form of chloride of sodium, which is a constituent of the blood. I have already stated that common salt, by the aid of water, is converted in the system into hydrochloric acid (found in the gastric juice) and soda. The latter substance exists in the blood in combination with albumen (*albuminate of soda*). While potassium is the usual metallic basis of the alkaline salts of plants, sodium, on the other hand, is the basis of the alkali and alkaline salts of animals. All the animal tissues contain sodium, and their ashes (as of feathers, bristles, hairs, &c.) accordingly communicate a yellow tinge to flame.

The common salt, used at our tables as a condiment, contains 40 per cent. of sodium. The soda, which exists in the blood in combination with albumen, passes out of the system in union with organic matter ($C^{70}\ H^{66}\ N^{2}\ O^{22}$) represented by *choleic acid*: in other words, bile may be represented as choleate of soda—that is, it contains the elements of this salt, though not necessarily arranged as such. Lastly, "the soda, which has been used in the vital processes, and any excess of soda, must be expelled in the form of a salt, after being separated from the blood by the kidney." (Liebig.) The acids with which, in the flesh-eating animals, the soda com-

* Brocchi, quoted by Leonhard in his *Handbuch der Oryktognosie*, p. 599, Heidelberg, 1826. When the gate St. Antoine at Paris was pulled down in 1778, there were found in the ditches of that place, where many years (300?) previously excrement had been deposited, grains and crystals of sulphur deposited on lime. (Fougeroux de Bondaroy, *Mém. de l'Academie Royale des Sciences*. Anneé, 1780, p. 105.) It is stated in the *Athenæum*, (Dec. 1, 1838, p. 860), that Maravigno "disputes the assertions of Prof. Gemellaro, who pretends that sulphur owes its origin to the decomposition of mollusca."

† See Dr. Burton's paper on this subject, in the *Medico-Chirurgical Transactions*, 2nd Series, vol, v. p. 63, 1840.

‡ The facility with which, under certain circumstances, the peroxide of iron loses part of its oxygen has been recently applied by Sir J. F. Herschel in the production of photographic pictures, termed *ferrotypes*.

ines, are sulphuric and phosphoric. These are in art formed in the system by the oxidation of the sulhur and phosphorus of the metamorphosed tissues.

Calcium.—This is a constituent of all animals. he bones of the vertebrata (as man) contain subhosphate (principally), but mixed with carbonate, f lime; while the shells and crusts of the invertebrated animals (as lobsters, oysters, &c.) consist of arbonate (principally), mixed, with sub-phosphate, f lime. Muscles, nervous matter, the liver, thyroid land, and, indeed, all the animal solids, contain alcium, usually combined with oxygen and phoshoric acid; the blood also contains it.

It is requisite that the food of young animals should ontain sub-phosphate of lime for deposition in the ones; accordingly we find it in the egg and in milk. The more mature animal is supplied with it in the various forms of animal food on which he feeds, as well as in most vegetables. Seeds (especially corn), onions, garlic, &c. contain it.

Oxalate and other vegetable salts of lime are found in some vegetable foods; thus, the stalks of rhubarb, which are eaten in tarts and puddings, contain crystallized oxalate of lime. It is the same salt which gives to Chinese and Russian rhubarb its grittiness when chewed. Gum and unrefined sugar yield ashes containing calcium; and the well known fact, that *strong* unrefined sugar becomes by keeeping *weak*, is ascribed to the presence of lime, which by its action on sugar converts it into a soft, clammy, gummy matter. Grapes also contain calcium. Another source of calcium is ordinary water, which contains both carbonate and sulphate of lime.

Magnesium.—Minute quantities of this metal are found in the teeth, bones, nervous matter, the thyroid gland, and several parts of the body; it exists also in the blood. In every case, I believe, of its occurrence in the animal body it is found in combination with oxygen and phosphoric acid, forming phosphate of magnesia; and in many cases with ammonia also.

Its source is of course to be found in the foods; not only the flesh but also the vegetables which we eat contain it—as seeds (especially of the cereal grasses) and potatoes. I have already referred to the large intestinal concretions (ammoniacal phosphate of magnesia), found in the intestines of horses, and which are derived from the husks of the oats on which these animals feed.

Potassium.—Minute traces of potassium have been detected in the solids (cartilage, liver, &c.), and in some of the fluids (blood, urine, milk, &c.). Liebig states, that "without an abundant supply of potash, the production of milk becomes impossible;" but I know not on what authority he makes this statement, for Schwartz found only seven parts of chloride of potassium (equivalent to 3.68 parts of potassium) in 10,000 parts of milk—a quantity apparently too minute to be of much importance.

The sources of potassium in our system are both animal and vegetable food. Most plants which grow inland contain it; thus, it is found in grapes and potatoes. Its presence may be readily detected: burn a grape stalk in the candle—the minute ash obtained at the point of the burnt stalk will, if introduced into the outer or almost colourless cone of the flame, communicate a violet tint, thus demonstrating the presence of potash.

Fluorine.—Berzelius detected minute quantities of fluoride of calcium in the bones and teeth of animals; but, more recently, Dr. G. O. Rees failed to detect it. If fluorine be a normal constituent of the body, it is doubtless introduced into the system in the small portions of the bones of animals occasionally swallowed with their flesh, for it cannot be derived from plants, since it has never been detected in these bodies. It is remarkable, however, that fluoride of calcium is abundant in fossilized bones, and in the human bones found at Pompeii and Herculaneum.

The Change which Extract of Rhubarb Undergoes in Keeping.—It has been observed some time ago, by Mr. Landerer, that old extract of rhubarb, when mouldy, acquires a strong smell of storax. This has been confirmed by M. Reinsch, in case of fluid extract of rhubarb which had been kept for several years in an unopened bottle the extract being covered with a film of mould. This liquid extract was submitted to distillation, and afforded a slightly turbid water, with a great number of small drops of oil. The product of the distillation had a strong smell of storax, and was neutral to test paper. Either, after agitation with it, becomes slightly coloured yellow and acquires the odour of storax; after the evaporation of the ether on a watch-glass, there remains only a few drops of an aromatic oil, smelling strongly of storax, but which is very volatile, so that in about an hour no trace of the smell could be discovered on the glass. This smell of storax in extract of rhubarb, which has become mouldy, arises from the formation of a peculiar oil. There will probably be many more of these oils discovered, originating in the putrefaction of vegetable matter. This oil of rhubarb appears to be analogous to the oil with the smell of musk, discovered by M. Rossignon, in decayed apples, which he has named *maloile*, and which is composed of C H N O.—*Repertorium fur die Pharmacie.*

Oil of Bitter Almonds is a most deadly poison in large doses; it was once extensively used in medicine, and is still very frequently employed by confectioners and others for flavouring custards, puddings, liqueurs, and sweetmeats. The bitter almond is the kernel of the amygdalus communis, a tree which is indigenous to Barbary, and is extensively cultivated both in the temperate parts of Europe and in Asia. It is well known in our gardens, and is distinguished by bearing its flowers before any of the leaves are produced, a circumstance which has been happily alluded to by Thomas Moore in "Lalla Rookh"—

"The hope, in dreams, of a happier hour
That alights on Misery's brow,
Springs out of the silvery almond-flower,
That blooms on a leafless bough."

The sweet and the bitter almond are derived from the same species, and no botanical difference is found to exist between them, although they differ so widely in their taste and other properties. They are in fact only *varieties* of the same *species*; the two plants are said to be convertible into each other—the sweet variety becoming bitter by neglect; the bitter becoming sweet by cultivation; and the seed of either variety producing plants of both. When the bitter almonds are subjected to pressure, they yield a sweet oil, altogether analogous to that produced by sweet almonds; but when the cake of bitter almonds is mixed with water and subjected to the action of heat, a volatile oil passes over of a very peculiar nature, which is the true oil of bitter almonds. This oil does not appear to exist ready formed in the bitter almond, but is produced only when the almond pulp comes in contact with water; for it cannot be separated by any process whatever from the almond, without the cooperation of water. The presence of prussic acid in this oil may be proved by dissolving it with agitation in water, and treating the solution with caustic potash, followed by sulphate of iron and sulphuric acid. The bitter almond acts upon the animal system in the same way as hydrocyanic acid, but it likewise excites at times signs of irritation. The symptoms it produces in animals are trembling, weakness, palsy, and finally stupefaction. Orfila states, that twenty bitter almonds will kill a dog in six hours, if the gullet is tied to prevent vomiting; but if vomiting be allowed, the animal will recover. He also found that six bitter almonds in coarse powder applied to a wound in the thigh of a middle-sized dog caused death in four days. This oil is hardly inferior in activity to prussic acid. A single drop of it applied by Sir Benjamin Brodie on the tongue of a cat, caused violent convulsions and death in five minutes. But if this oil be entirely freed from prussic acid, it is not more poisonous than any other essential oils, though it still retains its characteristic and grateful flavour. As the oil of bitter almonds is very extensively employed in flavouring articles of confectionery, a German writer suggests the propriety of removing the prussic acid from the oil by repeated distillation with caustic potash, which removes the poisonous ingredient, but does not at all injure its other properties.—*Mr. Semple in the Pharmaceutical Journal.*

Preparation of Calomel.—In France and in England medical men almost exclusively employ calomel prepared with steam; it is found to be more active and more certain in its effects. The mode of preparation generally adopted is that of Joseph Jewel, with the modifications made by M. Ossian Henry. It consists in conducting steam, together with the vapour of calomel, into a large receiver. The manufacturing chemists in France follow this process; I have adopted it for many years at the *Pharmacie Centrale*; but am far from being satisfied with it. The operation is difficult to conduct; it requires great expertness of manipulation, and too frequently is attended with accidents, which cause the loss of a great part of the product. Moreover, it must be admitted, that the calomel prepared with steam in France is neither so white nor so finely divided as that which is sent from England. I have now to present, for communication to the academy, a mode of preparation very superior to any other that is known to us. I would not occupy the attention of the learned academy with a simple manufacturing process, if it was not one of a peculiar character, being applied to a product, in the preparation of which we have been unable, up to the present day, to compete with the English manufacturer. For the vapour of water which is interposed between the particles of the vapour of calomel, and which prevents them from uniting, I substitute a current of air, which, passing over the heated calomel, enters the vapour as it forms, and causes it to condense in a subtle powder.* For this purpose, I heat the calomel in an earthen tube, passing through a furnace, and direct a constant current of air through the interior of the tube, by means of a small blower, so as to carry the vapour into a receiver. If the operation be conducted with a straight tube, a part of the calomel might be carried to a distance of more than twenty yards. To obviate this inconvenience, I cause the end of the tube to dip into water, and the calomel is thus wetted and precipitated in fine powder. This kind of termination to the apparatus is all that can be desired. It only remains for me to perfect the process by ascertaining the best form and material for the vessels in which the calomel is heated. I have not been able to meet with such, ready made, as combine the essential conditions, so that I am obliged to defer to another time the complete description of the process; but I may observe, that even my first attempts at the operation have proved quite successful. I think the same principle of operation may be applied to the division of other volatile bodies.—*By M. Soubeiran.—Comptes Rendus.*

BRANDISH'S SOLUTION OF POTASH.

Best American Pearl-ashes	6 pounds
Quick-lime, fresh prepared	
Wood-ashes (from the Ash) of each	2 pounds
Boiling water	6 gallons

Add first the lime, then the pearl-ashes, and afterwards the wood-ashes to the boiling water; then mix. In twenty-four hours, the clear liquor may be drawn off.

Linimentum Hydrargyri Nitratis.—There is a preparation of this name in the Pharmacopœia Mancuniensis, 1827, under the authority of Drs. Holme, Mitchell, Lyon, Carbett, Bradsley, and Hulme; and of Messrs. Simmons, J. Thorpe, Ransome, Ainsworth, R. Thorpe, and Wilson, Surgeons, viz.:—

℞ unguenti Hydrargyri Nitratis ʒiiss.
Carati Simplicis ʒviiss.
Olivæ Olei, fʒv. Misce.

ON THE ACTION OF CARBONATE OF POTASH ON GUM RESINS.

Some years since, Mr. Hulse's attention was drawn to the action of carbonate of potash on myrrh, which induced him to try its effect in reducing other gum resins, and the result was perfectly satisfactory.

With regard to myrrh, if one part of carbonate of potash be added to two parts of myrrh in the lump, and rubbed together, the alkali produces complete saponification; and if to this be added medicated or distilled water, we obtain an elegant emulsion of myrrh, and nearly the whole of the gum resin is retained in suspension, which would not be the case without the aid of the carbonate of potash. If the compound mixture of iron is prepared by triturating the myrrh with carbonate of potash, then with the usual proportion of sugar, using the raw instead of refined, adding first the rose water, then the sulphate of iron, powdered, and, lastly, the spirit of nutmeg, it will

* Dr. Christison alludes to an analogous process in his Dispensatory, which he gives on the authority of Mr. Dann, of Stuttgardt, p. 525.

not be an unsightly mixture, and the precipitate will be very trifling.

Again, in the compound pill of iron, if carbonate of potash in used instead of carbonate of soda, and raw or muscovado sugar in lieu of the refined, a pill mass can be compounded with less trouble than by following the college formula, and which will retain a convenient pilular consistency for any reasonable period.

Take of,

Myrrh in lump, two drachms, reduce it to powder in an iron mortar by

Carbonate of potash, one drachm, then add

Sulphate of iron, powdered, one drachm,

Raw sugar, one drachm. Mix, and beat all into a mass, without any liquid. Attention to this last remark is necessary, for the addition of any liquid renders the mass too soft, the raw sugar being sufficient to bring it to a proper consistence.

The solubility of this pill is such, that after having been made six months, Mr. H. put two pills, of five grains each, into a glass of water, about the temperature of the stomach, and they were completely disintegrated in the course of two hours. If water will thus serve to dissolve these iron bullets, as they are sometimes termed, we may expect the fluid of the stomach would have a much quicker action upon them.

The compound galbanum pill, can be as easily and as readily prepared as the preceding one, and becomes as tractable and as convenient for making into pills as any other mass.

Take of

Myrrh in lump } of each one drachm and a half.
Sagapenum }

Galbanum, one drachm.

Assafœtida, half a drachm. Triturate these with two drachms of carbonate of potash, in an iron mortar, until the whole are sufficiently reduced, add

Raw sugar, two drachms, and beat altogether into a mass, without any liquid, which mass will retain its consistency for any reasonable period.

The pill of aloes with myrrh, compound squill pill, compound rhubarb pill, and other similar preparations, will be considerably improved if made with the assistance of carbonate of potash and raw sugar; but with every other than the compound galbanum pill and compound pill of iron a small portion of water must be used. The raw sugar (saccharum non-purificatum), as an ingredient in compound pill of iron, is decidedly preferable to the refined, which alone will not form a mass. In all pill masses and mixtures containing gum resins, the Pharmacopolist will find it preferable to use ingredients that have been powdered in his own premises.

ON THE PREPARATION OF EXTRACTS.

By the term '*extract*' is meant a medicinal preparation obtained from a vegetable or animal substance by the dissolving action of a proper menstruum, and reduced to either a soft or solid consistence by the evaporation of the solvents. Extracts vary much in their nature, in consequence of the great number of proximate principles contained in the plants and animals from which they are derived, and dependent also in part on the character of the solvent that has been employed. Thus, taking the vegetables for example, extracts are commonly prepared from them either with their juice, or from aqueous or alcoholic infusions: in the first two cases, they may contain the *gum, sugar, salts, vegetable acids, and alcalies, colouring and tannic matters*; while the alcoholic menstruum may dissolve the *saccharine, saline, colouring, and resinous matters*. It must be self-evident that a classification founded on the chemical analysis of the extracts, containing, as they do, a very complicated series of proximate principles, would be both exceedingly difficult and unsatisfactory; to a certain extent, however, the system has been adopted, and these preparations are not unfrequently spoken of under the respective titles of *gummy, gummo-resinous, saponaceous*, and *resinous*, the predominance of one of the principles giving occasion for the name, but it does not at all follow that therefore no other proximate principle is present. Henry and Guibourt, in their Pharmacopée Raisonnée, divide extracts into vegetable and animal, and the former into inspissated juices, aqueous and alcoholic extracts.

Extracts are obtained from plants either by the evaporation of their juices, or by the intermedium of water, alcohol, or ether. In their preparation, the essential point is to obtain the active principle of the plant in solution as free as possible from those that are inert, and afterwards to evaporate this solution to such a degree of dryness, as to preserve the chemical properties and medicinal powers of the drug uninjured. To effect this purpose with the narcotic and some other plants, the process of inspissating the juice is now pretty generally recommended by authors on pharmacy, and there cannot be a doubt that the modification of the plan by the inspissation by spontaneous evaporation, introduced by Dr. Houlton, is a most valuable improvement, and deserving to be universally adopted. Storck, a physician at Vienna, who introduced the extract of cicuta, and other narcotics, as a cure for schirrhus, used to prepare them in a manner essentially different from the process that was then followed. He advised, with respect to the conium, belladonna, aconite, and stramonium, that the fresh juice of the plants should be obtained, and without filtering or any process of depuration, evaporated at a moderate heat, the preparation being kept continually stirred: and he thus obtained extracts far superior and much more active than those in ordinary use. Dr. Houlton was led to modify this process in the following manner: he says, about the year 1805, four years before the herbaceous extracts were introduced into the London Pharmacopæia, I first made the extractum cicutæ, (now the extr.: conii) precisely after the process of Storck, when I accidentally left some juice for some hours exposed to the atmosphere, and found it afterwards inspissated, of a beautiful green colour, and plastic. For a few years I occasionally made a small quantity of extracts in this way, merely on account of the beauty of the preparation, for, as it was not made *secundem artem*, but secundem naturam, I had no idea that it could be worthy the attention of a scientific profession. However, as years rolled on, and I began to think for myself, I determined to try the effects of this spontaneous extract. When I first used it, I do not exactly remember, but from about the year 1824, I have not used any other extract of conium in my own practice, being so well satisfied with its superiority over that of the pharmacopæia. The preparation can be readily made in the following manner:—the expressed juice is to be exposed to a current of dry air, in shallow dishes at the ordinary temperature, the rapidity of the evaporation being in an inverse ratio to the quantity of the juice in each dish: common table dishes answer the purpose very well. The current of air may be produced in any spare room, if the window sash be opened but a few inches, and the door of the room be also kept open; the dishes may be placed upon a common table near the window; if the room be in the upper part of the house, there will be but little dust brought into contact with the extracts. Some chemists seek to aid evaporation, by heating the current of air which is passed over the juice.

The mode of preparing these extracts was first brought before the public in the Transactions of the Society of Arts, for 1826. Soon afterwards they were brought before the Medico-Botanical Society as remedial agents; the process was detailed in some of the medical journals, and is adopted in the last edition of the Edinburgh Pharmacopæia; in Stephenson and Churchill's Medical Botany, they were favourably noticed; the process is also mentioned with approbation in the last editions of Dr. A. T. Thomson's Materia Medica, and of Dr. Christison's Dispensatory. The last named physician says, that extracts thus prepared will keep good for three years at least, and that they deserve to come into general use.

Storck's plan was objected to at the time on the ground that the extracts so prepared contained a large quantity of green colouring matter and albumen, which were probably almost inert; to which he replied, that experience showed that his preparations were the best. He was right; but the value of his extract did not depend on the presence of these inert matters, but on the low temperature at which they were prepared, and the continual agitation to which they were subjected during the evaporation. Henry and Guibourt advise a modification of Storck's plan, which consists in depriving the juices of their colouring matter and the albumen they contain, and then rapidly evaporating, by the aid of a sand-bath, the juice being continually stirred, so as to constantly renew the surface.

The process of evaporation in vacuo has many advocates; it consists simply in placing the juice to be evaporated in an intermediate pan with a covering vessel, having lunettes through which the process may be watched, and tubes for conveying steam. The vessels being strongly secured together, and a division effected between them, steam is let into the upper vessel at a very high temperature, and suddenly condensed by the application of cold water externally; this is repeated until a vacuum is effected, and the partition between the two vessels is then withdrawn, the air in the pan ascending. The admission of steam and its condensation is then to be repeated until the vessels are as completely a vacuum as possible; after which a slight degree of heat will serve to effect evaporation. While speaking of this process, Guibourt observes, that it is applicable only on a very small scale in chemical analysis, or else on a very large one, and has besides, the disadvantage of not destroying the life of organised germs which may exist in the juices, or which have been deposited during the preparation, so that it is not uncommon to see extracts thus made covered with mould, or filled with the larvæ of insects.

Aqueous extracts are prepared either from the cold or the hot infusion or the decoction. The plant from which they are obtained is previously dried, water is employed as the extractive menstruum, when the principal medicinal proximate principles are soluble in it; if resin be the chief ingredient, alcohol must be had recourse to for the preparation of the extract. The water employed should be distilled or rain water, in order to avoid increasing the quantity of the extract by salts foreign to its nature. Guibourt advises that vegetable extracts should be made by infusion and subsequent maceration, in the majority of cases in preference to decoction, the article thus obtained being generally finer, more homogeneous, more soluble in water and alcohol, and a larger quantity being commonly obtained. Cinchona is an exception to this. Whichever way the active principles of the plant are separated, the solutions may be inspissated either by the process *in vacuo* already mentioned, by distributing the solution on a number of flat vessels on a stove, by the heat of water or sand bath, or over an open fire. It may be well to observe that the quantity of fluid should be as small as may be consistent with the perfect extraction of the active matter, and the evaporation should be conducted as rapidly as possible.

Alcoholic extracts, which were formerly but little used, are now more commonly prescribed, because the spirit can dissolve a large number of the active principles, leaving untouched the inert starch and inuline, and thus the medical virtues are contained in a smaller volume. In the *Pharmacopée universelle* of M. Mohr, certain alcoholic extracts of the narcotic plants are mentioned of exceeding power and efficacy. They are prepared with the juice of the recent plant, deprived of its albumen and chlorophyllum by heat, evaporated rapidly in a sand-bath to the consistence of syrup, then mixed with an equal quantity of anhydrous alcohol, which precipitates the gum and a large proportion of insoluble salts, and is finally evaporated to the consistence of extract. These are very powerful. There are very few extracts made with either, and they are best prepared by lixiviation; they are generally composed of fatty or resinous matters, united to some other active principles. The evaporation of the alcoholic and etherial extracts is so conducted at first, as to recover as much as possible of the menstruum, and the remaining liquor is cautiously evaporated in a water-bath.

The extracts of conium and hyoscyamus should be made from the plant when just come into flower, or soon afterwards. The plants are never better for extract than when they just come into flower; from that period the lower leaves begin to die, and one week will deprive the plant of some of its best leaves, or render them of very little use for medicinal purposes.

The extract of Taraxicum should be made from the expressed juice of the roots taken up in the autumn. It is important that this juice should be quickly inspissated; if left for twenty-four hours in a basin, it will show symptoms of fermentation at the circum-

ference, and will then resist the process of inspissation strongly; and even if overcome by management, the extract will have an acetous odour, and will not keep well. If the extract has an acid odour, it is a sure proof that the process has not been carefully conducted. It is highly important that the roots should be fresh from their native localities. If they have been taken up and kept in sand for several weeks before they are used, they will not realize the expectations of the manufacturer. Good extract of Taraxicum should be plastic, saponaceous, and slightly bitter.

The various modes of preparing extracts just mentioned, by decoction, by evaporation of the expressed juice, by heat and by spontaneous evaporation, were not unknown to the ancients, as the following extracts from the work of Dioscorides will shew. With respect to the preparation by *decoction*, when speaking of gentian, he observes, "Contusa radix quinque diebus aquâ maceratur; postea in eadem tantisper decoquitur, dum extent radices: et ubi refrixit aquâ, linteo excolatur: mox discoquitur, dum mellis crassitudo fiat, fictilique reconditur:—*evaporation by heat:* the cyclamines:—exprimitur tusa radice succus, et ad mellis crassitudinem decoquitur:—*spontaneous evaporation:*—the chelidonium:—foliis, caule, radice, succus exprimitur, ineunte æstate, et siccatus in umbrâ, digeritur in pastillos. A similar process is advised for preparing the extracts of conium, hyoscyamus, and solanum.

MEDICAL NEWS.

Royal Society.—*On the Nerves, by James Stark, M.D.*—The author gives the results of his examinations, both microscopical and chemical, of the structure and composition of the nerves; and concludes that they consist, in their whole extent, of a congeries of membranous tubes, cylindrical in their form, placed parallel to one another, and united into fasciculi of various sizes; but that neither these fasciculi, nor the individual tubes, are enveloped by any filamentous tissue; that these tubular membranes are composed of extremely minute filaments, placed in a strictly longitudinal direction, in exact parallelism with each other, and consisting of granules of the same kind as those which form the basis of all the solid structures of the body; and that the matter which fills the tubes is of an oily nature, differing in no essential respect from butter, or soft fat, and remaining of a fluid consistence during the life of the animal, or while it retains its natural temperature, but becoming granular or solid when the animal dies, or its temperature is much reduced. As oily substances are well known to be non-conductors of electricity, and as the nerves have been shown by the experiments of Bischoff to be among the worst possible conductors of this agent, the author contends that the nervous agency can be neither electricity nor galvanism, nor any property related to those powers, and conceives that the phenomena are best explained on the hypothesis of undulations or vibrations propagated along the course of the tubes, which compose the nerves, by the medium of the oily globules they contain. He traces the operation of the various causes which produce cessation in giving rise to these undulations, and extends the same explanation to the phenomena of voluntary motion, as consisting in undulations, commencing in the brain, as determined by the will, and propagated by the muscles. He corroborates his views by ascribing the effects of cold in diminishing or destroying both sensibility and the power of voluntary motion, particularly as exemplified in the hybernation of animals, to its mechanical operation of diminishing the fluidity, or producing solidity, in the oily medium by which these powers are exercised

Experimental Researches in Electricity (18th series), by Michael Faraday, Esq., section 25. On the Electricity evolved by the Friction of Water and Steam against other Bodies.—The object of the experiments related in this paper is to trace the source of the electricity which accompanies the issue of steam of high pressure from the vessels in which it is contained. By means of a suitable apparatus, which the author describes and delineates, he found that electricity is never excited by the passage of pure steam, and is manifested only when water is at the same time present; and hence he concludes that it is altogether the effect of the friction of globules of water against the sides of the opening, or against the substances opposed to its passage, as the water is rapidly moved onwards by the current of steam. Accordingly it was found to be increased in quantity by increasing the pressure and impelling the force of steam. The immediate effect of this friction was, in all cases, to render the steam or water positive, and the solids, of whatever nature they might be, negative. In certain circumstances, however, as when a wire is placed in the current of steam, at some distance from the orifice whence it has issued, the solid exhibits the positive electricity already acquired by the steam, and of which it is then merely the recipient and the conductor. In like manner, the results may be greatly modified by the shape, the nature, and the temperature of the passages through which the steam is forced. Heat, by preventing the condensation of steam into water, likewise prevents the evolution of electricity, which again speedily appears by cooling the passages so as to restore the water which is necessary for the production of this effect. The phenomenon of the evolution of electricity in these circumstances is dependent also on the quantity of the fluid in motion, more especially in relation to its conducting process. Water will not excite electricity unless it be pure; the addition to it of any soluble salt or acid, even in minute quantity, is sufficient to destroy this property. The addition of oil of turpentine, on the other hand, occasions the development of electricity of an opposite kind to that which is excited by water, and this the author explains by the particles or minute globules of the water having each received a coating of oil in the form of a thin film, so that the friction takes place only between that external film and the solids, along the surface of which the globules are carried. A similar, but a more permanent effect is produced, by the presence of olive oil, which is not, like oil of turpentine, subject to rapid dissipation. Similar results were obtained when a stream of compressed air was substituted for steam in these experiments. When moisture was present, the solid exhibited the negative, and the stream of air positive electricity; but when the air was perfectly dry, no electricity of any kind was apparent. The author concludes with an account of some experiments in which dry powders of various kinds were placed in the current of air; the results differed, according to the nature of the substances employed, and other circumstances.

On the Structure and Mode of Action of the Iris: by C. R. Hall, Esq.

After reciting the various discordant opinions entertained at different periods by anatomists and physiologists, relative to the structure and actions of the iris, the author proceeds to give an account of his microscopical examination of the texture of this part of the eye, in different animals. He considers the radiated plicæ, which are seen on the wen in mammalia, as not being muscular; but he agrees with Dr. Jacob in regarding them as being analogous in structure to the ciliary processes. The white lines and elevations apparent on the anterior surface of the human iris, he supposes to be formed by the ciliary nerves which interlace with one another in the form of a plexus. The iris, he states, is composed of two portions; the first consisting of a highly vascular tissue, connected by vessels with the choroid, ciliary processes, sclerotica, and cornea; and abundantly supplied with nerves, which, in the human iris, appear, in a front view, as thread-like striæ, and which are invested on both surfaces, by the membrane of the aqueous humour. They are more or less thickly covered with pigment, which, by its varying color, imparts to the iris on its anterior surface its characteristic hue, and, by its darkness on the posterior surface, renders an otherwise semi transparent surface perfectly opaque. The second component portion of the iris consists of a layer of concentric muscular fibres; which fibres, in man and mammalia generally, are situated on the posterior surface of the pupillary portion of the iris; but which, in birds, extend much nearer to the ciliary margin, and consequently on a much broader layer. In fishes and some reptiles they do not exist at all. The author then proceeds to inquire into the bearings which these conclusions may have on the physiology of the iris. He thinks that the phenomena of its motions can receive no satisfactory explanation on the hypothesis of contractility alone, or that of the antagonism of two sets of muscular fibres, the one for dilating, the other for contracting the pupils. He is convinced that the contraction of the pupil is the effect of muscular action; but does not consider the knowledge we at present possess sufficient to enable us to determine the nature of the agent by which its dilatation is effected. He, however, throws it out as a conjecture, that this latter action may be the result of an unusual degree of vital contractibility residing either in the cellular tissues, or in the minute blood-vessels of the iris. It is from elasticity, he believes, that the iris derives its power of accommodation to changes of size, and its tendency to return to its natural state from extremes either of dilatation or of contraction; but beyond that, elasticity is not concerned in its movements.

Westminster Hospital.—*Operations and Clinique of Mr. White – Lithotrity—Tracheotomy.—Saturday, March 4, 1843.*—Mr. White introduced into the theatre the patient referred to in our last number in the clinical lecture of Mr. Guthrie, and in calling the attention of the pupils to the case, made some highly interesting and valuable practical observations on the subject of lithotrity. As the patient had already undergone one operation in presence of the pupils, Mr. White did not require to enter again into the history of the case. He referred, however, to the curious fact which that previous operation disclosed, viz., of a *pin* which formed the nucleus of the stone, and which the pupils had seen extracted along with a great mass of the calculus at the former sitting. How the pin got into the bladder was a subject of varied conjecture, but nothing certain was known upon the matter. Since the last operation the patient has passed a large quantity of the *debris* of the stone. In passing some of the fragments a little pain was experienced, and one of the pieces actually stuck in the urethra, and was thrust back by his colleague, Mr. Guthrie, into the bladder. That fragment consequently was still in the bladder, and Mr. White had reason to believe that there were other pieces that required to be broken down and pulverised. The learned gentleman then proceeded to demonstrate and explain the steps of the operation. The position of the patient best adapted for the operation (the recumbent) was exhibited; the mode of injecting the bladder was also shown. In the hands of Mr. White the silver catheter, through which the water is conveyed into the bladder, is converted into a sound, and by the ingenious application of a *sounding board* fixed to the end of the catheter like a handle, the contact of that instrument, with the smallest portion of the calculus is at once perceived. Having satisfied himself that fragments of stone existed in the bladder, Mr. White withdrew the sound, and easily and smoothly introduced the crusher. Mr. White carries the instrument into the lowest part of the bladder, then separates the blades of the instrument, and, by a slight vibratory motion, imparted to the instrument, the calculus is placed between its blades, and immediately seized. This part of the operation was effected with great facility, and several pieces, in succession, of the calculus, in a few seconds, were broken and crushed. A large portion of the pulverised stone was brought away between the blades and teeth of the crusher, and the remainder left to be evacuated with the urine. The operation of lithotrity is a glorious triumph of surgery, and demonstrates the railway speed at which surgical science is progressing. After the performance of the above operation, Mr. White visited his patients of the hospital, and among some interesting cases which he, in a few but pointed sentences, explained to the students that thronged around him, he particularly directed their attention to a case of tracheotomy that had recently been performed. The case was one of no ordinary nature. The female was brought, a few days ago, into the hospital, labouring under chronic bronchitis, and placed under the care of Dr. Roe; yet, notwithstanding the indefatigable exertions of this eminent physician, the difficulty of breathing gradually increased, probably from supervening ulceration of the glottis, till she appeared at the point of death. In this predicament Mr. White was sent for, and from the urgency of the symptoms, hesitated not for a moment the opening of the trachea. The operation was performed in the usual way, in the mesial line of the neck, between the thyroid body and the sternum,

and as soon as the trachea was opened the patient awoke, as if by magic, into new life. The eye, the complexion, and expression of the face, were immediately improved. The breathing was now free, and a smile of gratitude seemed to lighten up the countenance of the patient. To keep the opening in the windpipe of the patient, a tube was introduced into the aperture, and through which the patient breathed, and apparently with perfect comfort. About twenty-four hours after the operation the difficulty of breathing began to return, and ultimately became so urgent that the house-surgeon, Mr. Brock, had no alternative but to remove the tube, or see the patient expire. Mr. White passed a warm encomium upon Mr. Brock for acting as he had done, and referred to cases that had been lost by neglecting to adopt this precaution. As soon as the tube, which had been partially closed with mucus, had been withdrawn, freedom of respiration returned, and the improvement has gradually advanced to the present state, when the patient now breathes through the natural passage, and is proceeding satisfactorily to perfect health.

The Royal Medico-Chirurgical Society — At a meeting held on the 28th ult., the President in the chair, the following papers were read:— *On Fatty Degeneration of the Arteries, by* Geo. Gulliver, Esq., F. R. S., (*Communicated by Dr. Hodgkin.*) The author, remarking how vulgarly the epithets atheromatous, and similar ones have been applied by pathological writers to diseased arteries, and that the morbid deposit between the middle and inner coats, and in the substance of the former, has not, as far as he knows, yet been submitted to precise examination, gives the result of his own observations, from which it appears that the disease is really of a fatty nature. A microscopic examination of it brings into view a multitude of crystalline plates, fatty globules with albuminous and earthy particles. Several specimens of the crystals were sent for examination to Dr. Davy, who ascertained that they are of cholesterine. The fatty matter is easily extracted by boiling alcohol, and the chrystals of cholesterine are seen to be deposited as the solution acts. The author has examined numerous specimens of the diseases, and never failed to observe these crystals and the fatty globules in the deposit, and also generally in the substance of the altered middle coat. The microscopical characters are given in the two figures. The accuracy of Dr. Davy's observations, (see his researches Phy. and Anat., v. 1, p. 372 and 436), as to the thinning &c. of the middle coat of the artery is confirmed by Mr. Gulliver. The importance of fatty degeneration of the coats of the arteries is insisted on, especially as to its general connexion with thickening and puckering of the inner membrane, with aneurism, with obstruction, occlusion, or ossification of the vessels, and with those ruptures of them which are frequently the cause of sudden death. In a note the author adds that fatty degenerations are more common and of more importance than has yet been supposed. He mentions obstruction by fatty particles of the seminal tubes; and notices fatty degeneration of the blood, lungs, &c. The disease he describes as being more remarkable in "brown consolidation" of the lungs than in red consolidation; and these two diseases are described as affording distinct morbid product.

A Normal and Abnormal Conscious State, alternating in the same individual:—by John Wilson, Esq., M.D., Physician to the Middlesex Hospital — This case occurred in a boy, aged 14, a patient in the Middlesex Hospital, who was said to have complained of head-ache for two or three days, but whose appearance was healthy. For three or four days his appetite was inordinate, seizing upon any articlea of food he could meet with in the ward, though allowed full diet. When not eating or seeking for food he generally slept night and day. This abnormal state continued for three or four days when he recovered his natural state of sleep, appetite and consciousness. Then he had no recollection of what he had done, or of what had happened to him since his admission. He was shortly afterwards discharged, but was twice re-admitted, presenting each time, the same symptoms, viz., alternations of consciousness and unconsciousness. No treatment was adopted. The author for the present reserves his opinion and the inference he draws from this case; his object being to invite further examination for similar cases, and when that arives then will be the time for discussion.

Remarks on the Calculi in St. George's Hospital. — By Dr. Bence Jones—Communicated by Mr. C. Hawkins.—The number of specimens submitted to examination was 233. The author's object from the analysis of these Calculi, is to arrive at conclusions with regard to the comparative frequency of different states of the urine in calculus complaints; and thus to obtain practical hints as to the efficacy of remedies intended to alter the secretion, or act upon the stone in the bladder. He presents several tables: and taking 450 states of the urine inferred from the composition of the calculi, finds that in 139 it was alkaline, and in 311 acid, to the test paper. Omitting from the latter list 59 specimens of the oxalite of lime, 252 cases of the uric acid diathesis remain: and in 117 of these no free acid was passed, from which the author concludes that alkalies would have been of no benefit in them, so far as neutralizing acidity of the urine was concerned. Taking the cases in which the alkaline concretions prevailed, he infers, that in 52 the calculus might have been lessened by the injection of dilute acids, and in 12, the whole calculus might have been removed; while in others to which he refers, disintegration might have been effected. He concludes by describing a calculus in the possession of Mr. Hawkins, the nucleus of which consists of cystine, and which, from the history appears to have been formed when the patient was $2\frac{1}{2}$ years of age.

Case of Ulceration of the Internal Jugular Vein, communicating with an abscess: by Mr. Bloxam, Surgeon to Queen Adelaide's Lying-in-Hospital, and Lecturer on Midwifery, (Communicated by Samuel Lane, Esq.)—The patient, five years of age, after an attack of scarlet fever, had suppuration of the glands of the neck of the right side, near the angle of the the jaw. Five days after, the abscess burst, blood of venous character was discharged from the opening at first in small quantity, and afterwards more copiously. Graduated compresses were applied, but the hæmorrhage could not be restrained, & the child died on the fifth day from the commencement of the bleeding. On dissection an ulceration of an oblong shape, about five lines in its long axis, was found in the inner side of the internal jugular vein, and opening immediately into the sac of the abscess. Extravasated blood was also observed beneath the integuments of the throat and forepart of the chest.

The Pharmaceutical Society.—At a meeting of the members of this society, on Wednesday evening last, the president addressing the meeting said, that this was the first meeting since the society had obtained a charter of incorporation, by virtue of which it had become acknowledged by the law of the land, and thereby its political situation was materially altered. The preamble of the charter stated, that Her Majesty, with the consent of her advisers, had been induced to grant this boon, believing that the association would be the means of advancing the arts of Chemistry and Pharmacy: and of thus contributing to the welfare of the public interests. Now, whatever might have been the motives which had induced gentlemen to join this association, or might hereafter lead them to associate with it, this must be remembered—that they were pledged to do all in their power to elevate the profession to which they belonged, and to show themselves, in this way, deserving of the boon conferred upon them. He hoped it would not be thought by any of them, that, having arrived at this satisfactory point, their work was done. He for one did not think so, and he trusted that no man did; but, on the contrary, he felt called upon to employ every means in his power to carry out the great end the society had in view. He hoped that that object would be fully borne in mind; that it would not be considered, by the members of this society, sufficient to have three or four letters placed at the end of their names, unless they could do so with credit and honour to themselves. The meetings of this society would doubtless be the means of advancing the great object it had in view, and this ought to be a stimulus to a frequent and regular attendance at them. The council were most anxious, always, to cater for the enjoyment and improvement of the members, but they must look to the members themselves for an opportunity of so doing. He was very happy to say that competent judges had expressed themselves exceedingly pleased with the papers that had been read at the meetings of this society, from time to time. He hoped that the members of this society would always be disposed to speak and to act towards other corporate bodies with due deference and respect; but he would say this publicly, inasmuch as the government of this country, in their wisdom, had thought proper to recognise this society as an integral part of the medical profession,—he expected—and he hoped it was no more than he had a right to expect—that other corporate bodies—more especially the College of Physicians—would manifest the same disposition towards this society. This meeting would bear witness that he was a strong advocate for the strict observance of forms belonging to the authority of the land; but it was no more than right to expect that those forms would be of a scientific character and of practical utility; and whilst he and the members of this society would be quite willing and quite anxious to pay deference and respect to those who, by their education and station, were supposed to be best able to superintend such matters rather than matters of practical utility; in his humble opinion, practical matters were best left to the practical men, such as he hoped he should ever find the members of the Pharmaceutical Society. The mere possession of a long purse and an university education, whatever influence it might formerly have possessed, he was happy to say, was not now sufficient to constitute real distinction or confer honour. Every Englishman—every British tradesman if he was a man of respectable character and devoted himself to the advancement of that occupation in which he was engaged, was entitled to be regarded as a British gentleman.

At this meeting three papers were read. The first was by Mr. Hooper, on "The Preparation of Extracts by Spontaneous Evaporation assisted by a Current of Dry Air." The second, "On Certain Precautions Necessary in Using Chemical Tests," by Mr. Howard, of Stratford. And the third, "On the Preparation of the Syrup of Poppies by Cold Water." Mr. Hooper, in his paper on the preparation of extracts, observes that, according to the directions for making extracts in the *London Pharmacopœia*, the leaves of the fresh plants are to be sprinkled with a little water, and boiling water is to be poured on the recent roots, which are to be macerated twenty-four hours; after which a decoction is to be made and evaporated at a boiling temperature. He doubts the expediency of this method for the following reasons:— First, by sprinkling water on the leaves the amount of fluid to be evaporated is increased, as the water, as well as the juice, must be got rid of by evaporation; secondly, the maceration accelerates acetous fermentation; and thirdly, the boiling temperature tends to destroy and impair the proximate principles of the plants. He has tried many arrangements and various temperatures, and he is convinced, that by inspissating the expressed juice by a current of dry air, extracts may be produced of a more uniform character than arises in ordinary use, and that their quality is far superior. The dose is the same as that for the pharmacopœial preparation. The process he employs he conceives has these advantages—That it augments the current of air by which the evaporation is promoted; the moisture, as it escapes, is absorbed by sulphuric acid placed in trays alternately with those containing the juice; and by moderately warming the current of air, and keeping the shelves of the apparatus in constant motion, the evaporation is further expedited. He describes the apparatus, which is a very ingenious contrivance. We shall notice the other papers next week.

Punished Quackery.—A lamentable instance of the effects of empiricism was disclosed yesterday, before the Tribunal of Correctional Police. A man named Meulen, a native of Germany, and formerly a grocer's shopman, was tried for the illegal

practice of medicine. One of the victims, whom he attended for a cold, and reduced by his medicines to a helpless and incurable state, appeared as a witness against the offender, who was found guilty and sentenced to a fine of 500 francs.

Brentford Medical Association.—A full attendance of the members of this association took place on Thursday, 2nd March, when a paper, read by Dr. Day, the president, on Fever, was the subject of an interesting discussion. We are told that this association promises to be highly beneficial to its members by encouraging the diffusion of medical information and the discussion of scientific subjects.

PREPARATIONS OF IRON.

Experiments undertaken for the purpose of rendering more perfect the preparations of iron used in medicine, have led me to the discovery of several ferruginous products not yet studied, or but little known. I shall make known the more prominent properties of these products, so as to complete what I have already published on ferruginous compounds in general, and on the citrates of iron in particular.

Sesquicitrate of Iron.—The citrate of the sesqui-oxide of iron is obtained in transparent laminæ, of a beautiful garnet hue.

Protocitrate of Iron.—The citrate of the protoxide of iron is prepared by treating iron filings with citric acid previously dissolved in distilled water. This salt is white and pulverulent, and but slightly soluble. It is rapidly coloured by light, and by the action of moist air its composition is modified, the iron passing to a higher degree of oxidation. This citrate, like the other protosalts of iron, has a strongly marked chalybeate taste.

Citrate of the Magnetic Oxide of Iron.—Combined with the magnetic oxide of iron, citric acid furnishes an uncrystallizable salt, of a green colour, and susceptible of being formed into transparent laminæ. This salt is soluble and very active, but as its taste is decidedly chalybeate, it is on this account objectionable for internal use. It is remarkable, that its solution does not alter, but preserves its green colour, although exposed to the prolonged action of the atmospheric air.

Citrate of Iron and Quina.—The citrate of iron and quina is a new salt, which was required as a therapeutic agent. This medicine is formed by the combination of four parts of citrate of iron, with one part of citrate of quina. It is obtained in the form of transparent laminæ, soluble, very bitter, and of a garnet hue. This salt is best adapted for administration in the form of pills, on account of its great bitterness.—

SYRUP OF TANNATE OF IRON.

Take of

Simple syrup . . .	375 Parts.
Syrup of Vinegar .	125 "
Citrate of magnetic oxide of iron	10 "
Extract of galls	4 "

Mix and form into a syrup.

The iron in this preparation is in the state of the magnetic oxide united with an acid. It is soluble, tasteless, and susceptible of useful applications.—*M. Beral.*

PROCESS FOR THE PREPARATION OF ULTRAMARINE.

Take of

Fine clay, powdered and sifted .	100 parts.
Gelatinous alumina, representing of the anhydrous	7 "
Carbonate of soda, dried, 400 parts, or crystallized	1075 "
Flowers of sulphur . . .	221 "
Sulphuret of arsenic . . .	5 "

The mixture of these substances must be made with great care.

Into the carbonate of soda, liquified with its water of crystalization, throw the sulphuret of arsenic in powder, and when this latter substance is partly decomposed, add the gelatinized alumina (this alumina is obtained from the alum of commerce, precipitated by carbonate of soda—the precipitate collected on a filter, and washed once with river water). Afterwards add the clay and the flowers of sulphur previously mixed. This mixture, reduced by the heat, is put into a covered crucible, carefully heated, to drive off the remaining water, then raised to a red heat. The fire should be so managed as to agglutinate, but not to melt the mass. After allowing it to cool, it must be again heated to drive off any remaining sulphur; it must then be broken and rubbed down with river-water. The powder held in suspension in the water is collected on a filter. When the mixture has been well made, the whole of the product may be used; but in case the combination has been imperfect, there will be found a number of colourless particles, or when the heat has been carried to complete fusion, there will be some fragments of a brown colour, especially when the crucible is of a bad quality, and has been much acted upon. These results never occur when the operation is conducted with care. The filter should be allowed to drop without further washing the powder, and the latter is then to be dried. The product will be of a beautiful soft green colour, which afterwards becomes blue.—*By M. J. De Tiremon.*

Manufacture of the Oil of Vitriol from Iron Pyrites.—The manufacture of Sulphuric Acid and Soda is carried on conjointly, in a factory at Belgium, in the following manner:—The residue of the roasted pyrites are mixed with an excess of sea salt, having previously ascertained the contents of sulphate of iron contained therein. The mixture is then heated in an appropriate furnace, arranged so as to collect the muriatic acid. The sulphate of soda formed is obtained by solution and crystallization; the peroxide of iron remaining is separated by elutriation into two parts: the most finely divided is dried and mixed with grease or palm oil, serving as a lubricator for machinery, for which it is admirably adapted; whilst the coarser portions are made into balls, dried, and used as a mineral iron for the puddling furnace. In factories where soda is not made concurrently with sulphuric acid, in place of procuring the sulphate of iron from the roasted pyrites, it will be more advantageous to distil these residua; the sulphate of iron being first dried, so as to obtain the fuming sulphuric acid of Nordhausen, as it is termed. It would be very easy to arrange the apparatus in such a manner that the sulphurous acid, arising from the decomposition of part of the sulphate of iron, should be conducted into leaden receivers or chambers. By such an arrangement, nothing would be lost, since the colcothar or peroxide of iron remaining after the process has been completed, is always available.

Oxidation of Alcohol by Chromic Acids.—Chromic acid, as well as other substances, (for instance, spongy platina), converts alcohol into a liquid containing aldehyd, lampic acid, ethereous acid. If some dry chromic acid be thrown into absolute alcohol, it becomes suddenly red-hot, is reduced to protoxide; and, if the alcohol be only in very small quantity, it takes fire. Absolute alcohol, mixed with sulphuret of carbon, takes fire on the admission of the slightest trace of dry chromic acid; whilst sulphuret of carbon alone is scarcely affected by it. These experiments have been made with common chromic acid; that is to say, chromic acid contaminated with sulphuric acid, according to Tritsche's method.

Hæmatoxylin.—Dr. Schunk has read to the British Association, a paper "on Hæmatoxylin, the Colouring Principle of Logwood," by Prof. O. L. Erdmann, of Leipsic. The Hæmatoxylin used by the author in his experiments, was prepared by the process of charcoal. In a state of purity, Hæmatoxylin is not red; it is in itself no colouring matter, being merely a substance capable of producing colouring matters in a manner similar to lecanorin, orcein, or phloridzin. The colours which it produces are formed by the simultaneous action of bases (particularly strong alkalies), and of the oxygen of the atmosphere. By the action of these it undergoes a process of eremacausis, which, after forming colouring matters, ends in the production of a brown substance resembling mould; the colour of Hæmatoxylin varies from a pale reddish yellow to a pale honey colour. The crystals are transparent, possess a strong lustre, and may be obtained a few lines in length. Their form is a rectangular four-sided prism, sometimes with a pyramidal summit. The taste of Hæmatoxylin is similar to that of liquorice. With excess of ammonia, it forms what the author calls Hæmatein, analogous to orcein, &c.

Ether from Organic Acids.—M. Gaultier de Claubray has succeeded in procuring Ether from Organic Acids, by the use of heat: his process is to add alcohol, drop by drop, to the hot acids.

Constitution of the Sulphates.—Mr. Graham, F.R.S., has communicated to the Chemical Society, certain experiments "On the Constitution of the Sulphate as illustrated by late Thermometrical Researches," which he considers sufficient to demonstrate that no heat is evolved in the formation of double sulphates; and that their compounds are formed at once on mixing the solutions of their constituent salts, whether precipitation occurs or not. Sulphate of potash and water are, therefore, equivalent in the constitution of such salts, or *equi-calorous*, if a term may be coined to express this relation.

Chrystallization of Salts.—M. Longchamps has published some experiments tending to show that *all* Salts expand in the act of Chrystallization; and that the apparent contraction which often takes place arises from loss of heat in the solution.

Pure Boracic Acid.—The usual method of preparing boracic acid consists in decomposing borax by means of sulphuric acid; but the boracic acid thus obtained is always contaminated with a certain quantity of the sulphuric acid used in its preparation. M. Wakenroder has pointed out a better method, as follows: dissolve forty parts of borax in one hundred parts of boiling water, and add twenty five parts of hydrochlurie acid to the solution while hot. Collect on a filter the boracic acid, which will crystallize on the cooling of the liquor, wash it a few times with cold water, allow it to drain, re-dissolve it in a little hot water, and crystallize it a second time. Wash the crystals with a little cold water and press them between folds of filtering paper. The mother-water and the washings of the crystals may be evaporated so as to afford a further quantity of the acid. This boracic acid, when dry, will still retain a trace of free hydrochloric acid, which may be driven off with a part of the water of crystallization by drying the acid at a temperature of about 234° Fah. After this operation the acid is pure.

OUR INTENTIONS.

This volume will be concluded with the second weekly number after this, when we shall commence giving a short course of lectures on Organic Chemistry, by one of the very first of British practical chemists. Dr. Marshall Hall's course on Diseases of the Nervous system, will be terminated in our next number. If this course offer much that is extraordinary in treatment, and little that the judicious medical man will adopt into practice without suspicious solicitude, it will at least have gratified the avid curiosity roused by bold claims to grand discoveries, claims alike supported and resisted with equal pertinacity, though not with equal temper or reason. The course by Serres, on Organogeny—the most novel and important published in any journal for a very long period—will be concluded in about five more numbers. We shall continue the course of lectures on the Practice of Physic, by Dr. C. J. B. Williams, F. R. S., till the whole series be given. They are specially reported for us by Mr. Gregory, the short-hand writer, and may be depended upon by the general practitioner as containing the experienced and well-reasoned lessons of one of the most practical, judicious, and deep-thinking physicians of the age. Our Pencillings of Eminent Medical Men will be continued as usual; and our attention to the improvements every day being made in Pharmacy, Surgery, and Medicine, will certainly not be abated, by the triumphant success, every day augmenting, which has crowned our past labours in behalf of the amelioration and well-being of our noble profession

TO CORRESPONDENTS.

Our druggists' price list will appear next week, as well as the conclusion of our article on the Quack and Patent Medicines.

Our Correspondents' indulgence is craved: they are unavoidably postponed till next week.

THE MEDICAL TIMES.

SATURDAY, MARCH 11, 1843.

"Invitus ea tanquam vulnera attingo, sed nisi tacta, tractataque sanari non possunt."—LIVY.

WE have more than once recorded our opinion in emphatic condemnation of the timid and disingenuous policy *publicly* pursued by the ruling authorities of the Pharmaceutical Society. We complained—and with the force that truth gave us—that while the great bulk of the individual member's opinions were at once so well known and decided, yet that no one could pronounce what were the principles of the Society itself; and expressed a suspicion that though external influence had forced the heads and members into conjunction, they had only mutually to explain themselves to be again thrown into a state of repulsion and separation. Starting on the well-*understood* — (for how say, *avowed*, where nothing is avowed but ambiguity?)—starting, we say, on the well-understood principle of protecting druggists' interests, the chiefs have identified themselves with a knot of exclusive physicians, and have catered, and not vainly, for the support of some general practitioners. Now allowing much as we may--and we have never scrupled to allow much in the way of admirable *intentions*,—we cannot yet blind ourselves to the evident fact that a society so formed, and so acting, must either have no principles at all as a governing public body, or must with a tortuous and timid policy that can invoke no good man's praise, have completely compromised them. Such heterogenous materials, we have felt, could not have commingled without some loss of their originally distinguishing elements. That loss has not been on the part of the foreign bodies introduced. It has been that of the Society which has not yet dared to make a plain profession of its faith, and which when once obliged to act, and so in some measure demonstrate its principles, (*and it soon must act*) will not, we consider, be able to advance one step without dissipating some pretty bubble of elate expectation, which, if it has not itself raised, it has at least allowed unchecked to be blown, and casting from it in its onward course, in rapid succession, the numerous supporters, whose connection has been all along maintained but by the feeble tie of a delusive hope.

We may not have been right in these opinions. Time, the great teacher in that case will convict us of error; but we have sincerely entertained them: and the recent concession of a charter to the Pharmaceutical Society, in no way influences us to change them. We have never doubted the probability of such an event, but what we have strongly doubted, and what we still doubt is, the probability of that event giving a stability to the society it did not possess before, or giving to a body with the elements of disjunction and weakness essentially within it, the power and permanency of a true cohesion and unity.

A short description of the new charter, with a few words on the character of its provisions, as they have been made known to us from an authentic source, on which our readers may entirely rely, will serve to confirm the truth of our prognostications.

The charter in the first place leaves the Society a perfectly voluntary one. Any one may now, as before, vend or dispense medicines without the sanction of, or connection with, the chartered body. The diploma cannot be made a *sine qua non* to chemists and druggists without an act of Parliament. The *government* is declared to be in the hands of the President, Vice President, Treasurer, and eighteen other membeas. The election is in the members, but they are restricted each year to re-elect one third of the passing year's council, and the Committee elect the President, and Vice President, and Treasurer, from their own body. The quorum of the Council is to be seven, the meetings monthly. They have the power, as they had before, of making bye-laws for their own members, and they may sue and be sued. In one word, the Society is just what and where it was. The Queen has done what we and the world had done long before, recognised the *existence* of such a body as the Pharmaceutical Society. We have now what we had not before, her gracious sign manual for the fact that there is such an association!

The only use then of their diploma is its *honour*, as the only use of this Society to the great bulk of the members is its diploma.

We confess that with eyesight the most charitably microscopic, we cannot discover the *honour* of a diploma which is possessed by three or four thousand gentleme, merely because they have been found in practice, as chemists and druggists, in the year of grace 1842. Such a circumstance pre-supposes nothing of high character, morally, mentally, or scientifically, which can tend to give honour to the possessors of such a document. If it be no honour, where is its utility?—and where, consequently, the honour or utility of membership in the Society which gives it? We say this out of no enmity to the Pharmaceutical Association. As conducting a Medical Journal—still less, if possible, individually—we have no interest in the destruction of that body. If it would only boldly declare itself, the thing to be desiderated would be its flourishing existence. But, looking with the eye of attentive observers, we are bound to point out the course of coming events, as necessitated by the circumstances before us. We prophecy as we see, and if our prophecies are not the speakings of reason, they are certainly not those of hope. If we are wrong, time—we repeat it—will convict us of error. His recent course, however, has been in another direction.

One word on the possession of the diploma, as indicating the permanency of the Association. If two guineas, the price of one year's membership, shall purchase a diploma, why shall more years of membership be uselessly paid for? Does the Council think that it has such a property in the diploma, that it can recall it? If not, does it fancy that three or four thousand gentlemen will voluntarily pay six or eight thousand guineas, year after year, without any corresponding *quid?* We tell it, that after the diplomas are given, the members will secede, and we tell it further, that it will vainly apply to Chancery for injunctions against non-members using diplomas so acquired. The diplomas wi'l evidence a fact—the fact of a prior membership; and if there be no humiliating contracts specially and formally entered into for their return (the notion is absurd), no court of law or equity would or could intervene. The diploma, at present, is the *foundation* of the Society. The Council cannot too soon look out for a better.

"Exciseman—one who filches in the name of the law."
JOHNSON.

THE recent Excise prosecutions of chemists and druggists, for vending spirits, have caused a perfect consternation through the trade. No less than five hundred informations have been laid against as many druggists, and twenty-five have been amerced in fines of £50 each.

Now, there are two positions which may fairly be taken—one of which will not please the Excise gentry; and the other, probably, the higher-toned and more ardent sticklers for pharmaceutical privileges,—viz., first, that the druggists have been clearly in fault, when regard is paid to the state of the *law;* and, secondly, that the Commissioners have been still more in fault, when attention is paid to the state of *practice.*

Two things are necessary to sell any kind of spirits—a license, and a conspicuous public declaration of the fact of such vending. There is but one exception—the sale of spirits as a medicament. Alcohol, spirits of wine, are terms that are found in every Pharmacopœia, and if the pharmaceutist may not vend them for purely medical purposes he may forthwith shut up shop. So far, all parties are in perfect agreement. Nay, they agree further. If a druggist vend spirits of wine with the sincere notion that they are to be applied medicinally, and they are bought for another purpose—it is admitted that he is exempt from any penalty. His *bona fides* shall save him in the illegality.

But the usual, or at least a very frequent, purpose for which spirits of wine are sold, is for household purposes:—feeding lamps, scouring plate, making varnish. Now, there is no disguising the plain fact that, for all such purposes, the sale of spirits of wine, or of any "strong water," (as the Act calls it) by an unlicensed party,

is *illegal*—an illegality so decided, that, looked at purely in that light, no length of usage can countervail it. But shall it be said that no length of usage shall rescue the well-meaning offender if not from the law's notice, at least from its punishment? Here was a usage of thirty years' standing. Spirits of Wine have been retailed by no regularly licensed *vender*: it was universally thought completely out of their province. The druggists have as constantly kept and sold it. Society, whenever the article was wanted, went to them as its natural distributors. The very Commissioners who now hear the informations, yielding naturally to the useful custom, have positively been in the habit of so providing themselves with spirits of wine. The creature of law—a legal institution—a governing body—the Apothecaries' Hall, constantly kept and constantly sold spirits of wine for domestic purposes, and for thirty years no regular druggist has been disturbed or molested for the sale of the liquid.—And shall this universal practice, harmless to morality, convenient to society, strengthened by years, corroborated by the authoritative examples of the men most respectable, both in the Excise and Pharmaceutical bodies—shall this usage, we ask, without a single whisper of notice or warning, be suddenly made the subject of violent universal assault—*one side* of its abettors *charged by a portion of the other*, as little less than guilty of crime, and five hundred of them—most of them heads of families—suddenly involved in all the dreadful anxieties attendant upon what must have appeared to them a costly, if not ruinous, litigation?

To our minds the procedure of the Commissioners was very far from right. It was neither prudent nor humane. If the law were worth enforcing they ought to have enforced it before. They should never have allowed the usage to have grown up, or grown up, they should have left it undisturbed. If, however, the first were a bad laxity, and they were determined thus late to change it, they should have given timely and emphatic notice. If that were neglected, they might have acted: the complaint would then have been not against the law, but its administrators: if not neglected we should have been spared these harassing prosecutions, which are as profitless to the law as to society, to the prosecutors as the prosecuted.

The whole subject is now before the Government. Sir James Graham has countermanded all further proceedings till further consideration be given: and we shall not be surprised to hear that none of the penalties are to be levied.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, March 3, 1843:—

J. G. Davis, P. Bellamy, P. T. Kempson, F. W. Osborne, A. Lamb, C. N. Insta[illegible], T North, W. Paterson, S. Payser, J. Shaw, G. Fisher.

KITCHEN CHEMISTRY & MEDICINE.

Be[illegible] a Diet, by Dr. D[illegible].

COFFEE.

There are various methods of preparing a solution of coffee. Some authors recommend an infusion, others a decoction, as the best; but almost all concur in recommending the following essential requisites; namely, that the coffee should be good, properly roasted, and finely ground. From the experiments of Mr. Donovan, it appears that water extracts, by infusion, the same quantity of matter from coffee, in very fine powder, as by decoction. But as a fine state of powder is not to be expected in the ordinary management of culinary affairs, a decoction of coffee, ground in the usual way, will be stronger than an infusion; and more or less boiling is generally practised by economical housekeepers. Mr. Donovan recommends the following method as efficacious in preserving both the aroma and bitter quality of the coffee. The whole water to be used is to be divided into two parts. One part cold is to be poured upon the coffee, and merely brought to a boiling point, when the liquid, being allowed to settle a little, is to be poured off. The remaining half of the water, at a boiling temperature, is then to be poured upon the grounds, and kept boiling for about three minutes, and after a few moments' subsidence the clear part is to be poured off, and mixed with the former liquor. The object in this method is, first, to extract by a kind of infusion, the aroma of the coffee, by bringing the liquid to the boiling point, and second, to extract the latter property by decoction.

ADULTERATIONS OF COFFEE.

Ground coffee is extensively adulterated with chicory, and more rarely with roasted corn. Chicory is detected by shaking the suspected article with cold water, in a glass vessel; if the coffee be pure it will swim and give little or no colour to the liquid, but if chicory be present it sinks to the bottom, and communicates a pretty deep red tint to the water. Roasted corn may be detected by adding tincture of iodine to a cold decoction of the suspected coffee, which will produce a blue colour in the liquid.

CLOVES

Cloves are useful in dyspepsia by stimulating the digestive organs, and by retarding fermentation in the contents of the stomach. They also have a powerful effect in checking nausea and vomiting, particularly the essential oil. In ordinary cases the oil may be exhibited alone, in the form of pill made with flour; but in obstinate cases of vomiting, when the bowels are relaxed, its combination with opium is very efficacious, in the proportions of one drop of the oil to half a grain of opium every two or three hours. In the bowel complaints of children, accompanied with irritability of the stomach, it may often be advantageously combined with chalk mixture, laudanum, sweet spirits of nitre, and a proper proportion of syrup to render it agreeable to the taste. The oil of cloves is also well known as a palliative of toothache, although it sometimes proves inefficacious.

CINNAMON.

Cinnamon is an excellent and agreeable condiment for promoting digestion, and is used very extensively in dietetical and confectionary preparation. When employed medicinally, it is considered tonic, slightly astringent, useful in dispelling flatulency and in checking retching or vomiting, and is often mixed with other medicines to cover their disagreeable taste, or to prevent their griping effects on the bowels. The oil is sometimes applied to a carious tooth to relieve a paroxysm of toothache.

MUSTARD.

Mustard causes no injury to the digestive organs when used moderately; but when there is any tenderness about the stomach, as is often indicated by a red tongue, it should be avoided. Some authors recommend mustard for the table to be made with milk; but it is not well calculated for this purpose, as it becomes rancid in about two days. Water containing common salt in solution will give it the proper consistency, and at the same time ensure its preservation. Mustard is sometimes employed as an emetic, in cases of emergency, in the dose of a small table-spoonful mixed with eight or ten ounces of water. Externally, it is often used, in the form of poultice, to relieve spasms and local pains of various kinds, and if not deep-seated, is generally very efficacious. When long applied to a tender portion of the skin, it may cause blistering; but as the period is generally limited to half an hour, a deep red stain is only produced; which, however, often continues for a number of days.

ADULTERATIONS OF MUSTARD.

The inferior varieties of mustard are often composed, almost entirely, of flour, turmeric, ginger, and cayenne pepper. Turmeric is detected by a solution of potash, soda, or ammonia, which strikes a deep brown colour when the mustard is diffused in water. Flour is discovered by iodine which when added to a decoction of mustard, gives it a deep blue colour. When the quantity of flour is large, it forms a tough, elastic mass or paste with water. Dr. Christison states, that mustard for exportation is also adulterated with gypsum.

PEPPER.

Pepper is an excellent stimulant for promoting the digestive process, and is so universally employed as to be nearly as indispensable as common salt. It is particularly useful when taken along with vegetables that are liable to produce flatulency; but ought to be employed sparingly by persons who have any tenderness in the region of the stomach. In flatulent cholic, pepper mixed with hot milk is a popular remedy, and is often serviceable. It forms a good external application in cases of local pains, and in spasms of the stomach and bowels. The most convenient and efficacious method of employing pepper for this purpose, is to mix the powder with ardent spirits, dip linen or cotton cloths in the mixture, and apply them to the parts affected; and they should be frequently renewed until relief is obtained. The crystalline body, *piperine*, has lately been recommended for the cure of ague; and some writers consider it superior to quinine, but the statement has not been confirmed by other physicians.

ADULTERATIONS OF VINEGAR.

Sulphuric acid is employed in the re-distillation of wood vinegar, and when the heat has been too great, a portion of it passes into the receiver. Vinegar may thus be unintentionally contaminated with sulphuric acid. If it be very minute, it cannot be injurious, and, I believe, is tolerated by the excise laws. When it exists to any extent in vinegar, a solution of nitrate of barytes throws down a copious white precipitate. If copper or lead be present, sulphuretted hydrogen throws down from it a black precipitate.

WINES.

Counterfeit wines are sometimes so skilfully made, that an experienced connoisseur is required to detect them. Red wines are often artificially coloured with brazil-wood, myrtle-berries, elder berries, beet-root, and even it i

said with a solution of indigo. Mr. Accum states that spoiled cyder is employed in the manufacture of artificial port wine; and beetroot, logwood, rhatany root and a portion of brandy are added to it. Sweet-briar, orris-root, laurel-water and elder flowers are employed to form the aroma or bouquet of high flavoured wines. Weak wines often become acid, and to correct this state it was frequently the practice, at one period, to add litharge or an oxide of lead to them; but this plan is more rarely adopted at the present day. This addition communicates to the wine a sweetish taste, by the formation of acetate of lead, but renders it more or less poisonous. This sophistication may be detected, by adding to the wine a solution of hydro-sulphuret of potass, which produces a black precipitate if lead be present. Chalk or carbonate of lime is more frequently employed than lead, and is not injurious in small quantities.

ADULTERATIONS OF BREAD.

Potatoes are sometimes employed by bakers to mix with the flour, in order to increase their profit. In such cases 14 pounds of potatoes to a sack, or 280 pounds of flour, are said to be the proportions employed. As potatoes contain much less nutriment than flour, in proportion to their weight, and as they are apt to disagree with persons of weak digestion, the practice ought to be considered in no other light than an imposition on the public. Alum is also frequently used for the adulteration of bread. The addition of alum to bread improves its appearance, rendering it white and firm, so that it is less apt to crumble when cut with a knife. The smallest quantity of alum that can be employed to produce this effect is from three to four ounces, to a sack of flour, weighing 280 pounds. This small quantity of alum in the bread cannot, to any material extent, be hurtful to the constitution, for a quartern loaf, weighing four pounds, will only contain about eighteen or twenty grains of this salt. When, however, eight or ten times this quantity is employed, for the purpose of whitening bread made from damaged or inferior flour, it must prove very injurious, and increase the naturally astringent effects of loaf bread. The adulteration may be detected in the following way. Take two or three ounces of the suspected bread, and rub it carefully in a mortar with six or eight ounces of cold distilled water, then filter through paper. Add to the resulting liquid a solution of muriate of barytes; if a copious precipitate ensue, which is insoluble in nitric acid, the presence of alum may be considered as nearly certain. But this may be further confirmed by adding to another portion of the liquid a solution of subcarbonate of potass, which throws down from alum a flocculent precipitate.

PHYSIOLOGICAL CHEMISTRY.

(By Mr. PRATER, Lancet.)

Although Liebig has investigated the phenomena of fermentation and putrefaction after a most masterly manner, I think it may reasonably be affirmed that he has attempted to generalise too much on the subject; or, rather, that he has not succeeded in his admirable attempt. That fermentation is (as he says) produced by decomposing matter communicating the same sort of action (somewhat after the manner of contagion) to a solution of organic matter, otherwise not disposed to change, seems in his work pretty clearly established, and may be considered to be his own important discovery on the subject. But I propose in this essay to render it clear that his attempt to refer the peculiar action of decomposition, &c., to a more general principle, is unsuccessful. The only instances he seems to have given are the following, and these are rather to be looked upon as *exceptions* to the general law, that affinity in action *cannot* communicate such action to all substances that happen to be present. I say they should rather be considered as exceptions to the general law of inorganic matter, because they are so few, fewer even than Liebig supposed. The facts on which he founds his opinion are the following:—

1st. Metallic copper is not soluble in heated dilute sulphuric acid, while an alloy of copper, zinc, and nickel dissolve easily.

2nd. Platinum alone, even in minutest state of division, is not soluble in nitric acid, while an alloy of platinum and silver is so.—(Chimie Organ., p. 225, French translation.)

3rd. According to Khulman, no nitric acid is formed when spongy platinum is heated in a mixture of pure azote and oxygen, but only when heated in a mixture of cyanogen and oxygen in excess, or (p. 270.) (a less satisfactory example) hydrogen and oxygen and azote.*—(Opus. cit., p. 282, 3.)

I have put these three so-called facts together although they are placed in different parts of Liebig's work, because they appear the only ones which can be referred to the same principle, and also to a principle, if established, which is similar to that causing fermentation and putrefaction. As to the decomposition of the chloride of azote, by touching it; also that of peroxide of hydrogen, by the *contact* of different substances; contact or agitation immediately causing crystalisation from a saturated saline solution, &c. &c.; all these phenomena seem to have little or no relation either to the three so-called facts above stated, or to the phenomena of fermentation or putrefaction; for Liebig himself distinctly says, it is not by the mere contact of the ferment that fermentation is produced, but in consequence of that ferment itself being in a state of active decomposition. Besides, if mere contact, or any kind of agitation (similar to that causing crystalisation in a saturated saline solution,) were the cause of the spreading of fermentation, fermentation ought to be produced by such mechanical actions; but no doubt it is not. Ingenious, therefore, as is this attempt to generalize, it is pretty clear that the first three so-called facts, or the phenomena of fermentation or putrefaction, cannot be referred to the effect of mere agitation of particles, as in saturated saline solutions, &c. Let us, then, content ourselves with examining the three assertions in question, for if they are clearly made out, there will only be a shadow of reason to attribute fermentation to the same cause; and if they are unfounded, we must be content to consider fermentation, in the present state of our knowledge, as an ultimate fact, peculiar to organic matter, and in all probability peculiar to such matter in consequence, chiefly, of its facility of decomposition.

On subjecting brass wire to the action of boiling dilute sulphuric acid, in order to see if the zinc would communicate its solubility to the copper (according to Liebig's theory,) I found sufficient copper was dissolved to be turned blue by ammonia. As I thought it probable that copper filings (in a fine state of division) were really soluble in heated dilute sulphuric acid,* I subjected them to such experiment, and found them to dissolve in sufficient quantity to colour the solution, and to be rendered blue by ammonia; the part undissolved was, in a great measure, converted to the black oxide.

The experiments just related were made in reference to Liebig's assertion (1.) in regard to an alloy of copper, zinc, and nickel. But as we see that copper, in a fine state of division, is soluble in dilute sulphuric acid, of course solubility is not communicated to it by the zinc; indeed, the brass wire, though very fine, seemed only to a slight degree soluble in dilute sulphuric acid, and not so soluble as the copper filings.

In relation to experiment (2.) the *finest* platinum filings were put in nitric acid, in order to see if platinum itself was not, in some degree, soluble: but there was neither when the filings were boiled by themselves in nitric acid, nor in contact with silver filings, any appearance of solution, though these latter dissolved, of course, rapidly; nor when a platinum wire, *of the 1-500th of an inch in thickness only*, was put in the acid in contact with silver, was it in the slightest degree dissolved or even discoloured. But the reader, by referring to the note on fusion, at the end of this essay, will observe, that admitting the fact of the solubility of the platinum in nitric acid, when fused with silver (for Berzelius says the same,) I think such fact explicable on other views than those adopted by Liebig.

I have not repeated (3) Kuhlman's experiment in reference to the formation of nitric acid. But, granting the truth of his assertion, I do not think that this sole example is sufficient for Liebig's purpose, because the gases here made use of are those of which *organic* matter (animal) is in great part composed. We should hence expect some degree of such property in cyanogen, which seems to be considered a radical of animal matter, and at the same time contains combustible matter.

Cyanogen (like carbonic oxide) is inflammable; the carbon in the one case communicating its combustible property to the azote, and in the other to the oxygen; that is to say, when the oxygen is in small quantity: for when it exists to the same amount as in *carbonic acid*, we find the combustible quality destroyed. Now, on our views of this subject, *combustible* and organic matters should possess this property of communicating action.†

We say combustible and organic matters, because although organic matters are, for the most part, combustible in the dead (and dry) state, they are not so in the living; and because sulphur, phosphorus, and some other

* Again, pp. 112-13, the volatilisation of a *solution* of boracic acid, or muriate of soda, at a very low temperature, while the two *in substance* are perfectly fixed, even at a full red heat, is grouped by Liebig among the same phenomena, the solids continuing the action which the water begins. But this is a case of evaporation, instead of solution or oxidation, and has little or no analogy to an action continuing through the same fluid. The salts are probably rather *drawn up or forced up*, by the ascending current, as it were, than actually *of themselves* continuing the action. This consideration seems sufficient to put them into a distinct class; but we must not forget that Mr. Faraday says such evaporation is confined

* Most chemical authors seem to admit this; but if the alloy of copper, zinc, and nickel is soluble in weaker dilute sulphuric acid than copper is, Liebig had grounds for adducing this as an example of his theory: but that the theory *altogether* is erroneous, is shown, I think, in the note on fusion at the end of this essay.

† However, I do not know whether even these cases of communicated action are not better referred to the principle of compound matter, being, as it were, a *new substance* with new properties, as the reader will see more fully developed under the note "on fusion;" the ideas contained in which are the result of further reflection on this subject

matters (as the metals,) are combustible, without, as far as we can judge, being susceptible of vitalisation (if we may so speak) being, as we may conceive, too combustible for supporting the vital processes, these requiring only the "slow combustion," as Liebig calls it; at the same time, even animal combinations are, perhaps, *necessarily* of combustible elements.

In the foregoing remarks I have not alluded to the fact that hydrogen may be substituted for the carbon, because it is obvious that hydrogen is a substance of combustible nature and an organic element, and hence, of course, should, according to our views, be a fit substitute. But in this case there is also another reason, and one which makes this example not at all to Liebig's purpose, viz., that water is *indispensable* to the formation of nitric acid; and water is formed when ammonia, or hydrogen and nitrogen, are burnt in contact with a sufficient quantity of oxygen.—(Liebig, p. 284.) Liebig, in this part of his work, then accounts for the formation of nitric acid on other grounds, and is somewhat inconsistent with his statement at p. 270. Nevertheless, as he seems in some degree aware he could not properly bring this example under the same head as cyanogen and oxygen, we see how few solid examples he has been able to urge in favour of his theory; yet, if a general principle, he ought surely to have found numerous other examples.

But to return to our point. One thing is certain, that even if Liebig can bring forward one instance in favour of the property in question extending to matter that is not combustible, yet there seem to be a hundred examples where the precisely opposite case obtains, as in all the *electro-chemical combinations*. In all those cases the most oxidable metal has its affinity for oxygen increased, to the exclusion of the less oxidable one. In the well-known case of copper, zinc, and sea-water, the copper, which would otherwise have been oxidated, is prevented from oxidation by the contact of the zinc; that being, at the same time, oxidated more rapidly, the copper transferring (as it were) its property of oxidation to the zinc. And here we may observe, that all these electro-chemical combinations show that *contact* has often a wonderful action in modifying or altering affinity, acting in many cases, doubtless, and perhaps in all, by disturbing electrical relations. But however to be explained, the fact is obvious; and Berzelius, in pointing it out, and extending it to some other cases, such as the effect of dilute sulphuric acid on a solution of starch at a certain temperature, chlorid azote (mechanical contact,) &c. &c., seems to have rendered a service to science: not that I would assert that he has grouped only cases under this head that properly belong to it; on the contrary, I think Liebig's observations necessarily oblige us to refer *some* of these cases to another and a different principle, viz., that a body undergoing decomposition tends to communicate the same property to the matter in contact with it, if, we may add, that matter be organic. Thus, to this latter principle should be attributed the acts of fermentation, Liebig having clearly shown that in this case the mere contact of the ferment is not sufficient, unless that ferment be in a state of decomposition. Thus the ferment, being heated at a low *heat* in a close vessel, ceases to disengage gas, and, at the same time, to excite fermentation; but on being left in contact with the air some hours, it acquires the property anew, and, at the same time, disengages from its own mass carbonic acid.—(Op. cit., p. 957.)

This experiment clearly shows that *contact* and Liebig has, consequently, established his principle as regards the important action of fermentation. But here I conceive we may fairly stop, and say that all his attempts to include other phenomena, excepting contagion, and putrefaction, and combustion, under the same head, entirely fail.

(To be continued.)

ETHNOLOGICAL SOCIETY, Feb. 28.

The Secretary reported that, since the last meeting, there had been an accession to the list of members of 22, which included, among other distinguished persons, Dr. Knox, of Edinburgh, and Professor Clarke, of Cambridge. He then read part the first of a paper from his own pen, entitled, "Contributions towards a History of the Esquimaux." It appears this arctic race is spread over the whole of the northern coast, and of North America, down to Prince Williams' Sound. On the Pacific, including the Island of St. Lawrence; and to the coast of Labrador on the Atlantic, as well as along the opposite coast of Greenland, a computed distance of 5,400 miles, exclusive of the various indentations of the land. Throughout this vast country the same physical characters, language, and dress, is found. Dr. Prichard, in his "History of Man," has fallen into grievous error regarding this nation of fishermen, by trusting to compilations, instead of consulting the original authorities. By this means, he has figured a skull as typical of the race, which is falsified by the collections of Esquimaux crania existing in this country, to the number of fourteen. He has mistaken the summer for the winter dress, and placed the stature of the nation too low by upwards of six inches—no trifling error in their physical history. Even the little, therefore, that has been done in this infant, but, particularly to medical men, most interesting science, is in a very crude state.

RECOMMENDED BY THE FACULTY.

PATRONISED BY THE ROYAL FAMILY AND NOBILITY, THE ANTIGROPELOS.

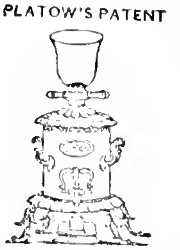
THOMAS WARNE, Patentee of the "ANTI-Gropelos," begs leave to solicit the attention of Noblemen and Gentlemen to his unrivalled Invention by the use of which they are enabled to walk or ride in the dirtiest weather, without soiling either their boots or trousers.

They are put on and taken off without trouble, worn without the slightest inconvenience, and cleaned in a minute with a wet sponge, while the elegance of their appearance renders them an ornamental appendage to the out door costume.

The lightness and elegance of this Invention (which is finished in a variety of ways), and the easy accomplishment of the object sought, can only be appreciated by trial or inspection, at the establishment of the Patentee, T. WARNE, 9, HENRIETTA STREET, COVENT GARDEN, and 165, NEW BOND STREET.

CAUTION.—As attempts are made by unprincipled parties to impose articles of an inferior and spurious quality on the public, E. W. thinks it necessary to request all persons to be particular in giving their orders at the correct address. Gentlemen will be waited upon by communicating to the Patentee, 9, Henrietta street, Covent-garden, and 165, New Bond street.

PLATOW'S PATENT



AUTOMATON COFFEE URN

PLATOW'S PATENT AUTOMATON COFFEE URN is now universally admitted to be the only instrument which fulfils all the conditions required for making the best Coffee By a train of simple natural processes that give no trouble, the Coffee is scientifically and delicately prepared in a separate vessel protected from too fierce a heat, and is then instantaneously filtered beautifully clear, and fit for use without the slightest loss of heat or flavor.

Sold in Tin, Japan, Bronze, &c., by all respectable Ironmongers, and by the Patentee, 55, High Holborn.

CHALLENGE.—In consequence of a party having recently advertised, he had the authority to publish the names of several gentlemen, moving in a superior station of life, afflicted with hernia, that it was their opinion no person could be supplied with a proper Truss unless from the party referred to; Messrs. F. HUGHES & Co. deem it a duty to disabuse the public from such unwarrantable and unjust assertions. Does this party assert that he can or has supplied all applicants to him with proper Trusses?—Will he send a dozen of his patent Trusses to any public hospital to be placed in competition with a like number made by F. H. and Co.?—MANUFACTORY, 217, HIGH HOLBORN; ESTABLISHED 1785; Inventors and Patentees of the SURGEONS' TRUSS for perpetual wear, Day and Night for Riding, Walking or Swimming, as nothing can injure it; also the DOUBLE ACTION SPRING TRUSS, and the TRAVELLING ditto. Ladies Surgical Stays, Steel Collars, Paramient Belts, and Gent's Elastic Hunting ditto. Improved Crutches, Monitors, Arm Slings, Dumb Bells, Elastic Stockings, Knee Caps, Steel and India Rubber, and every variety of Surgical Bandages and Suspenders of the best construction. Inventors and Patentees of the ROYAL ALBERT ELASTIC FRAME CRAVAT approved by the profession, and worn by all who study health, appearance, comfort, or economy, warranted to last for years.

N.B. An experienced female to attend on ladies, and all instruments examined by a qualified Medical Practitioner

---

Now ready, the Second Monthly Part, price 1s. 4d. of

THE ILLUSTRATED

POLYTECHNIC REVIEW, a Record of Science, the Fine Arts, and Literature, containing upwards of FIFTY ENGRAVINGS illustrative of various branches of Science, Literature, and Biography; and Two Hundred and Sixteen closely printed 4to. columns of new facts in Science; the Fine Arts; with Reviews of, and choice Extracts from New Books; Scientific Meetings, Music, Theatricals, Correspondence, and Varieties.

PART I. price 1s. 4d. contains upwards of FORTY ILLUSTRATIONS.

This Periodical is devoted to the following subjects:—

SCIENCE, including ARTS and MANUFACTURES, with Diagrams.

The FINE ARTS, viz. PAINTING, SCULPTURE and ARCHITECTURE, with suitable illustrations.

LITERATURE, in which Department will be included Reviews and Illustrations of New Works of interest.

AGRICULTURE, MUSIC, and the DRAMA, RECORDS of SCIENTIFIC PROGRESS.

Subscription for Stamped Edition (sent free by post), £1 1s. 8d. Yearly; 10s. 10d. Half-yearly; 5s. 6d. Quarterly; to be paid in advance.

London: Published by John Limbird, 143, Strand Sold by all Booksellers and News Agents throughout the United Kingdom.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, beg to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

DEPARTMENT OF MEDICAL STATISTICS.

William Farr, Esq., General Register Office

ACTUARY.

F. G. P. Neison, Esq.

This Office is provided with very accurately constructed Tables, by which it can Assure UNSOUND Lives on Equitable Terms. The Extra Premium discontinued on restoration of the Assured to permanent health. A portion of the extra premium may remain as a Debt on the Policy. Survivorship Assurances where the life in expectation suffers from disease, effected at cheaper rates than at any other office. Similar tables enable the Society to grant Increased Annuities on Unsound Lives, the amount varying with the particular disease. Members of Consumptive Families assured at Equitable Rates. Healthy lives are Assured on lower terms than at most other Offices. Application for Agencies to be made to the Actuary.

JEREMIE'S

SEDATIVE SOLUTION OF OPIUM,

First prepared at Patna, in Bengal.

THE great merit of this Preparation is its peculiar freedom from the noxious properties of Opium, and has, therefore, been found available in cases where other forms have been inadmissible, from its not disturbing the nervous system. The rest procured through its instrumentality is divested of the heaviness and stupor usually the effect of Opium, and the patient, though taking it continuously, is left in free possession of his faculties. It has for several years been supplied to the H. C. Dispensary, by order of the Medical Board of Bengal, from its being found to meet Cholera in India beyond any remedy that had been applied to that fatal disease. Captain Jeremie, from whose formula it is prepared, is well known to scientific persons as the talented improver of the Patna Opium. It will be found not to constipate the bowels, and to keep any time in any climate. It is exceedingly powerful in Cough, especially Consumptive Cough, wherein many have found it a great blessing, in Influenza, Gout, Tic Douloureux, Cholera, and Bowel Complaints, Rheumatism, and Cancers, in Accouchement, and all cases where Opium may be desirable. The exceedingly innoxious properties of the preparation have been proved by infants of a few weeks old having taken it without any cerebral disturbance. The testimonials of many talented Gentlemen of the Profession are on the envelopes of the bottles, a few only of the names are given here of those who have approved, viz.—

Medical Board of Bengal.
Sir Philip Crampton.
Sir David Dixon, Physician to the Royal Naval Hospital, Plymouth
Dr. Cookworthy, Physician to Plymouth Dispensary.
Dr. Watson, Physician to Middlesex Hospital, London.
J. G. Perry, Surgeon, Foundling Hospital, London.
Dr. Rae, Royal Hospital, Chatham.
J. R. Martin, Esq., (late of Calcutta,) Grosvenor-street, London.
Dr. Jackson, late Apothecary-General, Bengal.
Dr. Graves, Meath Hospital, Dublin.
Dr. Hannay, Professor of Physic, Glasgow, and Physician to the Royal Infirmary.
Dr. Yonge, Dr. Hingston, } South Devon Hospital.

Prepared only by Francis Lean, 27, George-street, Plymouth, whose signature is WRITTEN in red ink, on the pound and half-pound bottles put up for dispensing, as well as on the envelopes of the bottles sold at 2s. 9d., 4s. 6d., and 11s. accompanied by the stamp of Barclay and Sons, Farringdon-street, London, Wholesale Agents. Agents abroad,—Scott, Thompson, and Co., Calcutta, Bianey and Co. Madras, Treacher and Co., Bombay; Menzies and Co., Jamaica, W. Blake, Montreal, for the Canadas. Sold also by all respectable Druggists.

MR. E. E. BARRON, Demonstrator of Anatomy, continues to give COURSES OF PRIVATE MEDICAL TUITION, adapted to Students preparing for Examination at the College of Surgeons, Apothecaries' Hall, University of London, Army, Navy, and India Boards, College of Physicians, and Universities of Scotland,—at his Residence, and Class Room, 16, St. Thomas's Street East, Borough.

The CLASSICAL INSTRUCTIONS, by Mr. T. SLIPPER.

JOHN KING, Actuary.

BRIGHT'S NUTRITIOUS FARINA.—This new VEGETABLE Preparation is strongly recommended by the highest medical testimony, and by ROYAL and NOBLE patronage as the best DIET for INVALIDS, INFANTS and persons of impaired digestive powers. No article ever yet offered to the public contains the same amount of nourishment, is so economical, so easily prepared, or so peculiarly adapted to the delicate and dyspeptic. Sold in canisters by every respectable druggist; where also may be obtained,

BRIGHT'S UNIVERSAL SANATIVE BREAKFAST BEVERAGE,

held in the highest esteem for its refreshing and invigorating qualities. Either are prepared in two minutes, and require no boiling.

Sold in canisters,—the Farina at 1s. 6s., 3s., and 6s. each; the Breakfast Beverage at 1s. 2d., and 4s. each. Manufactory, 5, Holland-street, North Brixton. Wholesale—of Messrs. Barclays, Farringdon-street; Sanger, 150, Oxford-street, White, 24, and Johnston, 64, Cornhill, Messrs. Hill and Co., Red House, Bishopsgate, street, Messrs. Raimes and Co., Edinburgh; Newsom and Son, Cork, Anderson, Calcutta; White, Monk Bar, York; at the Western Depot, corner of Church-street, Frith-street, Soho; and retail of every respectable druggist in the kingdom.

For the use of Charitable Individuals and District Visiting Societies, both articles are put up in small packets—the Farina at 1s. 6d. and the Breakfast Beverage at 2s. per dozen.

N.B. A specimen packet of either, with testimonials, &c. will be forwarded (post free) to any address on an order, enclosing six Post-office stamps (post free) to the Manufactory, 5, Holland-street, North-Brixton.

None is genuine unless signed by the Proprietor, JOHN BRIGHT.

ROYAL COLLEGE OF SURGEONS' AND APOTHECARIES' HALL.

DR. STEGGALL continues his Lectures and Examinations for the College and Hall, and all other Medical Boards. Dr. S. has removed from No. 17, Bloomsbury-square, and his Lecture and Class Room will be in future at his private residence No. 2, Southampton-street, Bloomsbury-square.

ELEGANTIA, EXCELLENTIA, et ŒCONOMIA.

JUNERT'S FRENCH MATERIAL.—First-rate Workmen, Scrupulous Attention,—and Prices little more than half usually charged for articles of SAME quality.—Wellington Boots, 27s.—Grooms' Top Boots, 36s.

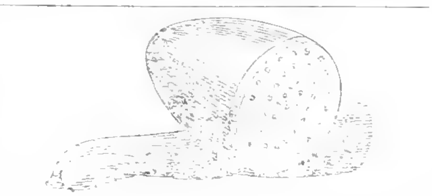
IMPORTANT TO THE PROFESSION!

A new and peculiar invention, noiseless in the Sick Chamber, elastic and elegant for the Promenade, durable, equalising the pressure of the foot, and immensely comfortable.

JAMES MEDWIN, 118, REGENT STREET.

BATH CHAIRS.—IMPORTANT TO INVALIDS.—A large assortment of BATH and BRIGHTON WHEEL CHAIRS for Sale or Hire, some with Patent Reclining Backs for spinal complaints, enabling an invalid to lie at full length, at G. MINTER'S, 33, Gerrard Street, Soho. Also MINTER'S PATENT SELF-ACTING RECLINING CHAIRS, for the Sick-Chamber or the Indulgent, and MINTER'S PATENT IMPROVED RISING COUCH or BED, which for variety of positions, and the ease it affords, ought to be inspected by every Invalid in the Kingdom, 33, Gerrard Street, Soho.

DIGESTIVE BROWN BREAD.—JAMES TURNER begs to inform the nobility and gentry, that his days of Delivery at the West End are Monday, Wednesday, Friday, and Saturday. Turner's Digestive Brown Bread is strongly recommended by the faculty for its nutritious qualities. The purity of the meal from which it is manufactured, and the improved method of making it into bread, render it the easiest of digestion and the most nutritious bread in use. Turner's Superior Household Bread, Fancy Biscuits, Cakes, &c. Preslonger Wine Biscuits, in tins at 2s. each. Families supplied within five miles of the Royal Exchange. Orders, post-paid to James Turner, Family Bread and Biscuit Baker, 67, Bishopsgate-street, within, and 4, Queen's-row, Dalston, will receive prompt attention.



GEORGE HARRIS Writer & Labeller to the Medical Profession, 15, Little Queen Street, Holborn.—G. H. most respectfully returns his thanks to the Medical Profession, and Chemists and Druggists generally, for the very liberal support he has received as a Labeller and Writer for 20 years and begs leave to observe, that he now undertakes to fit up Shops and Surgeries in any style of elegance or neatness, and to any price; and trusts, from the great experience he has had with the late Mr. Willats, Mr. Bruce, and for the last 10 years with the highly respectable firm of Ansell and Hawke, 8, Great Queen Street, Lincoln's-inn-fields, that he will be enabled to give satisfaction.

Stoppered rounds, 1s. per lb.; mahogany fronted drawers, 1s. 11d. each; labelling in the very best style, 3s. 6d. per dozen. Every article warranted.

INTERESTING INFORMATION for INVALIDS, Mothers, Infants, &c.—Mr. PREVITE'S PREPARED CEYLON MOSS is considered by the Faculty to be the best aliment for invalids now extant. According to the analysis by R. Battley, Esq., of London, every hundred grains of this fucus contain sixty-three parts of nutritive jelly, and three parts of iron; the latter ingredient is acknowledged by the learned profession to be one of the most invigorating chalybeats with which they are acquainted, consequently it has now become an article of great importance in the sick chamber, for it is daily recommended as the principal diet for invalids, especially for ladies in delicate health, young infants, and children, in preference to all kinds of animal food, or any other vegetable substance. See Dr. Sigmond's Treatise on Ceylon Moss, second edition, with the Analysis, by Professor Dr. W. B. O'Shaughnessy and R. Battley, Esq.

TESTIMONIALS.

From the "Medico Chirurgical Review" for January, edited by Dr. James Johnson, M.D., Physician Extraordinary to his late Majesty King William the Fourth:—

Ceylon Moss.—Mr. Previte has contrived to convert this nutritious substance into several agreeable forms, to suit the tastes and appetites of invalids. We have been trying and prescribing the jellies of late, and can speak strongly in their favour. This will prove a valuable dietetic article in the sick-room.

Sir—I can have no hesitation in speaking in the most satisfactory manner of the jelly prepared from your Ceylon Moss, for I have been in the continual habit of prescribing it as a diet for convalescents ever since I first heard of it, and I can with truth say that I know no better food in such cases.—Sir, your obedient servant,

(Signed) J. R. Martin, Presidency Surgeon.

Calcutta, December 8, 1836.

December 13, 1836.

Sir—In reply to your note, I beg leave to state that I have for many years past been in the habit of recommending the Ceylon Moss, as prepared by you, to all my convalescent patients; and a great majority of them have preferred it to any other, either vegetable or animal jelly.

(Signed) S. Nicholson, Surgeon, General Hospital.

To Mr. Previte.

I have used the Ceylon Moss frequently as an article of nourishment for invalids and children, and find it answer every purpose of arrow-root or sago; and in most cases to be much more agreeable to the habits of a sick person than the other descriptions of farinaceous food generally in use. (Signed) A. R. Jackson, M.D., Surgeon Officiating Apothecary, H.C.S.

H. C. Dispensary, Dec. 13, 1836.

I have much pleasure in giving testimony in behalf of Mr. Previte's Ceylon Moss. It is an admirable article of food, peculiarly well adapted to the delicate stomach of an invalid, light and easy of digestion, it is at the same time very nutritious, far superior indeed to anything of the kind I ever met with. I have employed it extensively, and can recommend it with confidence.

(Signed) W. H. Goodeve, M.D.

Professor of Anatomy and Medicine, Medical College.

Calcutta, December 15, 1836.

Fort William, December 13, 1836.

Dear Sir—I have examined and tried the Ceylon Moss, and am of opinion that it is a valuable article of sick diet; the more so in cases where animal jelly cannot be obtained without delay, and when it is not so fitting for a weak state of the stomach as that of the Ceylon Moss.—Very truly yours,

(Signed) Frederick Corbyn, Garrison Surgeon.

To Mr. Previte.

Calcutta, December 13, 1836

Sir—In reply to your note, in which you request my opinion upon your Ceylon Moss, I can merely repeat what I said in my capacity as editor of the "Indian Journal of Medical Science," viz.—that I have tried it myself, and found it unequalled as a light and nourishing food for the sick. I beg to apologise for not having sent this reply earlier.—I remain, Sir, yours obediently,

(Signed) J. T. Pearson, M.D., H. C. Service.

To Mr. Previte.

I hereby certify that I have made extensive trials of the Ceylon Moss, introduced into notice by Mr. Previte, and I have also subjected it to chemical analysis. For details as to its chemical properties, I may refer to my paper on the subject in the "India Journal of Medical Science." I need only repeat here that I consider it an excellent article of diet for invalids. It is very nutritive, easy of digestion, and free from any disagreeable or prejudicial qualities.

(Signed) W. B. O'Shaughnessy, Professor of Chemistry, Medical College, Calcutta.

December 10, 1830.

I have had many opportunities of recommending the Ceylon Moss, as prepared by Mr. Previte, in cases of extreme debility, and in early convalescence after fever, dysentry, and other complaints, where none other than the most delicate nourishment could be administered, and I can confidently bear testimony to its value as a light and grateful article of food under such circumstances.

(Signed) Walter Raleigh, Surgeon.

Calcutta, General Hospital, December 8, 1836.

(These certificates are taken from a paper furnished by me in 1837, and published in the "Transactions of the Royal Medico-Botanical Society." Vol. I., Part 4, p. 181.)

From the India Journal of Medical & Physical Science.

"We have seen a letter from an invalid whom we sent home in March last, when he had been so reduced by hepatic and dysenteric affections as to require great caution in his diet, stating that he found the Ceylon Moss, prepared by Mr. Previte, of essential service not only as a luxury, but as a means of restoring his debilitated constitution to health. To conceal such intelligence as this would, we conceive, be to neglect the duty we owe to the public. We should here mention that the public are indebted to Mr. Previte for bringing the value of Ceylon Moss to notice."

As a proof of the high estimation in which the Ceylon Moss is now held, in this country and in France, it is admitted into all the principal hospitals. For ship-board this Moss will be found invaluable, also for all culinary purposes, where isinglass, &c., is used, being far superior to them in strength, and at one-third the price, with the advantage of its not dissolving during the hottest weather. Prepared only by Mr. Previte, and sold wholesale at his depot, Messrs. Stephenson and Mayer's, Maiden-lane, Battle-bridge, London, and to be had retail at Messrs. Savory and Moore's, New Bond-street and Regent-street, Fortnum and Mason's, 182, Piccadilly; H. W. Beaufoy's, 11, Little Stanhope-street, May-fair, and at all the most respectable chymists and Italian warehousemen throughout the kingdom. Sold in Packets only, at 2s. and 1s. each.

N.B. Every Packet is signed and sealed "J. PREVITE," without which signature the Moss cannot be genuine.

WRIGHT'S PATENT DRAG.—The use of a drag to carriages being admitted, parties wishing for safety and relief to their horses have now an opportunity of having one on the most improved principle, such as has never been offered to the public before—the carriage being skidded or released at pleasure by the person driving without leaving his seat or stopping the vehicle.

All who are in the habit of driving must see the great benefit obtained of unskidding the wheel before reaching the bottom of a hill, so that if another is to be ascended the velocity shall not be impeded, which before is saved and the horses relieved from the drag, as well as the danger avoided in backing the carriage, which must be done under any other system to relieve the skid.

An obvious saving is also effected, the great wear under all former plans being, when the skid is not required yet cannot be released.

Wright's Patent Drag has now been in use for the last two years, being fixed to the Rocket Ventnor Coach, travelling daily on one of the most hilly roads in the Isle of Wight, the journey from Ryde to Ventnor, thirteen miles, being performed in less time by half an hour than by the former mode of skidding, with much greater ease to the horses, and to the satisfaction of the proprietors as shown by their testimonial.

It can be applied without regard to the pace in case of accident, and may be accomplished by a child ten years of age.

Parties may be supplied with the apparatus complete, on applying at the Office of the Proprietor, No. 22, Church St., Soho, London.

To the Proprietor of Wright's Patent Drag.

Royal Pier Hotel, Ryde, July 25th, 1842.

Sir,—Having had your drag in use on the Rocket Coach, running daily from Newport to this place and Ventnor and back, over one of the most hilly roads in the Isle of Wight, during the last two seasons, we express our satisfaction in its usefulness, affording a great relief to the horses, and a saving of time full half an hour between Ryde and Ventnor, a distance of thirteen miles, and feel assured your drag when known will be generally adopted.

We are, Sir,

GEORGE RENDALL,
WILLIAM LAMBERT, Coachman, } Proprietors.
JOHN WHITTINGTON, Coach Builder

All letters prepaid.

William Bevan, Esq., Old Jewry.

BANKERS.
Messrs. Drewett and Fowler, Princes Street, Bank.

This Institution is empowered by a special Act of Parliament, and is so constituted as to afford the benefits of Life Assurance in their fullest extent to Policy-holders, and to present greater facilities and accommodation than are usually offered by other Companies. The decided superiority of its plan, and its claim to public preference and support, have been proved incontestably, by its extraordinary and unprecedented success.

Assurances may either be effected by Parties on their own Lives, or by Parties interested therein on the Lives of others.

The effect of an Assurance on a person's own life is to create at once a Property in Reversion, which can by no other means be realized. Take, for instance, the case of a person at the age of Thirty, who by the payment of £5 3s. 4d. to the Britannia Life Assurance Company, can become at once possessed of a bequeathable property, amounting to £1000, subject only to the condition of his continuing the same payment quarterly during the remainder of his life,—a condition which may be fulfilled by the mere saving of EIGHT SHILLINGS weekly in his expenditure. Thus, by the exertion of a very slight degree of economy, such, indeed, as can scarcely be felt as an inconvenience, he may at once realize a capital of £1000, which he can bequeath or dispose of in any way he may think proper.

A Board of Directors in attendance daily at 2 o'clock.

Detailed Prospectuses, and every requisite information as to the mode of effecting Assurances, may be obtained at the Office.

Peter Morrison, Resident Director.

SILVER SUPERSEDED, and those corrosive and injurious metals, called Nickel and German Silver, supplanted by the introduction of a new, and perfectly matchless ALBATA PLATE. C. WATSON, (late Alderman,) 41 and 42, Barbican, and 16, Norton Folgate, aided by a person of Science in the amalgamation of Metals, has succeeded in bringing to public notice the most beautiful Article ever yet offered; possessing all the richness of Silver in appearance—with all its durability and hardness—with its perfect sweetness and use—undergoing, as it does, a Chemical Process, by which all that is nauseous in mixed Metals is entirely extracted—resisting all Acids—may be cleaned as Silver, and is Manufactured into every Article for the Table and Sideboard.

Table Spoons and Forks	per doz.	16	6
Dessert Ditto	ditto	12	0
Soup Ladles		6	0
Sauce Ladles		1	0
Tea Spoons	per doz.		
Gravy Spoons		3	0

C. WATSON begs the Public will understand, that this Metal is peculiarly his own, and that Silver is not more different from Gold, than his Metal is from all others: the Public will, therefore, have no difficulty in discovering the animus which directs the virulent attacks made against him by a party who is daily suffering from the unparalleled success which has marked the progress of his New Plate since its introduction. C. W., unlike this party, courts comparison, feeling confident that the result will establish its pre-eminence. Entire Services of Plate Purchased. 41 & 42, Barbican, and at 16, Norton Folgate.

PAPER TEA TRAYS, 42s.—a full-sized set of three, Gothic Pattern, and an infinite variety of others, up to 10 guineas a set; set of three convex japan trays, 10s.; very best London made tea urns, in every variety, from 33s. to 105s.; a dozen ivory knives, 11s.; a dozen dessert ditto, 10s. 6d.; carvers, 1s. 6d. per pair; fenders from 6s. to 63s.; fire irons, from 2s. 3d. to 25s.; American ovens, to bake before the fire, 4s.; copper kettle, 5s. 6d.; copper coal scoop, 11s. 6d. iron saucepans, enamel inside, 1s. 6d. upwards; and every article in furnishing ironmongery unusually low. Quality is here the primary consideration, hence its uninterrupted success for 50 years, and its present celebrity as one of the best and most extensive furnishing Warehouses in London.

Now ready, illustrated with 100 engravings, price 5s. cloth.

LECTURES ON ELECTRICITY: being an Elementary Course of Instruction, written in a familiar style, and divested of technicality, upon this interesting and delightful branch of science. From its practical character, this is the only work on the subject in the English language adapted for tuition, and calculated to become a class book. By WILLIAM STURGEON, Lecturer to the Victoria Gallery of Science, Manchester, Editor of the "Annals of Electricity," &c.

Similar volumes upon Galvanism, Magnetism, and Electro-Magnetism, will speedily follow.

London: SHERWOOD, GILBERT, & PIPER, Paternoster Row.

Just Published.

VIEWS upon the STATICS of the HUMAN CHEST, Animal Heat, and Determinations of Blood to the Head, &c., with an Appendix, examining certain Views of Professor Liebig. By JULIUS JEFFREYS, F.R.S., formerly in the Indian Medical Staff, Staff-Surgeon of Cawnpore, &c.

Longman and Co., Paternoster-row; S. Highley, Fleet-street; J. Churchill, Princes-street, Soho.

MACINTOSHES SUPERSEDED.

Important to the Medical Profession, and, indeed to all classes exposed to the vicissitudes of the weather.

ENGRAVING AND PRINTING

OF EVERY DESCRIPTION.

A PEN HARD OR SOFT AT PLEASURE.

IN no department of commerce has there been a greater want of improvement than in procuring a substitute for the Quill, which, from its so frequently requiring mending, and its unevenness in writing, occupied much time, and destroyed that beautiful appearance in books or correspondence so much admired. Innumerable have been the forms of Steel Pens to give elasticity and freedom, but many have proved utterly useless, and others have possessed some complicated difficulty to retard their being generally useful; but T. K. CLAY, the Inventor of the Patent Graduating Spring Pen, flatters himself that he has overcome every difficulty previously felt in the use of Steel Pens, by enabling every person instantly to adjust the Pen to their own style of writing, either hard or soft, and the Pen acting on a perfectly free and elastic principle, secures the nibs always retaining their original shape and value. T. K. CLAY impresses on the public attention that every pen is carefully finished and examined previously to being issued, whereby the utmost dependence may be placed on their uniform quality, and they may be obtained of any Stationer and Bookseller throughout the Kingdom, and at the Manufactory, 90½, Holborn-hill.

N.B. In consequence of the high approval this Pen has already received, T. K. CLAY cautions the public against any imitations, Every Pen being stamped "T. K. CLAY, LONDON," with the Patent Hieroglyphic dated Oct. 12th, 1842.

A FEW VERY SELECT

MEDICAL AND SURGICAL WORKS,

OFFERED AT REDUCED PRICES BY

HENRY G. BOHN, YORK STREET, COVENT GARDEN.

GOOD'S (Dr. JOHN MASON) STUDY of MEDICINE, improved from the Author's Manuscripts, and by reference to the latest advances in Physiology, Pathology, and Practice. (published at £3s. 3s.,) extra cloth bds., £1 1s. 1840

"The 'Study of Medicine,' as edited by Mr. Cooper, is brought up to the highest standard of the present day, and as a work of reference, at once systematic and comprehensive, has NO RIVAL IN MEDICAL LITERATURE."—*Medical Gazette.*

BURNS' (Dr. JOHN) PRINCIPLES of SURGERY, containing the Doctrine and Practice relating to Inflammation and its various consequences, Tumors, Aneurisms, Wounds, and the States connected with them: the Surgical Anatomy of the Human Body, and its Application to Injuries and Operations. 2 vols., 8vo., done up in one stout vol. (published at £1 1s.) extra cloth bds., 10s. 6d. 1838

The author is Regius Professor of Surgery in the University of Glasgow, and one of the most eminent surgeons of the present day. His esteemed work on the Principles of Midwifery has already passed through nine editions.

"A very excellent and comprehensive work."—*Medico-Chirurgical Rev.*

PAXTON'S INTRODUCTION to ANATOMY, containing a concise and clear Demonstration of the Structure of the Human Body, with Directions for Cultivating the Science in the shortest and most successful manner.—*Illustrated by upwards of 300 Engravings, and a Glossary* of Scientific Terms. By JAMES PAXTON, Member of the Royal College of Surgeons, Author of the Notes and Illustrations of Paley's Natural Theology, &c. New edition. 2 vols. 8vo., done up in one stout vol. (published at £1 13s.) extra cloth bds., 10s. 6d. Oxford, 1841

COCKS' (W. P., Demonstrator of Anatomy at Guy's,) CONCISE TREATISE ON OPERATIVE SURGERY, describing the Methods adopted by the English, Continental, and American Surgeons, selected for the use of Junior Practitioners and Students. 8vo., illustrated by 12 Plates, exhibiting 64 Operations, some colored, (published at 14s.) extra cloth bds. 6s. 6d. 1841

BATEMAN and WILLAN'S DELINEATIONS of CUTANEOUS DISEASES: exhibiting the Characteristic Appearance of the Principal Genera and Species comprised in the Classification of the late Dr. Willan, with a completion of the Series of Engravings begun by that Author, 4to. containing 72 plates, beautifully and very accurately colored, under the superintendence of an Eminent Professional Gentleman, (published at £12 12s.) half bound, morocco, extra, top edges gilt, £5 5s. 1840

"Dr. Bateman's valuable work has done more to extend the knowledge of cutaneous diseases than any other that has ever appeared."—*Dr. T. A. Thompson.*

HOPE'S PRINCIPLES and ILLUSTRATIONS of MORBID ANATOMY, being a complete Series of Colored Lithographic Drawings, from Originals by the Author, with descriptions, and summary allusions to Cases, Symptoms, Treatment, &c. Designed to constitute an Appendix to Works on the Practice of Physic, and to facilitate the Study of Morbid Anatomy, in connection with Symptoms. By JOHN HOPE, M.D. F.R.S., &c., Physician to Marylebone Infirmary, &c., Author of a Treatise on the Diseases of the Heart, &c., royal 8vo., with 48 highly finished colored plates, containing 260 accurate Delineations of Cases in every known variety of Disease, (published at £5 5s.) in extra cloth, £3 3s. 1834

HOME'S (Sir EVERARD) GREAT WORK on COMPARATIVE ANATOMY, being the subject of his numerous Lectures; including Explanations and Engravings of *nearly all the Preparations in the Hunterian Collection;* to which is subjoined, Synopsis, Systematis Regni Animalis nunc primum ex Ovi Modificationibus propositi, with the Supplements and a General Index. Six vols. royal 4to., Portrait and 361 fine Plates, after drawings by Bauer and others, (published at £18 18s.,) extra cloth, bds. £6 6s. 1814-28

Or LARGE PAPER, six vols. royal 4to. (published at £27 6s.) £8 8s.

Vols. III. to VI. of either size may be had separately at the same rate.

The most valuable and important work on Comparative Anatomy published in any Country. It contains all the materials of any importance collected by the author during fifty-five years, from the age of seventeen to seventy-two, being a longer life spent in the pursuit than most men engaged in scientific investigation have enjoyed.

BELL'S (Sir CHARLES) ILLUSTRATIONS of the GREAT OPERATIONS of SURGERY, Trepan, Hernia, Amputation, Aneurism, and Lithotomy, folio, with copper-plate engravings, (published at £3 15s.) bds. £1 1s. 1821

—— the same, folio, with colored plates, (published at £5 5s.) half bound, morocco, £1 10s. 1821

HOOKER'S (Sir WILLIAM) ENLARGED EDITION of WOODVILLE'S MEDICAL BOTANY, containing Systematic Descriptions of Medicinal Plants, with a Circumstantial Account of their Effects, and of the Diseases in which they have been most successfully employed, *Illustrated by* 310 *colored plates* by SOWERBY, 5 vols. 4to., (published at £10 10s.) half bound, morocco, uncut, £5 5s.

*** The Fifth or Supplementary Volume, entirely by Sir W. J. HOOKER, with 30 colored plates, is sold separately, to complete the old editions, (published at £2 12s. 6d.,) cloth boards, £1 11s. 6d.

LIZAR'S ANATOMICAL PLATES of the HUMAN BODY, accompanied by Descriptions, and Physiological, Pathological, and Surgical Observations, new and considerably improved edition, with additional plates, and the letter-press printed in folio, royal folio, containing 101 colored plates, (published at £12 12s.) half bound russia, £5 5s. Edin. 1841

This new edition has many additional and finely engraved plates. The letter-press also is enlarged and improved, and printed in the full size instead of in 8vo. as formerly. It is now the most complete set of Anatomical Plates, of moderate compass, on sale.

"These plates are by far the best of the kind that we have ever seen. They are elaborately correct both in outline and detail, and, at the same time, beautiful specimens of engraving. Each is accompanied by a lucid and well-written description, together with many appropriate physiological and pathological observations. To those surgeons who are at a distance from the dissecting-room, they must prove invaluable, and the exceedingly cheap rate at which they are published, entitles the proprietors to the sincere thanks of the profession."—*Lancet.*

MILLINGEN'S (Dr. J. G.) CURIOSITIES of MEDICAL EXPERIENCE, (as a Companion to the 'Curiosities of Literature,' second edition, considerably enlarged, in 1 large vol. 8vo. (pub. at 16s.) gilt cloth, 8s. 1839

The great success of D'Israeli's "Curiosities of Literature," induced Dr. Millingen to add to the ample harvest of this ingenious writer these pleasant gleanings from another field. The rapid sale of the first edition (which was published at £1 8s.) attracted extensive notice.

"There is a vast quantity of very amusing matter here—a fund of anecdote—the result of a great deal of reading, and of consequence much to interest and instruct, as well as to entertain us. Books like this recommend themselves to the public."—*Literary Gazette.*

CLOQUET'S GREAT FRENCH WORK on ANATOMY.—ANATOMIE DE L'HOMME, ou Description et Figures de toutes les Parties du Corps Humain, illustrated by 310 fine plates, complete in 5 vols. folio, (published at £24,) bound in 3 vols. half morocco, top edges gilt, £12 12s. Paris, 1828

"An admirable work—the grandest and most complete on anatomy ever published."—*Paxton.*

THE LIFE and CORRESPONDENCE of Dr. JENNER (the Discoverer of Vaccination,) Physician Extraordinary to his Majesty George IV., &c. &c., with illustrations of his Doctrines, by JOHN BARON, M.D. F.R.S., &c., 2 thick vols. 8vo., with two beautiful portraits, (published at £1 4s.) reduced to 9s., in extra cloth boards.

"To medical men these volumes are very valuable, as illustrations of the history of one of the greatest discoveries in their science, and the general reader will feel the greatest interest in the biographical portion of the work. We know of very few books more pleasantly written, or more likely to be of public benefit. Too much can hardly be said in praise of Dr. Jenner's private character, and every one who will peruse the history of his life will be sure to find himself the better for having spent a few hours in such company. We wish, for the sake of the public, there were more such biographies."—*Times.*

Just published, in 1 vol., demy 8vo., bound in cloth, price £1 11s. 6d. colored.

MONOGRAPHIA ANOPLURORUM BRITANNIÆ: or, an Essay on the British Species of Parasitic Insects, belonging to the order Anoplura of Leach, with the Modern Divisions of the Genera, arranged according to the views of Leach, Nitzsch, and Burmeister, illustrated by 26 colored plates, containing upwards of 200 highly magnified Figures of all Species, by HENRY DENNY, author of "Monographia Pselaphidorum et Scydmænidarum Britanniæ," Honorary Member of the Yorkshire and Leeds Philosophical Societies, and of the Norfolk and Norwich Museum.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 49, Essex Street Strand, in the Parish of St. Clement Danes, Westminster, in the County of Middlesex.—March 11th, 1843.

// THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs.

No. 182. Vol. VII. LONDON, SATURDAY, MARCH 18, 1843. PRICE FOURPENCE. Stamped Edition

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

PENETRATING WOUNDS OF THE CHEST.

Clinical Lecture, delivered by Mr. GUTHRIE, on Saturday, March 11th, at the Westminster Hospital.

Summary.—*The law of insanity—M'Naughten—the opinions of mad doctors not to be relied on—feigned diseases—penetrating wounds of the chest—advice to duellists—case of Sir Charles Bampfylde—of Mr. Richardson—of Lord Beaumont—of Lieut. Forbes—treatment of an incised wound, penetrating the chest or abdomen—case of Mrs. Magnus—of Mr. Drummond.*

I HAVE written four books recording the practice of the surgeons of the British army during the war in Spain, Portugal, France, and the Netherlands, from the first battle of Rolica, to the last decisive conflict at Waterloo. The fifth book will complete the subject, and contain such observations as I have to make on injuries of the chest and abdomen. It is not, however, yet written. I have little time to spare that I cannot dispose of in a more profitable manner as regards myself, and there has been until now, no encouragement to print or publish, as far as respects the public.

Mr. Churchill offers to publish the book, and to expend as much upon advertisements as I shall pay for printing, &c.; this, he says, will repay me well, inasmuch as many of the reading public frequent the advertizing gentlemen. There, is, however, some danger in doing this, for the Council of the Royal College of Surgeons will visit with their high displeasure those of their body who appear most prominently in the columns of advertisements, and if an ordinary member may not appear every day, or every two days, an ex-president could not be seen, with any propriety, above once a-week: and I do not think the plan in this case would succeed. Gentlemen, when they decide upon shooting themselves, generally try the thickness of their heads, and when they think their honor has been offended, and that they ought to make a demonstration of intending to shoot somebody else, submit themselves in a very sensible manner to the guidance of a friend, who in general very wisely thinks that killing a man does not at all prove he was in the wrong, and that the retracting an error ought in most instances to be a sufficient satisfaction to the party aggrieved. Fortunately for practitioners in surgery, there are some foolish fellows left, who think it right to fight first, and apologize afterwards; but they are becoming scarcer and scarcer every day, and the only hope on which we can repose with any confidence, is derived from the accidental support of the lawyers and the mad doctors, who have not only ascertained that a man must be mad when he shoots himself, in which opinion I cordially concur, but have also discovered that when he shoots his neighbour he must be equally mad, in which I do not concur, but from which I do not dissent, on account of the opportunities, which the dissemination of such opinions will doubtless occasion, of improving your knowledge of wounds of this nature; and as the punishment for the crime of murder is now reduced to a moderately long transportation, or a comfortable confinement, with every reasonable accommodation for life, provided the culprit can shew that he ever laboured under a delusion, why should any revengeful or misguided man leave his passions ungratified, or refrain from becoming a martyr for what he may suppose to be for the good of his country? The members of the medical profession are, apparently, according to the present state or practice of the law, the arbiters of life and death in such cases, without positively knowing on what principle they arbitrate. I listened attentively the other day, at the trial of M'Naughten, and heard the Solicitor-General state at length the dicta of Lord Hale, Lord Erskine, and others, each authority laying down the law somewhat differently; but I did not understand him to point out decidedly the precise law under which the prisoner was to be tried and convicted. He seemed to me to intimate that the jury ought to be guided by the authority of Lord Hale, whilst the counsel for the prisoner intimated as strongly, I thought, that they ought to confide in that of Lord Erskine. This state of indecision is exceedingly distressing to medical witnesses, and cannot be satisfactory to a jury: whereas, if the law had been rather more clear, and had declared that a prisoner on trial was to be found guilty according to the facts, and that the extenuating circumstance of his having been occasionally insane, was allowed to be urged in his defence, as entitling him to a recommendation for mercy, which the judges might grant or not, as they thought right, and in such manner as they thought fit, or might be afterwards determined upon with reference to the proofs given of insanity, previously to the committal of the murder, the absurdity of finding such a prisoner as M'Naughten "not guilty" of murder or homicide, would rarely or never take place. If I had been a medical witness on the point of insanity, I should have, in all probability, coincided with the other medical gentlemen; but if I had been one of the jury I should have found him guilty, recommending him, however, for such a degree of mercy as would be short of hanging. I should have done this on evidence, or considerations of a professional nature, foreign to the trial, or what was adduced in court, and which inclines me to the opinion that our forefathers acted wisely in excluding medical men from juries, not because by their profession they are inured to human suffering, and might be careless of preserving life, but because they might possibly be influenced, in a similar manner, by knowing too much or too little. In my own case, I am willing to admit that it would have been the last.

Looking at the prisoner from the side of the jury-box, I was struck by the peculiar manner in which he carried his head, which was so far backwards, both while standing and sitting down, that his chin would have pointed to the cornice of any moderately high room. This is a strange, constrained position, giving a singular expression to the countenance, and is not in any way natural, but under the controul of the will, for many muscles must be kept in constant action to maintain it.

The head is only usually thus thrown back when in the erect position, for the purpose of looking at something, when the eyes are kept open in the ordinary course of things, and the upper eyelid seldom moves. The muscle which turns the eye upwards, the rectus superior, and the levator palpebræ superioris, are supplied with nervous influence by the same branch of the third pair of nerves, in order that they may always act in concert, and, during this proceeding, the involuntary motion of winking is in a great measure suspended. I observed that M'Naughten's upper eyelid did not wink in the proportion of one to three, when I compared its motions with those of the eyelids of the persons sitting near him. Its motion then was merely the involuntary action by which the eye is cleaned. I have heard, since the trial, that he usually carried his head in the same manner when under observation; and if he should continue to do so for the future, it will be a very inconvenient position involving no light degree of punishment in itself, and will prove that he is not mad upon one, but upon two points. I mention it in order that you may draw the attention of the young ladies, your friends, to this physiological fact when they go lionizing to Bethlehem. They may also observe how intellectual the eye appears when the head is brought forward, as in answering a question, and they will then come to the conclusion that he is rather a sensible, good-looking person, in spite of his double insanity.

I have no reliance whatever on the opinions of mad doctors, however eminent they may be, as to the sanity or insanity of any person, when those opinions are formed only from what they may have observed after the committal of a great crime. A man must be very ignorant and a very bad actor, who cannot deceive any number of doctors, who are sent to look at, or converse with him for an hour, from time to time, all of them being naturally anxious (from the kindness and humanity which pervade the profession at large) to find that he is insane, rather than otherwise. An utterly ignorant fellow may perhaps so grossly exaggerate the part he is desirous of playing, as to deceive no one; but this will rarely happen if the crime has been really premeditated, and due preparations have been previously made to obviate the ordinary consequences. It is not only against the feelings of a medical man, but it would be greatly against his pecuniary interests, particularly if he should be what is called a mad doctor, for there are a great many wayward philanthropic old ladies and gentlemen who would never cease abusing him if he were to declare a person sane when such a declaration would hang him, and I suspect very few will be found who would come to this decision when they can find even a shadow of doubt upon the subject.

Feigned diseases were in former days very common in the army, when its numbers were great, and the service more disagreeable than at present, and among these simulated maladies, the various kinds of insanity and of contractions, were not the least difficult of discrimination. I have seen more than one man recover his intellects in a wonderfully short space of time, after he had been discharged on the certificate of the doctors that he was incurably insane. I remember one clever fellow, who had crawled about in various places for nearly two years, with his body bent at a right angle with his legs, on whom the doctors had tried all sorts of experiments to straighten him, by stretching him up against a wall with pulleys, &c., he roaring all the while, and the perspiration pouring down his face. He danced a hornpipe at the hospital door with considerable grace and agility five minutes after his discharge had been safely deposited in his pocket, to the great mortification of the surgeons, who had certified to the incurable rigidity of the muscles of his abdomen.

I do not know whether any of you go to the French plays; if you do you will have seen Mad. Albert acting in the mad scene in "La Perle de Savoie" remarkably well, and if she were to commit a murder from motives of revenge, I strongly suspect she would beat all the doctors sent to see her, provided only that she would sometimes act below her part, and remember that monomaniacs are not insane, even on one point, every day in the week. I am aware that many persons may have had particular means of acquiring information on the subject, but this makes it the more necessary that the conviction of a murderer should in no way depend on his or her being a good or bad actor. Kindness will do much towards the cure of many who are afflicted with insanity, but it is equally well known to those who have the care of mad people, that they are frequently deterred from com-

mitting crimes through the fear of punishment, which they believe will certainly follow

I will not take up your time any longer with a subject which you will say scarcely constitutes a clinical lecture, although what is to follow, perhaps, can hardly be deemed such, at least, within the walls of this hospital. Penetrating wounds of the chest are of two kinds; one from knives, swords, spears, or sharp-cutting instruments; the other from musket or pistol balls, or other foreign bodies, which bruise or tear. The treatment of a wound made by a knife or sword, is diametrically opposite to that made by a musket ball, and the treatment of a wound made by a musket ball is usually much more simple, and requires much less aid from scientific surgery than that made by the smaller ball of a pocket or duelling pistol. A few years back I was laughed at in the newspapers, and declared to have outdone Sir Lucius O'Trigger, because I recommended that, when gentlemen were about to fight a duel, they should present a bold front, and not stand sideways, for, if in that case they were wounded in the chest, one lung only would be shot through instead of both, thus giving them a greater chance of recovery; and I further advised that the pistols should be made larger in the bore, and that more powder should be put into them, so that the ball should be sent clean through a gentleman, and not stop half way—advice, I can assure you, of the soundest nature. I do not, however, positively insist upon the ball being larger, inasmuch as the surgeon can always, and must, in most instances, enlarge the hole, and remedy the evil occasioned by a small opening; there is little humanity in not having powder enough in the pistol to send the ball quite through the person fired at, provided it hits him; on the contrary, I should deem myself guilty of murder, as much as the man who actually fired the pistol, if, knowing that thirty grains of powder would, at twelve paces, send a ball through a man, I were only to put in twenty, and let it be driven half way. I speak surgically and humanely, and always with the view of saving life.

The late Sir Charles Bamptylde, who was shot in the back about twenty years ago, by one of his servants, was an instance of the mischief following the pistol not being loaded with sufficient powder: the ball lodged inside the ribs, in front. He was a tough old gentleman, and, if the ball had gone through him, might have escaped, provided it had been bigger, or either of the holes it had made had been larger. He survived about eight or ten days, dying eventually from the oppression caused by a large quantity of fluid which had filled the right side of the chest, and had encroached by its pressure on the left. If the hole made by the bullet had been bigger, or I had enlarged the wound, this fluid would have escaped, he would have lived a day or two longer, and have then died from a different cause; but this my older colleagues would not let me do, and I did not dare to do it in those days without their consent. There is always a difficulty in carrying out a practice which has not received the stamp of antiquity or universal custom. People of condition, in this country, will discuss every branch of physic and surgery as readily and as stiffly as if they really knew something about the matter, and to their own great disadvantage; inasmuch as their medical attendants are often prevented from saying and doing what would be both proper and right to say and do; for if unsuccessful in what they did, they would run the risk of being ruined in reputation by the absurd and exaggerated stories which are told in every direction, just as the individual who tells them happens to fancy the practice to be right or wrong, and often without even knowing any one of the facts of the case. If I had thought I could have saved him by enlarging the opening, I would have done it, fight for it, but not knowing where the ball was lodged in the chest, and never having seen one spit up, although I have seen a piece of rib coughed up, and have known a man go all the way from Waterloo to Paris with part of his breeches in his belly, the operation was not done. My excellent friend and colleague, Mr. White, some years back had a very instructive case, in the person of Mr. Richardson, who was shot on Blackheath. The wound speedily healed, but the patient became worse and worse, with exceeding difficulty of breathing; until, in a violent fit of coughing, the wound re-opened and discharged two or three pints of fluid, after which, Mr. Richardson did well.

We had in this hospital in September 1840, a lad of 18, who had shot himself for love with a pistol on the left side of the chest. The little ball went in just over the eighth rib, and lodged in the lung, the pistol not containing sufficient powder to send it through. He dragged on a painful existence until the 5th of December, when he died. His life was prolonged for a short time by emptying the chest of its fluid, but the ball was loose and rolled about on the diaphragm. If it had gone through, he might have lived.

The ball, in the case of Lord Beaumont, did not go through, and is still lodged: it did not, in the first instance, open the cavity of the chest on the left side, but it ultimately did so, and he was near dying, not from fluid, but from air which escaped from a small hole in his lung, and caused as much oppression and obstruction as if it had been fluid. You will find the particulars of this case stated in a clinical lecture, which was delivered in this hospital ten years ago, and which is reported in the second volume of the *London Medical and Surgical Journal*. The first inflammatory symptoms were subdued by the loss of more than 100 ounces of blood from the arm, and not less than 150 from the application of more than 400 leeches at different times to the chest. The symptoms having very much diminished in severity, he was removed from Long's Hotel to private apartments, when he caught cold, which brought on a fresh attack of inflammation with cough and spitting of matter, and he would have died from the quantity of air which had been pumped by his respiratory organs into the cavity of the chest, and through the lung which had ulcerated, if I had not enlarged the opening made by the pistol ball, until the instrument I used, a piece of hard sponge tent, had entered the chest, and allowed the compressed air to escape on its withdrawal. The wound in the lung healed, and his lordship is now as sound in health as any man in England. He owes his life to the right application of the principles of physic and surgery and nothing else, and I will venture to say there is no other case like this in Europe; he is a man, as I have often told him, *per se*. Dr. Roe has told me of a case of pneumo-thorax, where the wrong side of the chest was opened, and air admitted, the man dying directly from the consequent compression of both lungs, so that in performing an operation of such a nature, it is requisite to ascertain first which side of the chest is full of air.

Lieutenant Forbes, of the Royal Navy, desired me, within these few days, to examine a wound he had received in the right side of his chest, on board the *Africaine*, in 1810, at the Mauritius. A musket-ball entered the right side in front, diagonally upwards and outwards, about two inches from the nipple of the breast. The ball did not pass out, but, luckily for him, it went through the wall of the chest behind, and lodged in the muscles of the back, and soon ceased to be a source of irritation; it may now be felt and seen under the skin, and he said I might take it out if I liked, but as it was quite harmless and I recollected there was such a thing as raising the devil without being able to lay him again easily, I advised him to keep it. The ball made a large hole, and passed through the outer part of the lung. When a ball passes through the middle, or nearer the root of the lung, where the vessels are larger, the sufferer usually bleeds to death. This gentleman says he lost a large quantity of blood by the wound, was bled afterwards to a great extent by the doctors, and was nearly in a state of insensibility for six weeks, during which period large quantities of blood, air, and matter were constantly pumping out at the wound, which was large enough to admit of their all passing through. He thought this was very odd and very wrong, but it was the only thing that saved his life. The great and important distinction between a wound from a musket-ball and a pistol-ball is, that in the former case the wound is a large one, in the latter a small one; which is a great misfortune, for nothing can be done with it unless it be enlarged. When a patient is in the state described, the whole cavity of the chest passes into a state of suppuration, and if he is to recover, the wall thickens inside, the lung becomes more or less impervious, and adheres to it; the size of the chest diminishes, the ribs fall in to a certain extent, and the breathing becomes very imperfect. Mr. Forbes is in this state, and I have certified to the Lords of the Admiralty, not only that he is deserving of reward from them for his sufferings, but on account of his case being one of the best examples of good surgery that I am acquainted with, and well deserving of being known.

When a sword or a knife penetrates the wall of the chest, the cut should be closed as soon as possible; it should be regularly sewn up. When I used to lecture on surgery, and came to the subject of amputation, I advised you all to get broomsticks, and saw them up by inches, in order that you might acquire the necessary facility in doing it, for I am inclined to believe none of you are sawyers by intuition. In like manner, I judge you are not able to sew. It has been said, that a surgeon should have an eagle eye, a lion heart, a lady's hand. As to the eagle eye, and the lion heart, I make no doubt you have all got them, but I doubt the lady's hand. I have often thought my hand as light as that of any other man engaged in the practice of surgery, nevertheless, I never could stitch up a hole in my glove, nor in anything else, to my satisfaction. I would recommend you, then, to practice the art of mending gloves, until you can do it neatly: if you cannot arrive at this, you must in the event of an accident occurring, avail yourself of the assistance of some good old lady, who is past the time of fainting and hysterics: if she will only sew up the wound with as much care and neatness as she would a hole in her best cambric pocket-handkerchief, taking in with her stitch nothing but the edge of the cut skin, she will have done your patient an essential service. The skin is then to be wetted, and a piece of dry gold-beater's skin laid on it, then a larger piece, and next some lint; the whole to be retained by plaster, but no bandage is to be applied. The patient is then to be laid on the wounded side, and is not to be moved on any account whatever.

The older surgeons thought it right to begin to bleed, to purge, and to glyster forthwith—but I never could see the advantage of bleeding a man because he had the misfortune to be stabbed, and was half-dead already with fright: nor could I see how anything was to be gained by purging a man all day and night, whose great object was to lie as quiet as possible: and when I used to hear some of my old friends, of the Court of Examiners, recommending bleeding, purging, and glystering without mercy, without hesitation, I could not refrain from smiling at the recollection of the rebleedare, the repurgare, the reclystarizare, of Moliere. Adhesion of parts cannot take place under such circumstances, and the less physic a person takes the better. If he should have been so unfortunate, as to have swallowed it, he must nevertheless lie still, happen what may.

An ordinary wound in the abdomen ought to be treated in a similar manner, although a very long one may require a stronger stitch here and there. I have heard it recommended, in such cases, to send a needle through the muscles, and to sew them together; but this was done by gentlemen who did not know, practically, that the muscles of the abdomen do not unite by muscular or tendinous fibres—they adhere by cellular membrane, become afterwards separated, and a hernia is always the result. Fancy a person with his curved needle, three inches long, working away at the belly of a gentleman who has two inches of fat under his skin, and you may understand what a pretty business it must be for the stitcher as well as the stitched—and all for nothing.

A plastic fluid of a very adhesive nature soon begins to exude from the edges of a clean cut wound, and reunites them to each other. If the lung should fall against the cut part, the object sought for by placing the patient on the wounded side will be attained; and if it should be so, the safety of your patient is ensured. He is a

lucky fellow, if there have been any previous inflammation in the chest within a few months, by which the two pleuræ are agglutinated. When a ball enters the cavity of the chest, it deprives the parts it injures of the capability of adhering to each other, until after some portion of their abraded edges have separated by a process which occupies several days, and suppuration has taken place, which, with the fluid secreted during this time from the inflamed surface of the cavity generally, will fill the chest and, if not evacuated, destroy the patient. I have seen in London, and have had more or less the charge of eight recent cases of wounds of the chest, implicating its cavity; two only have survived. Lord Beaumont is one, Mrs. Magnus the other. I saw her at ten o'clock in the morning after the injury, with Mr. Adams, who came to my house for me. The ball—a small pistol bullet entered on the right side from behind, between the seventh and eighth ribs, just under the arm, when hanging down, and passed out in front, over the cartilage of the sixth rib, more than an inch from the pit of the stomach. She had not spit blood, and it was easily ascertained by the ear, when carefully applied to the wall of the chest, that the lung was pervious to air, which induced me to suppose that the ball might not have penetrated the cavity, although it might have injured or grazed the membrane lining it. I abstained, therefore, from probing the wound, lest I might make that a penetrating wound, which was not so at the moment. She was suffering great pain, had great difficulty in breathing, and was much oppressed. And now as to the question of enlarging the hole thus made? If I had believed that the ball had passed into the cavity of the chest, I should have at once enlarged it, as a hole is a hole whenever made, and it is as well done at once as afterwards, for a secretion of fluid will take place about the fourth day, and must be evacuated. As I did not believe that the chest was penetrated, Mr. Adams bled her in two bowls and a wash-hand bason, till I found by my finger on the pulse that she was in the act of fainting. She lost at this bleeding more than a pint and a half of blood, about half as much as was taken from Mr. Drummond altogether; it shewed the strongest signs of high inflammatory action, and she was so effectually relieved by the quantity removed, that it was not necessary to bleed her again during the treatment. At the end of three weeks of gradual improvement, she was removed from the Auction Mart Coffee House to a private lodging, the excitement of which was, in all probability, the cause of her spitting a little blood, which she did on three occasions, when I was desired to see her again. It then appeared to me that the injury of the lung was probably confined to a small point, and as the symptoms were not urgent, the palliative system was persisted in. I saw her with Mr. Adams a third time, to confer on the propriety of her being examined before the magistrates: I went alone a fourth time to see her in order to ascertain her actual state after the wound had healed, and she was, in my opinion, able to take care of herself. I came to the conclusion that the ball had not struck the lung, nor penetrated the cavity of the chest in the first instance, although it had injured the membrane lining it, and had given rise to ulceration of a small portion of the lung after it had adhered, and by thus adhering (which can be ascertained by the ear) the patient was saved. This case reflects the greatest credit on the ability, talent, and attention of Mr. Adams, and shews the propriety of not probing these wounds when there is a hope of their not having penetrated the cavity of the chest, and for not doing which he merits the highest praise.

It would, however, be wrong in me who know better, and it would only lead you into error, if I were to allow you to suppose that a penetrating wound of the chest and lungs could ordinarily be treated with success in so simple a manner. There never has been any case of wound of the lung which recovered without extreme hazard and great loss of blood. Mr. Drummond was wounded in the back, about two inches from the spine, and the ball was found half an inch under the skin, nearly at an opposite point in front. From the absence of all the symptoms of alarm or shock that usually indicate the lesion of a vital part, I was willing to hope that the ball might not have penetrated the cavity of the chest; and as the opening made by it was too small to allow the finger to follow it, especially as Mr. Drummond was a very stout man, I did not choose to run the risk of examining it with a probe, which, if the ball had run round, might have done much mischief. The extraction of the ball was a matter of no consequence; it would have remained where it was without doing any harm, but there is a common prejudice in favour of removing it; and I also did it, because I was anxious to find, if possible, some confirmation of our hope that the ball had gone round outside the cavity, by being able to trace it from before backwards, if only for an inch. I could not, however, trace its passage in any direction, nor could I do it in a satisfactory manner on the examination after death. It passed from the omentum to the edge of the end of the eighth rib, but how it jumped thence to the place where it was lodged, I cannot exactly explain, and would recommend your applying for further information, if you require it, to the Lord Mayor. His Lordship was able, from hearing a statement of the case of Mrs. Magnus, according to the report in the papers, to decide without knowing anything of the nature or treatment of Mr. Drummond's wound, that the two cases were exactly alike in all respects. Now his Lordship could only have discovered this from that omniscience which naturally falls upon a chief magistrate, on his attaining office, and which I trust, he will exercise on this point also for your edification and mine, and that of all other ignorant people, who are willing to rely upon his knowledge and discretion upon so delicate a subject.

The ball was extracted at 5 p.m. on Friday evening, and I saw Mr. Drummond again at 8 and at 12, and, as he was quite easy, I left him with the hope that our best wishes might be realized. At five in the morning of Saturday I was sent for, and found him suffering from great uneasiness, and difficulty in breathing, accompanied by a particular catch or jerk in respiration, that indicated a wound of the diaphragm. The chest sounded well to the ear in every part, and I had no doubt of the substance of the lung having escaped any serious mischief although it might have been injured by the ball passing between it and he diaphragm. I opened two veins in each arm, and obtained, with great difficulty, about 12 ounces of blood, the veins being small, and the arm very fat, so that the bleeding was stopped by the fat closing the openings I had made. It gave him some relief: the blood was neither cupped nor buffed: at 10 o'clock Mr. Cooper and Mr. Jackson decided, that as the difficulty of breathing was greater, the jerk had increased, and there was great oppression and misery, although he was not in absolute pain, and the pulse was 112, (they only varied from 108 to 112 during the remainder of his life,) he ought to be bled again. Mr. Cooper tried and failed to draw blood from either arm, and I requested him to open the left temporal artery. This he did with his accustomed dexterity, but the artery would not bleed, nor another small branch which I opened myself, and only four or five ounces, at most, could be obtained. He had taken four grains of calomel over night, and was to have had a saline aperient draught every six hours; the nurse, however, who obeyed my directions to examine carefully all the excretions, informed me, that he had passed a tea-spoonful or two of blood, and the aperients were immediately suspended. I now had reason to believe, that the ball had not only wounded, but had penetrated the diaphragm, and had probably opened an intestine, and that the cavities of the chest and abdomen had both been injured, and must become inflamed. With a constitution apparently unequal to bear an inflammation of the most dangerous character, which I knew must ensue, or the remedies necessary to subdue it, the prospect was a melancholy one, and I did not conceal it from his family. Three dozen leeches were applied to the side, but they drew very little blood, and the bites would not bleed afterwards. Dr. Hume, an old friend, having called to enquire after him, I requested Mr. C. Drummond to add him to our consultations, night and morning, and we had the advantage of his assistance during Sunday and Monday. The symptoms of inflammation, which appeared on the Saturday morning, did not increase during the whole of Sunday, and at the consultation at 10, on Monday morning, we entertained some hope that they would remain within reasonable bounds. At 12, Miss Drummond sent to tell me that he was much worse. I found him suffering great pain and uneasiness at and under each wound, with a greater jerk and oppression in breathing. I ordered him half-a-grain of the muriate of morphia, and summoned Dr. Hume, Mr. Cooper, and Mr. Jackson for two o'clock. He slept a little, from one till two; the symptoms were, however, urgent, pulse 112, and it was at once decided he he must lose blood, and the cupper, Mr. Mapleson was in attendance; but as cupping is but a bad substitute for general bleeding, I determined to try again to bleed him, and the same vein which could not bleed before, now yielded twelve ounces, when the fat interfered, and no more could be obtained. The blood, before it separated into its solid and fluid parts, was actually like size in colour, and soon cupped to an extreme degree; its abstraction gave him relief. Two grains of calomel with half a grain of opium were ordered every two hours. At ten at night Dr. Hume, Mr. Cooper, and Mr. Jackson saw him again and although he had been relieved by the bleeding, and had slept a little, the oppression and painful uneasiness had returned with even greater severity, and he was again bled to the amount of from 12 to 14 ounces, when the blood ceased to flow, apparently from the same cause, the fat intervening, although the pulse remained unaffected. This again greatly relieved him. At five next morning (Tuesday) Mr. Jackson and I were sent for in consequence of the return of all the symptoms, and particularly the jerk and difficulty of breathing in a more aggravated state. He had slept but little from the opium, and it was not to be doubted that he would soon die unless relief could be obtained; twelve ounces more blood were accordingly drawn from the other arm. This time he bled freely, and more might have been obtained, had it been prudent to let it flow. It was equally as yellow, as cupped, and as firm on division when coagulated, and the solid part was in as due proportion with the fluid, as on the two previous occasions, and the relief obtained was equally satisfactory. I had seen Mr. Drummond six times in each 24 hours, besides an hour or two spent with him during the night. I had ascertained by ear, three times a day, the state of his chest, and when we met on Tuesday, at the usual hour of ten, I knew that our patient could bear no further loss of blood with advantage—that fluid was collecting in his chest, and that if he lived, it must soon be evacuated to prevent another evil more certainly fatal than even inflammation. It was with very mournful feelings I said to Mr. Cooper and Mr. Jackson, for whose able and cordial co-operation I am grateful, "If we bleed our patient again, we shall lose him, and we shall lose him equally if we do anything else."

Dr. Hume could not attend and as there was some doubt as to the quantity of fluid which there might be in the chest, and I was determined to leave nothing undone that could give him the smallest chance for life. I requested Mr. Charles Drummond to allow the nearest physician of repute to replace Dr. Hume. Dr. Chambers, on his arrival, approved of all that had been done, but could, unfortunately, add nothing to what was doing, and the calomel and opium were continued with an additional dose of morphia. I explained to him what would be necessary to be done in regard to the evacuation of the fluid in the chest, as soon as we could be sure that the quantity collected (which is easily ascertained by the ear) was seriously compressing the lung, and preventing he due admission of air into it. We met again at 4 P.M., by which time he had had some sleep, the uneasiness and oppression had lessened, the breathing was easier, he was in good spirits, and the pulse 112, compressible and soft, but not weak. He had lost about fifty-six ounces of blood by Mr. Jackson's computation, in four or five days. We thought him better, and expressed our hope

to his family that when we met at 10 at night we should be able to give a more positive assurance of real amendment. At 7, Miss Drummond sent to say some change had taken place, and that he was worse. I went to him directly, and found he had no pulse at the wrist. At 10, when the other gentlemen arrived, they were not less surprised than I had been at so sudden an alteration. He died at 10 the next morning without any greater suffering than that which he had always complained of, and particularly of an insupportable uneasiness and difficulty of breathing.

The *post-mortem* examination you know. The blood which was diffused over the right side of the abdomen must, I think, have been forced out on the separation of the injured part of some vessel, which had been hurt in the transit of the ball through the abdomen, but which was not discovered from the parts injured being impacted together from the effects of inflammation. I am of opinion than this bleeding principally took place on Tuesday afternoon, and was, in addition to the destroying and incurable nature of the wound, the immediate cause of his dissolution. The quantity of blood in the abdomen could not well be ascertained, as it was diffused over every part of the right side; it was not less than twelve ounces, and might have been twice that amount. He never complained of uneasiness in any part of the abdomen under the most careful examination, except beneath the part where the ball was extracted.

As I do not think, gentlemen, I shall write the fifth book, or at at all events, for some time, I will take up each of these subjects separately in some future clinical lectures.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

THE substance, *iodine*, so allied in many of its leading properties to chlorine, was discovered in 1811 by M. Courtois, a manufacturer of saltpetre, at Paris; its properties, however, were first investigated by Clement, Davy, and Gay-Lussac. On account of the properties it has of yielding violet coloured vapours when heated, it has been termed iodine, from *Ioudes*, violet. Iodine is found in both kingdoms of nature rather widely, if not largely diffused. In the inorganized kingdom we find it united with certain ores of silver, of cadmium and zinc, and of lead. Sea-water from every region, so far as experiment has been made, contains it, probably united with sodium and magnesium, constituting iodides, or iodurets of these metals. Certain mineral waters also contain it: for instance, in a brine spring at Nantwich, in Cheshire, there was about a grain of iodine in twelve gallons. It has also been discovered in the rock salt of the Tyrol. The fact of its discovery in brine springs and rock salt is exceedingly interesting; for, on the supposition that both are the results of depositions from an antediluvian ocean, (which is the theory generally received) the latter must have had the same constitution as the oceanic waters of our own era. Iodine has also been found in several other mineral springs. Mr. Copeland detected it in the carbonated chalybeate of Bonnington; Dr. Daubeny found ten gallons of Robbin's Well at Leamington to contain about one grain of iodine; Cheltenham water contains it too, but in a much smaller proportion; iodine has moreover been discovered in several German, Italian, and South American mineral springs. In the organized kingdom the presence of iodine seems confined to certain of the lower animals and vegetables. The animal genera, Spongia, Gorgonia, and Doris, have been proved to contain it; and it is, moreover, found in the envelopes of the eggs of the *sepia*, or *cuttle-fish*. One instance occurs of its presence in the order *insecta*: near Acolti, in Italy, an insect has been found, termed by Savi *Iulus fœtidissimus*, which, when irritated or disturbed, emits a yellow fluid strongly smelling of iodine, and which yields a blue colour with starch: a character, as we shall see hereafter, which is peculiar to iodine.

In marine cryptogamic vegetables, iodine is very generally diffused, and it has been found in several species of phrenogamous plants. Iostera marina and a Mexican species of Agave, and of salsola, may be mentioned as examples.

Extensively diffused throughout nature, as we have described iodine to be, yet the only commercial source for this body is kelp—the result of the combustion of plants belonging to *Fucoidæ*, one of the divisions of the family *Algæ*.

The substance kelp, which is a semifused mass of ashes, from the plants just mentioned, and which contains a great number of saline materials, was formerly prepared almost for the exclusive purpose of forming the carbonate of soda; now, however, this salt is obtained from the decomposition of chloride of sodium, and kelp is almost exclusively manufactured for the purpose of obtaining from it ultimately the body *iodine*. The theory of the process will be rendered intelligible, by remembering that the iodine of kelp is in union with sodium and magnesium, as iodides, or iodurets of the metals; that these salts are more soluble than any other simultaneously existing in kelp; and that, when separated, they may be decomposed by heating with sulphuric acid and binoxide of manganese, yielding pure iodine,—just as chloride of sodium is decomposed under precisely similar circumstances, yielding pure chlorine.

In order, then, to proceed in accordance with these principles, kelp is first lixiviated with water, by which means a carbonaceous mass is left undissolved, and all the saline materials obtained in solution. This solution is then evaporated in an open pan, when the various salts which it contains are deposited in an inverse order to their solubility. First are obtained the soda-salts, namely, common salts, carbonate, and sulphate of soda,—all of which are separated by a perforated shovel. The liquid is then run into narrow pans, and allowed to cool, by which means are obtained chrystals of chloride of potassium. The same operations are several times repeated until certain indications of color and density prove that little except the iodides of sodium and magnesium remain. To this is added sulphuric acid in excess, which decomposes any carbonate there may be present, and also the sulphurets which have been produced during the burning of the plants. To the ley thus prepared is added peroxide of manganese, in a leaden retort imbedded in a sand bath, and heat being applied, iodine comes over, and is collected in proper receivers, mixed however with a variable portion of water, which is rather difficult to be separated entirely, and indeed which the manufacturer has no great inducement to attempt. Should it be desirable however to ascertain the quantity of water thus mixed with any sample, the problem may be thus solved:—Heat the iodine in a tube with a little fused chloride of calcium, which substance absorbs all the water, and at the same time becomes mechanically mixed with iodine; on increasing the heat, however, the latter may be entirely dissipated, leaving nothing but chloride of calcium, and the whole of the water, consequently, the increased weight of the chloride of calcium corresponds to the amount of water; originally present in the specimen. The theory of the liberation of iodine by the action of sulphuric acid and the oxide of manganese on the iodide of sodium, or magnesium, or both, is precisely analogous to the change which takes place when chloride of sodium is similarly treated, and on the supposition that iodide of sodium is alone present is represented by this formula—

$SO^3 + MnO^2$ and NaI give $MnO.SO^3$ NaO and I.

Iodine has a bluish black color, something resembling in appearance plumbago, or black lead. It is a non-conductor of electricity, and whether passed through red hot tubes, or treated in any other way, it has never yet been resolved into any simpler form. It is soft and friable; its specific gravity has never been correctly determined. Thomson makes it 3.08—Gay-Lussac 4.946. It produces a yellow stain upon the skin, which, however, is removed by the application of liquor potassæ, or by heat,—thus distinguishing it from the yellow stain produced by nitric acid. When moist, it is exceedingly volatile, yielding at a temperature between 70° and 80° a pale violet colored vapour. At 220° it fuses, and at 350° boils, and produces fumes of a denser color, which yield brilliant plates, and acute octohedrons on cooling. Iodine may be obtained from solution in the form of oblique octohedrons, with a rhombic base, or in prisms. The vapour of iodine is exceedingly heavy, its density being, according to calculation, 8707. Iodine is slightly soluble in water, seven thousand parts of the latter dissolving about one part. In alcohol and ether its solubility is much greater. It may also be dissolved very readily in solutions of the iodides. The peculiar color of iodine vapour is, in many cases, a sufficiently characteristic test; but a far more delicate one is starch, as was discovered by Messrs. Colin and Gaultier de Claubry. To this it imparts a blue colour, capable of removal by the application of heat or an alkali. Microscopic experiments teach us some very curious facts in relation to the mutual action of iodine and starch: the latter substance is composed of minute globuloid molecules, composed of an external envelope, *amydon*, and an internal gelatinous mass, *amyline*. Now it is on the former alone that iodine exerts any agency. We learn, too, that no two vegetables of different kinds yield starch molecules of the same shape or size; thus preparing us to expect some differences in chemical composition. Such have not always been satisfactorily established, but at all events, iodine yields with different varieties of starch different shades of blue, and *inulin*, a starchy substance obtained from the *inula hellenium*; or elecampane merely tinges a solution of iodine slightly yellow. In testing for iodine with starch, it is indispensable that the solutions be neither alkaline nor hot; in the former case two salts are produced, namely, an iodide of the metallic radical, and an iodate of the alkali, neither of which is capable of acting on starch. The action of heat in removing the colour is not understood; theory would indicate that the iodine, being volatile, is eliminated—such cannot be the fact, inasmuch as the colour returns when the solution has again become cold. Iodine is said to be occasionally adulterated with plumbago, sulphuret of antimony, or peroxide of manganese; frauds which can be easily detected by the action of alcohol,—all except the iodine remaining undissolved. The atomic weight of iodine may be considered as about 126. In all its relations, iodine presents a remarkable analogy to chlorine; but its action is not so powerful. Like chlorine and oxygen, it appears at the positive pole or anode of voltaic arrangements, and is hence classed with the electro-negatives. Thus much, then, for the properties of iodine in its simple or uncombined state; we now come to its combinations with oxygen. Of these there are three, or according to others, four, represented by the accompanying table.

	O	I	
Oxide of iodine....	1	1	?
Iodous acid	2	1	?
Iodic acid	5	1	
Periodic acid......	7	1	

Of these only the iodic acid is important or interesting; the composition even of the two first is undetermined. Periodic acid is prepared by a tedious process, and is so unimportant an agent that I shall not mention it further. Iodic acid is, as you will have perceived by the table, a compound of one eq. iodine and five oxygen, being analogous in this respect to the nitric, chloric and bromic acids, with all of which indeed it corresponds in many leading properties. Iodic acid cannot be obtained by the direct action of oxygen upon iodine, hence the processes for making it are somewhat complicated. According to Mr. Connell it may be prepared by boiling iodine for several hours with about five times its weight of strong nitric acid. The theory of the preparation of iodic acid by this process is very obvious; nitric acid, as is the usual result under similar circumstances, that is to say when boiled with substances greedy of oxygen, yields up this latter element in the requisite proportion. I have tried this process several times, and have never found it capable of yielding a good result. A better process, although exceedingly tedious, consists in bringing the vapour of iodine in contact with protoxide of chlorine, prepared by the action of hydrochloric acid on chlorate of

potash; two bodies result, chloride of iodine and iodic acid, the former of which may be driven off by the application of heat, leaving iodic acid pure, in the form of a white powder, very soluble in water. Its solution possesses acid properties in a very marked degree, tasting exceedingly sour, and strongly reddening litmus. On a solution of cold starch it does not exert any action, but when mixed with deoxidizing bodies, such as sulphurous acid, or chlorine, and then added to a cold solution of starch, the usual blue colour appears, on account of the abstraction of oxygen, and consequent liberation of iodine. Hence it is that iodic acid is a very valuable re-agent for determining indirectly the presence of sulphuric acid. The theory of this action involves certain substances not yet spoken of in these lectures, but still I hope to render myself intelligible. I must premise that although we possess a very good direct test for sulphuric acid, or oil of vitriol, in baryta, or soluble barytic salts, yet it is absolutely necessary to their complete action that the sulphuric acid be uncontaminated to any very great extent with organic matter. It follows, therefore, that in case of poisoning with sulphuric acid the determination of the presence of this substance is by no means easy according to the usual course of proceeding. If sulphuric acid, which is composed of one eq. of sulphur + three of oxygen, be heated with almost any carbonaceous body, two eq: of oxygen are removed from every two eq: of sulphuric acid, carbonic acid escapes, as also does *sulphurous acid*, or SO^2. That sulphurous acid really is eliminated during this proceeding may be determined by heating a fragment of vegetable or animal matter, such as cork or feather, with sulphuric acid in a test tube, when there will presently be given off a gas smelling like an inflamed brimstone match; this is sulphurous acid. Sulphurous acid then is nothing more than sulphu*ric* acid deprived of a portion of its oxygen, which portion will be absorbed again on any convenient opportunity. Now iodic acid yields up its oxygen with great readiness, and a stream of sulphurous acid being passed through it, there result free iodine and sulphuric acid. From a consideration of these facts we learn a very easy process for determining the presence of sulphuric acid in a stomach. We will suppose that it is there mixed with all manner of animal and vegetable substances. The latter *cannot* be separated, nor *must* they if possible; but the whole of the contents should be placed in a capacious retort, together with a little powdered charcoal, to insure the presence of a sufficient quantity of carbonaceous matter; the beak of the retort being inserted under a mixture of starch and iodic acid, the heat of a sand bath should be applied. Presently, under these circumstances, sulphurous acid is liberated, which decomposes iodic acid, abstracting oxygen, and necessarily eliminating iodine, which latter immediately tinges the starch blue, whilst sulphu*ric* acid, proportionate to the quantity originally existing in the stomach, is left in the vessel containing the starch and iodic acid. For sulphuric acid, then, iodic acid is a valuable test; it is also a test for morphia, which abstracts oxygen from it, although slowly, and of course renders it capable of imparting a blue colour to starch. Chlorine and iodine unite together in two proportions, but the resulting compounds are unimportant.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c. &c.

(LECTURE IX., Delivered December 21st, 1842.)

GENTLEMEN,—Before I proceed to the subject of the true spinal marrow, I wish to draw your attention to a point or two which I left unnoticed at the former lecture. Now, if you fix your eye on the line marked A B in the diagram before you, you will see that it denotes the seat of hemiplegia, arising from blood effused in the cerebrum. You will remember that when laceration takes place, then hemiplegia occurs in the opposite side of the body; so that, when the paralysis is complete, the patient cannot move the hand or the leg—or, if he can move it at all, he does so very inefficiently and very imperfectly. The act of volition, in that case, has been by some power or other severed from the paralytic side; there is a division between the seat of volition and the muscles, which ought to be moved by the action. At the same time, when the patient is affected by any emotion or anything of that sort, it is precisely that arm and leg which are the most moved. Therefore, though the volition be severed from the paralytic muscles, motion is not; the seat of volition is, but the seat of motion is not. What is the conclusion to which we must here come? Most assuredly—that the seat of motion, wherever it be situated, must be seated near the spinal marrow in that line which I have indicated; and I want you to see distinctly that the seat of volition is higher in the nervous system than the seat of motion. The same thing applies with regard to respiration: if a patient yawn you find that the paralytic arm is moved, though he cannot move it by any effort of the will. What is the conclusion here? That the source of motion in the act of respiration is situated lower down than the seat of volition. This you see is an important practical point.

Now we know that the source of volition is in the medulla oblongata; why should not the source of motion be in the medulla oblongata? Now I believe that motion has its sole source in the medulla oblongata, and the argument I have adduced goes far to prove, at any rate, that the seat of motion is below the seat of volition. Now we know that in paralysis, which takes place from a lesion of the spinal marrow, producing paraplegia, though both the seats of volition and motion are entire, the arm is moved independently of the former. The conclusion is, inevitably, that the seat of volition is higher in the brain than the seat of motion. This is not all, for there is an extraordinary set of facts respecting pain. You are aware, because I have repeatedly mentioned the fact, that lacerate the brain as you will, you have no pain—the olfactory nerves exhibit no pain—the optic, or the acoustic nerves exhibit no pain; there is no pain inflicted in any of these nerves of the brain, but touch the fifth pair of nerves, which are the nerves of touch, and you have pain. Does not it strike you as an extraordinary fact, that the nerve of one sense should be susceptible of pain, and that the nerves of all the others should not? Yet it is so, and what is the conclusion? It is this, that the fifth pair of nerves contain, besides the nerve of sense, some other nerve that belongs to the spinal marrow, which is the seat of pain.

Now I will detail a very interesting experiment, performed in the most perfect manner, many years ago, upon a rabbit. This little animal was entirely deprived of the cerebellum, and there was no brain left, but the medulla oblongata remained and the animal breathed. When the tail was pinched violently with the forceps, the animal actually cried; therefore I must not only conclude that the medulla oblongata is the seat of motion, or that it is the seat of the power of respiration, but most probably that it is the seat of pain. There is another thing with which I conclude this observation; it is this—that not only is the fifth pair of nerves capable of conveying pain, but under peculiar circumstances the internal nerves, those nerves going to the intestines and the stomach, and the pleura, are capable of conveying pain. With regard to the intestines and the stomach, that which is said to have nothing at all to do with pain, is actually the seat of pain. I have not time to go into this subject, for it would take too long.

We now return to the first part of the argument; when the cerebellum is removed, or disease cuts off the seat of the will, still emotion agitates the paralytic limb, therefore the seat of emotion must be situated lower down than the seat of volition. The seat of respiration we know is in the medulla oblongata. I give that as a reason why the seat of pain is there too. Now I want to bring before you a practical argument; and it is this. You will bear in view the different portions of the spinal marrow, and the manner in which the nerves of the lower part of the spinal marrow are sent off, not only those that constitute the *cauda equina*, but the others situated above. Suppose a patient comes to you with paraplegia, as a patient came to me not a very long time ago,—I am alluding to the case from Manchester—saying, "I have no sensation above this part of the body; my inferior limbs are destitute of sensation and voluntary power, I have lost the power of the sphincters. I am not conscious of sitting down; I have no sensibility." That patient came to me marked with setons and issues on each side of the sacrum. Now it is quite certain that if the disease had got as low as the sacrum, these measures would not have affected those nerves going to the inferior extremities, and therefore I do not see the use of the setons and issues below the sacrum. In order to apply this to disease, we must consider, naturally, the parts affected which produce sensation; we have not to think of those nerves that go to those parts, but it is the origin of them that we have to see to. There was not merely paralysis of one limb, but of both; and in order to have paralysis of both the inferior extremities the disease must be situated in the spinal marrow, that part of the spinal marrow from which these nerves derive their sensation. If you have a reflex action in spite of the disease, a portion of the spinal marrow is left entire; but if you have no such reflex action there must be disease as low as the point at which the spinal marrow terminates. Now when you apply your setons you will adopt—what measures? Certainly apply them a great deal above the parts to which they have been usually applied. Therefore suppose the loss of sensation and the loss of voluntary power is at the ischium and the ilium, we must consider the nerves from their origin in the spinal marrow, and apply the setons accordingly; how much higher the disease may be it is impossible to say, except the height of it can be traced by some other symptoms. For instance, suppose a patient has a sense of a cord passing round the stomach, I need not tell you that the disease is at the epigastrium, and therefore, in the former case, you might apply your remedies higher than in the latter; but suppose, as very often happens in some diseased states of respiration, the spasmodic affection takes place in one or both sides in the intercostal muscles, then the remedies must be higher still. Suppose the patient has difficulty in breathing, and there is an affection of both upper extremities, then your setons must be applied above the origin of the cervical plexus. After what I have said, you will in the application of your remedies be quite careful not to apply them below the seat of the disease.

You are aware of the peculiar paralysis that takes place in the colica pictonum; the muscle paralysed is called the *extensor carpi radialis longior*, and has the peculiar power of sustaining the wrist: the bones of the thumb are incapable of being extended, though the wrist does not drop, and the ball of the thumb is exceedingly emaciated, so that you can trace the bones of the thumb with great facility.

There is only one concluding remark to this subject which I ought to make. I believe that the affection in this case as, for instance, in inflammation, may run along all the nerve, and create undue sensibility a good way up the arm; and it is quite plain it takes place along the whole course of the nerves, and I can only compare it to the inflammation you see in some severe cases of typhus. The blood becomes congested, its power is annihilated, and the muscles do not contract for want of nervous influence. The nervous influence is not there, for the reason I stated to you. In palsy of the hand you have therefore three things, a loss of nervous power running along the whole course of the nerve, an absence of irritability in the muscular fibre, and atrophy.

I said I had only this concluding observation to make, but it appears I have another concluding observation, and it is this: I told you that, in reference to apoplexy of the brain, the opposite state of the brain is what I call an adynamic state. I told you what occurred in the case of *delirium tremens*, and in that case of affection of the brain there was intolerance of light and sound, and symptoms of mania arising from intestinal irritation and the loss of blood, as well as other symptoms. This I consider to be an *adynamic* state, a true adynamic state of the spinal marrow. We know that there is inflammation, congestion, and apo-

plexy in dynamic states of the spinal marrow, and we know that there are also adynamic states, such as frequently happen in paraplegia, not perfect but imperfect. In this affection of the spinal marrow, when it is perfect, sensibility is gone, the muscular motion is entirely gone, entirely eradicated. This case I believe very often ensues from excessive sexual abuse of any kind. I mention this to you as a fact, and you have to trace to this, the practical effects exhibited in the future life. This takes place in a dynamic stage.

I have now to bring before you the subject of epilepsy. With regard to epilepsy, it, like many other diseases, may be traced first of all to the centre of the spinal system, and, in the second place, to the incident nerves that lead to that centre. In the first place, I have to refer to centric epilepsy—I use the term centric for want of a better term,—and, in the second place, to excentric epilepsy. Another phrase for centric epilepsy has been adopted—centripetal; that is to say, diseases referred to the centre of the whole nervous system, as contra-distinguished from those distant from the nervous system. I must, first of all, say a few words respecting centric epilepsy. Centric epilepsy comes on from some affection of the brain, inducing some morbid state of the centre of the spinal system; a disease of the brain communicated to the spinal marrow, and leading to a state of irritation, and to nothing more; for I need not tell you that if the state of the disease went on to produce any further effect you would have paralysis with epilepsy. It has been found that a spicula of bone has passed into the cavity of the cranium, or into the spinal canal; and this acts as an irritant. You will remember the remark I made some time ago, that this irritant passing into the cerebrum will produce no epilepsy, because no irritation of the brain can produce any muscular motion: therefore it must be taken as certain, that in the case of a small bone producing epilepsy in the way I mentioned, it must produce epilepsy, not by irritating the brain, but by irritating something else. You will remember the brain is incapable of sensation; you cannot produce any effect by irritating the substance of the brain, but you may by irritating the membranes of the brain. We know, that irritation of the fifth pair of nerves going to the brain, will cause epilepsy. Now, it has been proved that injury of the lining membranes of the spinal marrow will produce certain states resembling epilepsy: therefore if you have spicula of bone producing epilepsy, you have not only the nerve irritated but the membrane of the nerves, and not the brain itself. And therefore, a tumour, or any source of irritation, may be the means of producing epilepsy; in fact, other things produce epilepsy, as, for instance, congestion of the brain, attended with convulsive motions; a state of congestion once produced, may, therefore, produce similar motions, which may go on to the extreme state of epilepsy.

There is one other cause of epilepsy which I must mention. It is a disease the most severe of any I have ever met with, and which seems to be almost incurable; it is that disease which results from fright. I am not aware of any case that has yielded to any remedy; probably some may, but I have not met with any yet. Epilepsy arises from fright, and whenever fright produces epilepsy, it is a spinal affection, and you cannot trace it beyond the spinal system—the true spinal marrow itself.

I have now gone through all the symptoms of centric epilepsy, and, therefore, what I am now going to say refers to the subject of excentric epilepsy. Excentric epilepsy may be traced to three causes, as shown in this diagram:

TABLE OF EPILEPSY.

1. THE EXCITORS.	2. THE CENTRE.	3. THE MOTORS.
1. The pneumogastric in the stomach	The Medulla Oblongata.	1. The recurrent of the pneumogastric, closing the larynx
2. THE SPINAL.		2. THE SPINAL. Producing
1. The intestine		1. Forcible expirations
2. The uterus		2. Convulsions
		3. Expulsion of the urine, &c.

In tracing the causes of epilepsy we must go to the nerves. In the first place, the *gastric* nerve is affected from some morbid state of the stomach; or, secondly, it may be the *splanchnic* nerve from some morbid condition of the intestines; or it may be, thirdly, uterine, where it indubitably does arise from an affection of the uterine system. When the stomach, the bowels, and the uterus are in a morbid state, this morbid state may act on the nerves proceeding from those organs just in the same way that cold water acts on the nerves of the face, affecting through their medium the centre—the spinal marrow itself; and then, reflected from the spinal marrow, you may have all the symptoms of an epileptic seizure. What then are all the symptoms of an epileptic seizure? You have only to refer to what I said respecting the true spinal system, and just call to your mind all the points supplied by that system, and then you can account for all the symptoms characterising an epileptic seizure.

Now I shall first of all describe an epileptic seizure, and I can do so the better because I have seen such a case this morning. Now the first thing I observed was some impediment in the breathing. The larynx is affected in an epileptic seizure. It often happens that the larynx is partly closed, and there is a feeling of nausea and stertorous breathing. There is, you cannot fail to observe, a difficulty to expire, and in consequence of that the patient becomes flushed in the face, and by and bye becomes comatose. The larynx, then, is the first part affected in an epileptic seizure. Now I have to state a fact which is an exceedingly interesting one; and that is, an affection of the larynx sometimes precedes an epileptic seizure. I have a patient whose wife can partly tell when the affection is coming on, because he is affected with a husky voice, something like that of a catarrhal cold; yet, his wife was enabled to distinguish it from the voice of a cold, from the habit of frequently observing it. This is one of the premonitory symptoms. The larynx, too, remains affected after an attack. After a short time he lost his voice altogether. What do we next observe? The eyes are affected. I have seen the eyes rotate, and when that happens one side of the body is affected more than the other. The eye, therefore, is the next point offered by an epileptic seizure. I need hardly tell you, that with the state of the larynx to which I have alluded, the respiratory muscles are affected more or less under the influence of the true spinal system. Another thing not to be forgotten is the difficulty in swallowing. I was almost terrified by the attempts of the patient to swallow a little sal volatile. Gargles were tried, but scarcely ever swallowed; and at other times the matters that were given were all withdrawn into the larynx. One thing should not be done: you should not attempt to give anything to the patient during an epileptic fit.

All the muscles of the frame are violently convulsed: both the superior and inferior extremities. Now what takes place next relates to the true spinal system, and these symptoms relate to the lower part of the abdomen. You have very frequent evacuation of the bladder and of the rectum; these are not uncommon symptoms in a state of epilepsy. What more can be said to prove that the true spinal system is affected! You observe that the flow of the catamenia occurs in the female sex, and you find that every function that relates to the true spinal system is partly affected in this terrific disease. Now, to revert to the causes—what are the causes of epilepsy? Precisely those that happen through the medium of the incident nerves; for instance, any crudities in the stomach. I have been called to see a patient who died in a state of epilepsy and whose stomach revolted against everything. That patient, who never had an attack of epileptic seizure, and, probably, never would have had it but after meals, was a lady, who for a long time, had an attack every day after dinner. The object to attend to there, was to pursue mild measures, to give a mild breakfast, a similar lunch, and a similar dinner; and being put upon this diet, which comprised asses milk, she was for a long time without any epileptic seizure. This lady a very short time ago, ate water cresses for breakfast, and that very day she fell down with an epileptic seizure. Now, if the bowels get wrong the patient may have an epileptic seizure; the patient may go on very well afterwards, but is liable every moment to a renewal of the old attack.—Nothing tends so much to produce an epileptic seizure, as anything that irritates the intestines; and if true epilepsy arises from the intestines you may be perfectly sure that the intestines are in a disordered state. In fact, every disorder in the intestines will produce it. Here the true source of the affection is the *excito-motor* nerves; but it is singular enough that the very same nerves, when irritated, will produce epileptic seizure in one person, and in another, those nerves will produce vomiting. I have observed, with regard to the female sex, that the epileptic seizures occur more at one period than at another; it is either just before the catamenial flow, during it, or just after it. Here you have a proof of the epileptic seizure, being one of the excentric kind, and induced through the incident nerves in that state of the uterus. I shall by and bye show another fact that relates to the pregnant state of the uterus, for you are aware of the convulsions that take place in certain states of the uterus during pregnancy. I have proved to you that epileptic seizure has reference to the true spinal system. Does that leave the brain entirely out of the question? By no means. Then you will say, why place it out of the question in a case of epileptic seizure? With reference to what I said at the beginning, that the larynx is frequently closed, and that there are violent efforts of expiration, the veins of the neck and face are swelled, and there is a flushed face, you may be perfectly sure, that if there is a flushed face, there is congestion: it is plain, therefore, that the brain is congested *pari passu*, with the diseased state of the nerves. Now, I go further than this: you find on the face ecchymosed spots, which do not disappear under the pressure of the finger; and I suppose, in that case, that under the effect of this closure of the larynx, and the violent expiratory efforts to expel the air from the lungs, the capillary vessels are filled, and the blood is not expelled;—it is venous blood—not arterial blood. This is one of the consequences I have repeatedly seen in a state of congestive apoplexy of the brain. Now, there is a curious idea I have often heard, and it is this,—that in this state of the brain, when the patient is so convulsed, tracheotomy will prevent the violent congestion of the brain, which occurs during an epileptic seizure. I do not recommend it to be done. Now, why do I think there may be congestion?

I want to introduce to you one or two interesting facts. I spoke of epilepsy as being a true spinal disease, but there are cases of epilepsy so different from anything I have described to you, that I am not very sure that they are produced by disease. In one case an epileptic patient shall be reading, and all of a sudden will stop reading. There is an annihilation of thought, a loss of all recollection—what some have described as absence of mind. The oblivion, however, is so short that the patient comes to himself almost immediately, and it is not accompanied by any of the consequences observed in the more determined disease. I have had a number of such cases, in which there has been a sudden loss of recollection, a loss of mind for a moment. The patient has stopped reading, and in a moment or two he has continued with the word with which he stopped. You see this is a case of epileptic seizure, and not of the true spinal system. But I think there is some little difficulty in this. I think it very probable that the muscles closing the larynx, are contracted from the disease so as to produce a momentary congestion, and that issues in momentary delirium from the determination of blood. However true my explanation may be, the fact is true, namely, that the patient is attacked with a momentary loss of mind and consciousness. There is another form of epilepsy I must mention to you, a form that you may be acquainted with, as it is a form not unusual, that is, a loss of the power of the muscles of the head. There is a momentary loss of consciousness, and a momentary loss of power in the muscles of the head.

These are the principal forms of epilepsy

that I have to mention to you, and I think that in what I have said, I have given you a clear idea of all the symptoms of the disease. We now proceed to the treatment. The treatment almost suggests itself to you; yet there are a great many remedies, and it is exceedingly important that you should ascertain which to use. In the first place you have to endeavour to abate the symptoms. In the second place we must look to the intestines. With regard to the intestines, drastic purgatives do not do good; the best plan is to give some mild aperient over night, and wash out the intestines next morning. I may give an illustration of this injection. If the syringe is used repeatedly the intestine is distended, and the pain is increased by stimulating and irritating the intestines, and the plan to adopt is to fill the intestine but not in the least to distend it. Having washed out the intestine, the next plan is to give something of a soothing and quiet nature; to desire the patient to take a warm bath, and to give warm drinks. I am quite sure that this plan has a very important advantage, particularly with reference to the uterine region. It is not only important to prevent an attack, but if a person has had one attack he is almost sure to have another; and sometimes—and it is a very curious fact connected with attacks of epilepsy—if a person is some time without the usual attack, there is great danger of another attack. Sometimes you find that there is one attack, then some time after, another, and after another relapse, two together. Until something has taken place in the constitution, the attacks are liable to be repeated. If a patient has been without an attack some time, there is danger of another, and when that does take place you have no longer the same degree of danger; but, when he has had only one attack, there is danger of a second or a third, it may be one, more frequently two, and sometimes three, before the tendency is entirely exhausted. Now, I have sat by a little child, with a feather dipped in cold water, and have dashed the cold water on the face to prevent the larynx closing, and to produce an act of respiration, and I have kept off the violent convulsions for hours together. With a patient residing near me, I have occupied nearly three hours in that way. I dashed cold water into the face, the air passed into the lungs, the larynx opened, and the attack was kept off for the moment. There is a very interesting paragraph in the work of the late Dr. Davy on treatment for convulsions; he adopted the same measure, that of dashing cold water on the face, and kept off the convulsions. I have a patient who for some time was afflicted with epileptic seizure; I was obliged to tell him to give up his office, for he had been a good many years subject to epileptic seizure. He had a little husky voice, and whenever his lady observed his husky voice she gave him plenty of boiling water to drink, and tickled his fauces with a feather, so as to produce a kind of vomiting. Again the attack came on, and she kept it off in that way again and again. He was obliged to adopt a degree of fasting. Suppose the attack made its appearance in the morning, he would take no dinner, except a little barley water, and a mild aperient at night, and he would thus escape the attack. Now you will observe there are a number of things to do. In order to go to work immediately, look to the state of the stomach and the state of the bowels, and then you have to consider whether you cannot do something by dashing cold water on the chest, and then try to produce vomiting, by the application of something to the fauces. Sometimes a pinch of snuff, to produce sneezing, upon the same principle prevents epileptic seizure. These things should be borne in mind, because they are of constant operation, and are therefore of great importance when you are called to see a patient in a state of epileptic seizure.

Before I conclude this subject I must say one word respecting that state of the brain that occurs after an epileptic seizure. Generally speaking, it is a state of apoplexy or coma, a state of stupor or sleep; the patient almost invariably sleeps after an attack of epilepsy. This fact may lead you to adopt some important measures with respect to this disease. Sometimes the patient sleeps for a day, or even the next day: sometimes he may continue to sleep for a day and a night. I remember a case of a patient in a state of deep coma, but he died of apoplexy. He ought not to have died, that patient was not bled. If I were called to such a patient I should bleed him, because I should know that there was apoplexy. After such a state a patient becomes liable to such attacks, and I would relieve the brain for fear it might undergo some injury. If this state continue, I need hardly tell you that it will lead to effusion, and the longer it does continue, the more injury will the brain suffer.

PHYSIOLOGICAL CHEMISTRY.

(By Mr. PRATER, Lancet.)

(Concluded from p. 390.)

All the various actions already alluded to, platinum in nitric acid, crystalisation of a saturated saline solution, &c. &c., cannot be referred, as he would insinuate, to the same cause: we have only to look more narrowly into the phenomena, to be convinced of this.

There is one thing in regard to fermentation, where vegetable juice (where gluten) is present, that distinctly separates such phenomenon from the great bulk of chemical actions; I allude to the reproduction of the ferment, which, says Liebig, is sometimes twenty times its weight.—(*Op. cit.*, p. 588.)

Now the resemblance between this action and that of nutrition or generation in living matter, cannot fail to excite notice: for here we have matter converted into its *like* from the contact or action of other matter, carbonic acid and heat being evolved too, as when new organic beings are produced. And to make the analogy still more complete, this reproduction of the ferment only takes place when the solution contains gluten; or, in other words, a vegetable juice, possessed, like the blood of animals, to a certain extent, of life, as containing *globular* particles; for (says Liebig) when only a solution of sugar is used with the ferment, there is no reproduction of this latter: the action then, when no gluten is present, merely *extends, or spreads,* as it does *in combustion.* In the mere fermentation, &c. of sugar, the whole of the matter is *changed* into combinations of a less organic character than sugar, viz., alcohol and carbonic acid: so it is also where gluten is present; but besides this, in the latter case is a real formation of *organised*, or *incipient* organised, matter. And it is worthy of observation, that, as when sugar and yeast only are present, there is no reproduction of this latter; in like way, when only gluten is present in solution with the yeast, the yeast is not reproduced. Sugar must be present, which is for the most part changed into carbonic acid and alcohol, the remaining part, by its decomposition, affording oxygen to the gluten, which in this way is changed, says Liebig, (*Op. cit.*, p. 239,) into yeast. If we adopt this explanation, the presence of sugar only becomes necessary in the formation of yeast, by imparting oxygen: but there are some objections to this view, which would almost reduce fermentation to an action of ordinary inorganic chemistry, Liebig's express object. These objections are,

1st. From experiments that I have lately made (with a different object in view indeed,) it was obvious that when polished iron, or bright iron filings, was put into the thickest syrup, or into hot fused sugar, no oxidation whatever took place. So far then as iron is concerned, a solution of syrup is not so much an oxidising agent as common water.

2ndly. Why, if oxidation only, be the cause of the reproduction of the yeast, is it not reproduced when a solution of gluten containing yeast is merely left exposed to the atmosphere? * Liebig says, "in different parts of the work under consideration, that gluten has a strong affinity for oxygen." And, indeed, the fact seems, that when a vegetable or animal juice is exposed to the air, oxygen (as in all cases of putrefaction) is absorbed: and although the product in that case is a fluid or mass that will excite fermentation, for Liebig says expressly (p. 259) that perhaps all matters (see his long list), animal or vegetable *themselves in a state of putrefaction*,† have this effect, still this product would not, I suspect, be *yeast*.

As, then, the production of carbonic acid and alcohol from sugar can be effected by no other known means than the presence of yeast (Graham's Elements, p. 196), so, likewise, in all probability, that can be formed by no other known means than by the *action of itself* on sugar and gluten in the same solution.

This view of the subject, will make the formation of yeast very similar to the reproduction of life in the highest order of animals; and Cazniard de la Tour's paper in the Annales de Chimie, is in support of the action arising from the reproduction of vegetable germs; an opinion, indeed, opposed by Liebig, but, as appears, in my humble opinion, on insufficient grounds. But for the sake of argument, let us take the opposite view of the subject (for Liebig does not seem to give a very clear opinion on this case), and conceive that when a piece of putrid vegetable or animal matter excites fermentation in a mixture of sugar and gluten, yeast is produced, just as when yeast itself excites the action; then let us also conceive that yeast may sometimes be produced when a mixture of vegetable juice (gluten),‡ and sugar is exposed to the air (simply to enable it to absorb oxygen), no yeast being added, and what would be our conclusions? Why, if yeast could be produced under such circumstances, the formation of that substance, doubtless, could not well be likened to the generation of a seed from a seed; to the production of life, as among the *great mass* of plants and animals; to the production of life from its *like*. But, still, under such circumstances it would be

* At p. 379, when comparing the action of fermentation with contagion, Liebig says, "The ferment acts on the sugar, and occasions in it a change, in which the gluten takes no part; but by the influence of the *air*, this undergoes an alteration of form and composition, in consequence of which the ferment reappears again with all its properties." This statement seems, in some degree, incompatible with that at pages 288, 289, already quoted, but perhaps not entirely so; for both agree as to gluten being changed into ferment, by absorbing oxygen. However, in p. 288, it appears that this change may take place, and generally does take place, without the access of air; and in such case Liebig supposes that the oxygen necessary is derived from the sugar.

† Colin, however, seems to have made this discovery, or other authors previous to Liebig. There are fewer new facts in Liebig's essay than might be supposed; its great merit consists in an attempt to generalise well-known facts. I somewhat regret that such an attempt should be unsuccessful; since it is setting so good an example to the chemical world in general, *who neglect too much the classification of well-known facts.*

‡ Ferment or yeast would only be produced under such circumstances in case *sugar* were present. Now, as sugar is present in vegetable juice, and also in an infusion of malt, ferment or yeast can, in all probability, be generated when such matters are exposed to the air, inasmuch as a decomposing or putrid solution will be produced; for vegetable juice produces ferment under such circumstances, and Liebig says (p. 288) that seems identical with yeast in properties.

similar, if not identical, to *the action of equivocal generation among animalcules*, or nutrition in the animal and vegetable kingdoms. For the production of animalcules (the infusoria) all that seems necessary is, that the conditions of putrefaction (i.e. an organic solution at a certain temperature in contact with air) be present; the air in this case seeming in some degree to supply the place of a previous living monad, and exciting to action by the absorption of its oxygen; but if yeast were formed, when sugar was put into the organic solution in question, instead of, or in common with, infusoria, the production is only that of the lowest vegetable, instead of the lowest animal, life. The analogous formation of infusoria (an organic solution being absolutely necessary for the formation of these) would make the action still come under the class, if we may so speak, rather of vital or organic, than common, chemical actions, *particularly as the yeast once formed has, like the infusoria, a power of propagating its like.* This is the consideration that would make the formation of a yeast, under *any circumstances*, rather like an organic or a vital, than merely a chemical, action. In all probability, the products in organic bodies are the result of the operation of *ordinary chemical affinity*, modified only by the circumstances in which the molecules are placed by the operation of vital action: but there is this difference in vital operations, viz. that many kinds of matter, different in appearance, taken into the living body, are all converted into the same substance, or go towards forming a whole, similar to the one in which they are received. The only point in which these different substances must resemble each other is, that they must consist of *organic matter*: just so, if we suppose yeast may be formed from various decomposing organic products, supposing that may be the case, it is still certain that none but *organic* matters will do for such transformation; but if yeast can reproduce itself from such matters, such matters will be similar to food, as taken by living beings, and the production of yeast will resemble the act of nutrition.

Value of Quinine in Typhus.—A commission appointed to examine into the correctness of a memoir addressed by Broqua to the French Academy of Medicine, reports that some of the cases cited in the memoir are not proved to have been veritably typhoid, and that no proof is adduced of the quinine administered having been the means of cure. The report remarks, that "one interesting fact confirmed by Sig. Broqua's memoir is the general harmlessness of the sulphate of quinine in full doses. In the discussion that followed its reading, M. Piorry stated, that in typhus fever, with engorgement of the spleen, he had seen quinine prove serviceable, which had not been the case when the fever was unaccompanied with splenic lesion. M. Martin Solon, who had employed the remedy under the personal inspection of Sig. Broqua at the Hôpital Beaujon, admitted that in cases in which the fever assumed a remittent type, quinine was useful, but that remittent typhus was rare,—at least at Paris. Much doubt was expressed by several members of the academy as to the innocuity of large doses of quinia or its sulphate.

Solution of Aconite in Rheumatic Affections.—M. Busse recommends a mixture of 4 *grammes* of extract of aconite with 30 *grammes* of antimonial wine. Thirty or forty drops to be taken every two hours. In one patient M. Busse administered as much as two *grammes* and a half of the extract, without producing narcotism. M. Busse states this medicine to be of great efficacy in chronic rheumatic pains, as also in pains in the teeth originating from the same cause.

TO CORRESPONDENTS.

We tender our acknowledgments to our talented contemporary, the "Shropshire Conservative," for his flattering notice of our work.

H. W. Dewhurst, Esq.—*We are obliged to decline this gentleman's liberal offers of literary aid.*

Dip.—*The two numbers named will be sent: the cost will be 8d. On Dr. Sinclair's Joint Stock Medical Institution at Hulme, we are loathe to express our opinion. We are told that the president, or medical officer is a medical reformer, and the author of a pamphlet on medical reform. But if the members of a Medical Reform Association can club together to get a journal at the mere expence of paper and stamps, (that is, without profit to any body but themselves) is it wonderful that such men's patients should join together to get medical attendance a bargain? The spirit of avarice, the philosophic motor principle, intense selfishness—the characteristic of our age—is to acquire the commodities we need, at the least possible cost to ourselves, without troubling ourselves very much as to the results on those producing them. The affluent have carried out this policy in their Clubs, Art Unions, and Joint Stock Companies; and it may be expected that the poor will follow in their wake.*

A. Z.—*It is illegal in a wholesale druggist to supply spirits of wine to his customers, and equally so in a retail druggist, except for medical purposes.*

A. H.—*Our Almanac was published in December, and as, from the very large sale we received for it, we were compelled to have it stereotyped, our supply is inexhaustible. Our Correspondent should order it through another bookseller.*

Mr. Sale.—*The Medical Charities' Bill has not passed through Parliament and there is an opinion abroad in well informed circles, that it is not very likely to pass this session. The inspectors would of course not be appointed till the act received the royal signature. We see that it is not to be considered till the 26th of April.*

A Visit to a Magnetic Patient.—*This narrative (from the "Glasgow Argus") has been sent to us. It wants all that such relations should never want—*names, places, times. *What nonsense to write about zeal for science and truth, and be ashamed to give one's name to statements which are utterly useless to either truth or science, without all the weight which the publication of responsible authority can give them?*

Diamond Cement.—*S. W. H. sends us the following recipe. It is proof, he says, against boiling water after being allowed to stand a week.*

℞ Gum Mastich ℥ij.
S. V. R. ℥iss.
Solve cum calore.
℞ Isinglass ℥ij.
Aq. bullient. ℥iss. misce omnia.

The article intended to be mended must be made warm when the cement is used, it needs to be placed in boiling water to dissolve.

G. H.—*The inhaling instrument enquired about is, we understand, one of the simplest construction. The smaller of the two unequal ends is the one placed in the mouth. Sir Charles Scudamore uses a similar instrument for his iodine inhalations. As the object, we presume, is only to get much air into the lungs, not much complication would seem necessary. We are not aware of any professed vendor.*

Mr. Richard King *has our thanks both for* performances *and* promises.

Mr. Cronin sends us a letter, intimating that if Mr. Thornton plagiarised Mr. Yearsley, Mr. Yearsley had first plagiarised Mr. Cronin. The three aurists are by the ears, and how the squabble will terminate, who shall predict? Mr. Cronin's charges it must be owned, are far more general than those made by Mr. Yearsley against Mr. Thornton. He confines himself to the endeavour of shewing that Mr. Yearsley's etiology and treatment are similar to those propounded by him in his book on ear diseases, (which reached two editions) published "as far back as 1838." But we must cease. The "Medical Times" has a higher office to serve than being a mere Aurist's Pillory.

L. S.—*It is confidently expected that Sir James Graham's Medical Bill will be brought in soon, but there is less certitude felt than at the beginning of the session that he will succeed this year in carrying it. There is no probability that it will contain an enactment allowing* surgeons *to dispense their own medicines. Our Correspondent's case is a hardship, but we must always have such till there be some uniformity established as to the course of proceedings which shall make (what we may call) a* full *medical man in every part of the empire.*

The Phrenological Society.—*We have been favoured with letters from Dr. Elliotson and Mr. Atkinson, which satisfy us that the notes furnished of the proceedings at the last meeting we noticed are not in many particulars perfectly accurate. In future our own reporter will attend the meetings.*

Mr. J. Jones.—"*The Philosophy of Health*" *is finished. Dr. Arnott's "Elements of Physic" remains, alas! still uncompleted. We regret, with our correspondent, that there are so many pledges remaining unfulfilled by* medical *authors who have undertaken the publication of large works in parts; but our censures, if we were to utter any, could not but be meek weak the delinquents are headed by an Arnott and a Copeland. Who would believe that either of these could be in wilful fault?*

A.—*The paper by Mr. Foote on the Improvements in Pharmacy is not an abstract, but was written expressly for the* "Medical Times."

C. H. *will find the rules required for the East Indian Medical Service laid down in our Student's number of October 1st, 1842.*

Fair Play.—*We should think £600 a fair premium under the circumstances.*

THE MEDICAL TIMES.

Saturday, March 18, 1843.

Primum nam inquiram quid sit furere hoc si erit in te
Solo, nil verbi, pereas quin fortiter, addam.

Though subscribing fully to the justice of the jury's verdict in the case of M'Naughten, we yet—strange as it may appear to the *Times*, and the many others who have been eagerly crying out for blood—believe in what has been called the sanguinary principle that punishments are justifiable only on the ground of *prevention*, and should rise or fall in amount according to the rule required by the good of society. While retributary punishment is no prerogative of ours, the absolute power of preventive punishment *is*. While the charter of our power over each other allows of not even a momentary increase of human misery, save with the clear purpose of humanity's greater amelioration, it allows us that in full plenitude. In punishment, the salus populi, the bonum publicum, is at once the *lex suprema* and the *lex unica*.

If it be said that—this principle admitted—we must discard the maxim which connects responsibility with mental sanity, we briefly answer, that punishments undeserved, or punishment out of all proportion with the offences, are as bad for society as they are unjust to the individual. They exasperate the circle or class in which the sufferer moves—shock the sense of equity—throw discredit on the law—and, rousing all men's sensibilities to revolt, are more apt to encourage men to wrong, than to wean them from it. The teachings of Justice, which is indeed but another name for the Common Sense of mankind, are thus in perfect harmony with the requisitions of society.

Now, the broad maxim we would lay down on a man's legal responsibility is, that it should hold in law, as it does in human equity, a precise proportion with the sanity of the mind on which it depends. We need not say, in discussing the nature of insanity, that it is no metaphysical malady. We know that the spiritual essence has a physical residence, and receives its knowledge, and exercises its behests, through physical agents. The mind may not be the brain, more than the instrument is the musician, or the type in which Milton's works are printed, are Milton's ethereal thoughts—but the mind is still wholly and entirely dependent on the brain. Derangement, disease, disorganization of the substance of the brain, are evils, then, that *necessitate* greater or less aberrations of mind.

The evil may be in various degrees of magnitude. The patient may be sensible of the aberrations. There will then be no lesion of that part of the brain on which the mind depends for forming a just estimate of the actions immediately under review. There may be no consciousness of the aberration—in which case, *cæteris paribus*, there is a larger extent of physical malady. There may be again, a limitation of the malady to that portion of the brain on which the mind is dependent in reference to its propensities; or to that other portion through which it perceives, compares, remembers, judges—or to *both*. If the disease extends to all, we have lunatics in the most desperate of stages: if to the former only, we have men in various stages of passionate irregularities, accordingly as their intellectual powers are strong or weak—or their past training has been good or bad. If the disease, instead of attacking the moral feelings, has triumphed over the part of the brain dedicated to intellectual labours, we have hallucinations, delusions, phantasies, varying with the especial seat of the malady, as well, probably, as with the past character and habits of the patient. Irresposibility, therefore, is rarely total. There are few even confirmed lunatics who, for a certain class of actions, are not as responsible as men in sanity. This man may, by one of those obliquities of mental action by which a *fragment* of memory or sensation is turned into a solid conviction, mistake his own identity, but his notions of *meum* and *tuum* are healthy as ever: nay, on every thing unconnected with—it may be—one point of memory, his judgment and feelings may be as sane as his soundest neighbour's. This suggests considerations as to the punishment of lunatics, which we cannot dwell on, but which our legislators might turn to account,—and, on the other hand, shews how foolish is the policy which, considering monomania as a pretty fiction of modern times, holds it not to be a true insanity, nor one which exempts the actor from responsibility on the special matters that come under its range. Monomania is far from an uncommon phase of insanity; and no reason can be mentioned why monomaniacs should be visited with punishment for the *direct* consequences of their mania, which would not equally apply to all other madmen for acts immediately the result of a wider lunacy. If reason, with the power over one's volitions, be admitted the source of all responsibility, by what sophistry shall it be argued that M'Naughten should have been punished for his recent act? We are told that *motive* and *intention* are the things that give an action its character,—and that the fixed design frustrated, and the fixed design carried out, only differ in there being a more consistent and persevering course of mischievous intention shewn in the one than in the other. If fixed intention, if mischievous design, then, be the test of guilt, where shall we look for either in M'Naughten? If any one believe that a fixed delusion, sincere, strong, invincible, held possession of his mind—and few surely can doubt that—what difference can he point out between M'Naughten's act, and an assassination committed in a dream? The design of either assassin would be equally under the control of reason.

It appears to us no proof of wisdom to assert, with Sir William Follett, and some other lawyers, that the incriminated act of a supposed monomaniac should not be narrowly scrutinized as evidence for or against the insanity of the accused. A single act may contain a mass of evidence proving madness, and there is no reason why the act first offering such proof should be the very one accused. If the act happen to offer evidence of long premeditation, cunning or unnecessary cruelty, the circumstances are duly enlarged on, as aggravating the crime. Is there any reason why circumstances proving a want of intention (and there must always be such a want, where there is no reasoning intellect) should not as fully be urged in palliation for the accused? We confess we can see none.

The *Times*, in rather an ingenious spirit, affirms that the mental delusions of M'Naughten offer no extenuation of his guilt. If the supposed injuries he complains of, were real, and he had avenged them in the way he is accused of—the law, it argues, would have held him guilty of murder; *a fortiori*, therefore, when the provocation was merely imaginary. Now, we have here a clear *petitio principii*. If M'Naughten be not mad, he certainly deserved to have suffered for his act as much (we will not say more) if his complaints were fictitious, as if they were real. But M'Naughten, we affirm, was mad; and the extraordinary delusion he laboured under, affords, with other evidence, proof of the assertion. But the argument carries on its face its own answer. In leaving it, we must content ourselves in expressing our admiration of the journal's powers, which can derive, from an agent's hallucinations, proof of *increased* responsibility.

We regret that the length of Mr. Guthrie's lecture will exclude for another week one or two articles we are engaged to give.

PENCILLINGS OF LIVING MEDICAL MEN.

SOUTH, SOLLY, M'MURDO, AND TRAVERS, JUN.

THE first in this list is one of the surgeons, and the other three are the assistant surgeons, of St. Thomas's Hospital.

John Flint South is a pale, thin, delicate man, about 40 years of age, with a very prominent long nose, long face, and a most methodistical mode of wearing his hair. His manner is unpresuming and retiring. He walks along with his long neck outstretched, his eyes fixed on the ground, and his head covered with an old fashioned hat, giving him a very strange and eccentric appearance. He looks like a great ungainly girl in male attire. He is the son of a respectable chemist, many years resident in the Borough; and is brother of Sir James South, Astronomer Royal, about whom there is so much diversity of opinion:—

"Some deem him wondrous wise,
"And some believe him mad."

He was elected on the council of the College of Surgeons, in 1841. He is a very studious, industrious man. He resided for some time in St. Helen's Place, in patient expectation of professional employment, to which his connection with the hospital, and his own acquirements gave him a natural claim. It has not, however, been realized. Possessing property, and suffering under occasionally severe indisposition, he avoids the bustle and inquietude of professional rivalry. He prefers the cool breezy shade of private life, as much we believe from inclination, as from an inherent, modest, reserve of disposition. He lives at Blackheath, and amuses himself in his Tusculan retreat, by scientific research. He is passionately fond of comparative anatomy, and has, and is printing several interesting articles in the Encyclopœdia Metropolitana, on the subject of sharks. With Mr. South, as with many others, failure is their own fault; it is a question of fear. They shrink from grappling with the realities of life. They want the persevering courage to drag on, amid difficulties and trials, or are deficient of that worldly tact, which is so practised at present. Mr. South was never under the influence of that stern stimulant, necessity, that incites so powerfully to exertion. I never fought a good battle, said a celebrated prize fighter, after I had a fifty pound note in my pocket. This feeling may explain the event of success of some very learned and scientific men. Commence your profession without a shilling, is a very inconvenient and disagreeable prescription. Yet to be poor to perfection, is oftener a surer road to fortune, than either wealth or connection. It holds good in law. Old Eldon once truly remarked, "all our Chancellors come from the garrets."

In 1831, Mr. South translated Dr. Otto's Compendium of Human and Comparative Pathological Anatomy, with notes and references. It is a simple and literal translation, and highly creditable to his research and industry. The introduction notices all the authors who have written on this subject, from Antonio Beneveni. The author considers all deviation from the healthy organic condition of animal bodies as either the disturbance of their normal nutritive activity, in quantity or quality (Liebig's present theory), or the mechanical separation of the natural connexion of their parts; whence, again, are necessarily produced changes of the nutritive activity. He considers the chemical peculiarities naturally to belong to Pathological Chemistry, on which account Pathological Anatomy excludes generally from its sphere the animal fluids, and only concerns itself incidentally with the more important fluids, in reference to their quantity, color, and consistence. The vices of animal organization are divided into congenital and acquired.

Second section, into vices relating to number, deficiency, and multiplication of parts; and the others, to those consecutive to the vices of size, &c.

He subsequently edited St. Thomas's Reports, in one volume, of which the following sensible observations occur:—"A detailed account of cases occurring in our Hospitals, to which several physicians and surgeons are attached, must be considered valuable, as affecting a comparison of different modes of practice, and their results." He adds

It is, therefore, matter of surprise, that no such cases have hitherto been published by any of the large Hospitals with which Medical Schools have been connected—but have been left to the periodicals, and by them selected more with reference to rarity than general utility, to the neglect of a legitimate and ample field for professional improvement."

The premises so judiciously advanced in these preliminary remarks were never carried out. The conception was better than the execution. The cases were selected "not wisely." There was no interest in them. They were too formally and circumstantially detailed. They were such simple and familiar cases that the reader felt it was a waste of paper and of observation to collect, and of time and attention to peruse. There were no scientific deductions to compensate for such simple and frivolous premises, and needless illustration. There were no statistical documents to give value and importance to its pages,—no grand generalization,—no novelty, nor improved modes of practice—no comprehensive views, to repay the purchase or the expectations: and the work went down the Acherontic stream, and is known only as a record of the failure, amid such ample materials, of a very hard-working, well-informed, and in every way respectable and intelligent young man.

In 1839, he brought before the Medico-Chirurgical Society a case of fracture of the coracoid process, with partial dislocation of humerus forwards, and fracture of the acromeon process of the clavicle.

He has published a third edition of his work on the Bones, in which he has introduced great improvements, and many valuable engravings. The students have affixed the name of Bony South to him, either from having written this work, or his illustrating the osseous system so perfectly in his own person. It is a didactic work, and facilitates and simplifies the study of this structure. It is not much sought after, nor read. Some say that the energy of his mind is not of the first order. But all admit that the compass of his knowledge is very extensive, and that his activity and perseverance deserve our respect. He is attentive to his Hospital duties, kind, affable, and instructive—slow, but sure, as an operator. In general politics he is of the Conservative tendency. Active, earnest, and enthusiastic, as a medical reformer—deeply penetrated with the conviction of the evils and abuses of the present system, and sincerely solicitous of their removal. In private life, pleasing and prepossessing; full of a dry quaint humour, and much estemed and highly valued by his associates. He has all the elements that compose a good consulting surgeon, and ought to be encouraged by the general practitioners.

Samuel Solly, F. R. S. Lecturer on Anatomy and Physiology, is a dapper little man, but of high fancy, as Sterne said of Hammond Shandy. Dark twinkling eyes, and visage chubby, with the rose of health crimsoning his cheek, in despite of the midnight oil, and toil, and study. His round pleasing face, the nattiness of his attire, the convolutions of his cravat, his profound acquaintance with the art of the toilet, manifest a very laudable desire to stand well in the eyes of the fair sex, as well as in science. He is about 40 years of age, but looks younger. He is a mixture of the sanguine and bilious temperament. His head is fairly divided. The animal propensities are not forgotten, over which the moral sentiments and the intellectual certainly predominate. The observing or perceptive organs are large. He is evidently of the impulsive class of medical men. In 1835, he published a letter in one of the periodicals, on the the advantages of drawing to the medical student. In 1836, he published his work on the Human Brain, its Structure, Configuration, Development, and Physiology, illustrated by references to the nervous system in the lower order of animals.

In his introduction he remarks very justly, that according to the plan generally pursued, in treating the anatomy of the brain, in systematic works of the present day, all the information conveyed amounts to little more than a vain catalogue of names applied to parts, without reference to their structure, their function, or even their analogies in the nervous system of the lower order of animals. Such a barren prospect as a list of names, holds out but little to attract the most zealous among students; while the dryness of unconnected detail, and the obstacles to clear conception engendered by the absence of every thing like arrangement, almost constantly deter him from attempting to learn more than is required to prepare him for examination for the diploma.

It is unfortunate that the old method of slicing should be followed, a method most unphilosophical in its conception, and totally inadequate to impart any real information in regard to the structure.

Reil, Gall, Vic d'Azyr, Serres, Cuvier, and others, by commencing with the dissection of the spinal chord, and tracing it upwards, were enabled o throw great light upon this interesting branch of physiology, and to prove that the chain is perfect, and that such differences as do occur, simply consist in the abstraction of parts, and the loss of those powers which have been proved to be dependent on them.

By pursuing this course, we shall be rewarded by finding that the enkephalon, this apparently most complicated organ in the human body, is but a gradual development from an extremely simple fundamental type on one uniform and harmonious plan,—that the seeming complexity of the cerebro-spinal axis in man really arises from the great concentration, as opposed to the extreme diffusion of its component parts in the lower order of animals: for in no particular are the higher orders more strikingly distinguished from the lower than in the concentration of functions within circumscribed spaces.

"Let honour be given where honour is due." He may be well proud of this production; it is equally excellent in conception and execution. The demonstrative principle is beautifully and philosophically exhibited in the progressive ascent of the series by the successive additions of new parts, and of increased and corresponding functions.

The language is simple, scientific, and perspicuous; his descriptions are lucid, accurate, finished, and complete. His reference to the opinions of Herschel shows that his mind is deeply imbued, and that he ambitioned not "unsuccessfully" to imitate the excellence and purity of the style in Herschel's noble work—his Discourse on the study of natural philosophy.

In 1839 he read a paper on a case of dry gangrene in a boy, before the Medico-Chirurgical Society.

In 1841 he was elected assistant-surgeon. The same year he wrote some remarks in the Gazette on the Pathology of the Nervous System, in which he tries to refute the opinion that disease of the cerebro-spinal axis is not discernible after death. He imputes it to the want of properly noticing the colour of the cineritious neurine; this he did not evidence as clearly as he might.

We once heard him deliver a lecture before the Royal Institution. He very respectably acquitted himself. His language apposite; his manner neat and appropriate; his drawings and diagrams good, and carefully executed; his reasoning succint and clear. He was not eloquent, but he was successful in communicating information, and in confirming the remark of Horace.—

> That if the mind with clear conceptions glow,
> The willing words in just expression flow.

He said he considered a nerve to be a chord proceeding from some sensitive or motive surface to a medullary centre, to which it conveyed impressions, which were converted into sensations, and whence was reconveyed the energy which produced voluntary and involuntary motions. In the human subject, the olfactory nerve, which ministers to a sense not highly developed in man, terminates in an oval or pyriform bulb of cineritious matter, which is joined by a long commissure to the cerebral mass. In other animals, as the horse, in which the sense of smell is much more acute, this thalamus grows to an extraordinary size, and in some animals it is altogether deficient. He proved in the most satisfactory manner, that in the most simple as well as in the most complicated system, two conditions of nervous matter alone existed, the fibrous and pulpy tissues. He made it popularly and scientifically interesting.

In 1842, he published a short article on some of the functions of the organs of the circulation, independent of nutrition, which went to establish that blood, independent of its vital properties, performed a most important part in the economy as a mere mechanical agent. He is a very intelligent hard-working young man. He will never, as a surgeon, rival his predecessors, Cheselden or Cline; but it is very likely that he will afford an additional instance that success is the result of unceasing and well directed exertion, and that the road to eminence, though steep and painful, is to be travelled over by perseverance and industry, and that the aphorism is equally true in medicine as in religion,—*no cross, no crown.*

He is very diligent in instructing all under his care, and very well qualified to give instruction. As a professor, he is proud without arrogance, and dignified without effort. His well managed familiarity and desire to be useful, make him respected and esteemed by his class.

McMurdo is the son of a rich wholesale chemist in the city. By interest, wealth, and apprenticeship—like Solly—he procured his appointment as assistant surgeon. He has a dull large Dutch countenance—such a face as you could easily cut in a Cheshire cheese, without animation or intelligence; but an astute cunning Scotch expression that it would be very difficult for the knife to impart. He wears a very spicy wig, with rich flowing and luxurious ringlets; his whiskers are cultivated with great care and tenderness, and spread far over his cheek. Time having rather prematurely given them a very venerable complexion, and "Wisdom's silver" being unacceptable to the other sex, his knowledge (not confined to surgery) has led him to have recourse to chemistry to dye them dark. By such ingenious devices he has contrived to elaborate a rather agreeable face. He has graduated in the school of Sir Pertinax Mac Sycophant, and pays the most oriental homage to his patron, Mr. Green, whose opinion is with him oracular and infallible. He goes round the wards frequently for him. The one goes round with the pupils as if they were performing a gallopade; the other is often tedious from the time consumed and the monotony of his observations. L'un va en tortue, l'autre court la poste, the latter dropping here and there a practical hint, a world of knowledge in a word—a pearl that the student values as it deserves. In Mr. M'Murdo's demeanour there is a good nature or kindliness of manner that makes itself felt by the bystander, if it were not spoiled by a hybrid mixture of pride, or pomp and politeness that it is difficult to describe or understand, and which makes you suspect its sincerity. He is affable to the students, and anxious to communicate instruction; or rather, to persuade them that he knows something. One moment he is labouring severely to perpetrate some witticism, and going to the verge of coarse familiarity in the endeavour. All of a sudden he stops, and addressing some pupil with an emphatic *sir*, that the others may not forget the vast disparity in their respective stations. Pope, in his prose, says, that true wit may be defined a justness of thought and a facility of expression, or, in the midwives' phrase, a quick conception with an easy delivery. Our pencilled friend, if he thinks of Pope, will save us the pangs, and himself the pains of his *witty perpetrations.* His genius is evidently too ponderous for a *joke.* Canning sarcastically called Hobhouse Lord Byron's man Friday; M'Murdo is in the same relation to Green. There are many envious of his situation, who assert that if a man be insinuating but worthless, stupid but sly, and have the malleability of a leaden mind to bow and cringe and be as ductile as his patrons please, and serve apprenticeship and pay the premium, there is no office, however important, that he may not reach. The metamorphosis of Mr. M'Murdo into an hospital surgeon would appear marvellous in any other part of the world; but where you have non-entities presidents, hypocrites, imbeciles, sy-

cophants, maw-worms, and renegades, councillors and examiners—while men of high order, of intellect, great acquirements and practical merits are excluded—the wonder ceases.

In other countries a man must obtain the confidence of the public before he can challenge the suffrage of the profession; he must secure eminence before he aspires to superiority. No man could be in his situation unless he had fought and conquered his way to high distinction by the exercise of great qualities, by patient study, and unwearied industry.

We have sought in vain in the medical, chirurgical, and philosophical transactions, in the periodicals, weekly, monthly, quarterly, and annual, for Mr. M'Murdo's opinions on scientific subjects. The only reference to his name is the notification of his appointment to St. Thomas's. In Paris, the publication of the candidates are put in as evidence and claim to professional capability. *N'importe.* Interest and money are the most potent and talismanic of agents in London. The lives or happiness of the poor—but we must stop—we must not be too severe, we find no fault with the individual, we war with the system.

Admonere volumus, non mordere—prodesse non lædere, consulere scientiæ non officere.

McMurdo thinks that there is no reputation to be gained from writing now-a-days, and we agree with him. The *cacoethes scribendi* is rife. The books that are published now-a-days are professional advertisements. You can have histories of expeditions, pleas of insanity, diseases of the skin, by paying for it, works without one original idea, manufactured and compiled by librarians and eminent surgeons, who never had any practice. The only trouble is to put their name upon the title-page They make their books upon the same plan the cuckoos build their nests. We have long elaborate essays upon complicated diseases, which the author never saw, and we have books which the author never read, translated out of a language which he does not understand. He purchases by the quantity, and some disagreeable critic informs that it is Mr. So and So's work, with Dr. So and So's name, prefixed to it. This is double felony, the author and the purchaser are robbed, and the reader imposed upon. We feel the subject ginning to expand. We shall shortly devote an article to it, and endeavour to pencil the master manufacturers, from Willis down to Winslow.

Mr. McMurdo, (why is it the Mr. seems misplaced to this name?) McMurdo then, like Chaucer's Monk, has three or four scraps of Latin in his mouth, with which he is trying to pass off as a scholar. Also a few pet phrases, such as "This is a most gratifying case, gentlemen, very. He came in in a very bad state. He is now better, much better, gentlemen:" to which we once heard the following rejoinder.

"The devil a bit, your honour, nor the first day I came in, nor ever will be as long as I stay here, and that's the God's truth now." He relates an anecdote of a brewer's drayman having acknowledged to drink daily sixteen gallons of porter. It is told to introduce *Credat Judæus Apella, non Ego.* In his treatment he is judicious and unexceptionable. He follows implicitly the directions of his seniors. He is bland and humane to the poor, courteous to his equals, and kind to the pupils. His treatment of the poor is the heroico-generous.

We heard him order to one patient six pints of porter, four glasses of wine, one of brandy; one pound of chops, two eggs, milk, and beef-tea, a day. The Poor Law Commissioners, and Dr. Truman, and those who have written on dietetics, would derive benefit from a visit to St. Thomas's. We must say, that this generous fare seems to have the best effects. He matriculated in Trinity College, and married a very elegant and accomplished Irish lady. He is the surgeon, or rather medical officer to Newgate, where he is much respected.

Benjamin Travers, jun., is a young, well-looking, flaxen-haired man, modest, and unassuming in his manner; the son of one of the most accomplished surgeons and original thinkers we have. We expect something from him. He published the history of a case of tracheotomy in 1840. He is biding his time, and we have reason to think he will not shame his sire. But our limits have been exhausted, and we are prevented doing justice to him. PROBE.

INGREDIENTS OF STAMPED AND PATENT MEDICINES.

(*According to Dr. Paris and other Authorities.*)

Chamomile Drops.—The nostrum sold under this name is a spirit flavoured with the essential oil of Chamomile. It cannot possess the bitter tonic of the flowers.

The *Everlasting Pill* of the ancients consisted of *metallic* Antimony, which being slightly soluble in the gastric juice, was supposed to exert the property of purging as often as it was swallowed. This was economy in right earnest, for a single pill would serve a whole family during their lives, and might be transmitted as an heir-loom to their posterity. We have heard, says Dr. Paris, of a lady, who having swallowed one of these pills, became seriously alarmed at its not passing; upon sending, however, for her physician, he consoled her with the assurance that it had already passed through a hundred patients with the best effect.

Permanent Ink for marking Linen.—This preparation is a solution of nitrate of silver, thickened with sap green, or cochineal. The preparing liquid, or pounce liquid, as it is technically called, with which the linen to be marked is previously wetted, is a solution of soda, boiled with gum or some animal mucilage. It is a curious circumstance, that if potass be used for this purpose, the marking ink will run.

Plunkett's Ointment consists of arsenious acid, sulphur, and the powdered flowers of the Ranunculus Flammula, and Cotula Fœtida, levigated and made into a paste with the white of an egg, and applied, on a piece of pig's bladder, to the surface of the cancer.

Pate Arsenicale.—This favourite remedy of the French surgeons consists of 70 parts of cinnabar, 22 of sanguis draconis, and 8 of arsenious acid, made into paste with saliva, at the time of applying it. This combination, observes a periodical writer, is similar, with the exception of the ashes of old shoes, to that recommended by Father Cosmo, under the name of "Pulvis Anti-carcinomatosa."

Davidson's Remedy for Cancer, arsenious acid, and powdered hemlock.

Singleton's Eye Salve, or Golden Ointment.—Under this name is sold a preparation which consists of sulphuret of arsenic (orpiment) with lard, or spermaceti ointment. The Unguentum Hydrargyri Nitrico Oxydi of the London College, is also sold under the same title. The latter, Dr. Paris, believes, is that which is more usually sold under the name of the Golden Ointment; Mr. Clarke has stated, in the *Glasgow Chronicle*, that it is composed of a drachm of red precipitate and seven drachms of butter.

Delcroix's Poudre Subtil, "for removing superfluous hair in less than ten minutes.—This fashionable depilatory appears, upon examination, to consist of Quick-lime and Sulphuret of Arsenic, with some vegetable powder. It is, however, so unequally mixed, that in submitting it to analysis, no two portions afforded the same results. The composition is incapable of fulfilling the intention for which it is so confidently vended.

Tolu Lozenges.—Sugar eight oz., Cream of Tartar one oz., Starch two drachms, Tinct. Toluiferæ Balsami E., one fluid drachm, mucilage of Gum Tragacanth q. s.

Fumigating Pastiles. Trochisci seu Candelæ fumales.—Benzoin generally forms the chief ingredient in these compositions, to which may be added any variety of odoriferous substances; the following formula may be offered as a specimen:—

℞ Benzoin ℥j.
Cascarillæ ʒss.
Myrrh ℈j.
Olei nuc. moschat. ol. Caryophyll. āā gtt.x.
Potassæ nitratis ʒss.
Carb. ligni ʒvj.
Mucilag. gum. Trag. q. s.

Virgin's Milk.—A spirituous solution of Benzoin mixed with about twenty parts of rose water, forms a cosmetic long known by this name. Under the same title also a very different preparation is sold, vid. Liquor Plumbi sub acetatis.

Friar's Balsam, Wade's Drops, Jesuits' Drops.—These preparations are nothing more than the Tinctura Benzoni composita.

Pectoral Balsam of Honey is merely the Tincture of Benzoin, or that of Tolu.

Essence of Coltsfoot.—This dangerous preparation consists of equal parts of the Balsam of Tolu, and the compound Tincture of Benzoin, to which is added double the quantity of rectified Spirit of Wine.

The *Specific of Herrenschwand*, which formerly excited so much interest in Germany, consisted of ten grains of Camboge with twenty of sub-Carbonate of Potass; although it is said, that on its being analyzed by order of Elizabeth of Russia, there were also found in it both Mercury and Arsenic.—Camboge is also the basis of the *Specific of Clossius.*

Golden Spirit of Scurvy Grass.—This is merely a solution of Camboge in the Spir. Armoraciæ comp.

Towers's Solution of Camphor.—Under this title, a strong aqueous solution of Camphor was sold in London, which was supposed to be indebted for its strength to the agency of carbonic acid.

An *Odontalgic Remedy*, in great repute, consists of a solution of camphor in oil of turpentine; a fluid ounce of which will dissolve two drachms.

Rymer's Cardiac Tincture..—It is an infusion of Capsicum, Camphor, Cardamom Seeds, Rhubarb, Aloes, and Castor in Proof Spirit, with a very small quantity of Sulphuric Acid.

Lardner's Prepared Charcoal consists of cretaceous powder, or chalk finely powdered, rendered grey by the addition of Charcoal, or Ivory Black.

Concentrated Solution of Charcoal.—A preparation is sold under this absurd name for cleaning the teeth, and is nothing more than a Tincture of Catechu. The name was probably suggested by the experiments of Mr. Hatchett, who succeeded in producing artificial tannin by the action of Nitric acid upon Charcoal.

Bateman's Pectoral Drops consist principally of the Tincture of Castor, with portions of camphor and opium, flavoured by anise seeds, and coloured by cochineal.

Kirkland's Neutral Cerate is formed by melting together ℥viij. of Lead Plaster with f℥iv. of olive oil, into which are to be stirred ℥iv. of prepared chalk; when the mixture is sufficiently cooled f℥iv. of acetic acid, and ʒiij. of pulverized Acetate of Lead are to be added, and the whole is to be stirred until nearly cold.

Marshall's Cerate.—℞ Palm. Oil ℥v., Calomel ℥i., Acetate of Lead ʒss. Nitrate of Mercury ℥ij.

Cold Cream (Ceratum Galeni.)—Ol. Amygdal. lbj., Ceræ alb. ℥iv.; melt, pour into a warm mortar, and add, gradually, Aq. Ros. oj. It should be very light and white.

Essential Salt of Bark.—The public should

know that the preparation sold under this empirical title, is merely an extract prepared by macerating the bruised substance of bark in cold water, and submitting the infusion to a very slow evaporation.

Eau Medicinale de Husson.—After various attempts to discover the active ingredient of this Parisian remedy, it is at length determined to be the colchicum autumnale, which several ancient authors, under the name of hermodactylus, have recommended in the cure of gout. The following is the receipt for preparing this medicine. Take two ounces of the root of colchicum, cut it into slices, macerate it in four fluid ounces of Spanish white wine, and filter. Some practitioners affirm that the French preparation is a vinous infusion of the *Flower* of the Colchicum.

Dr. Wilson's Tincture for the Gout.—This is merely an infusion of Colchicum, as Dr. Williams, of Ipswich, has satisfactorily shown. Since the discovery of colchicum being the active ingredient of the Eau Medicinale, numerous empirical remedies have started up, containing the principles of the plant in different forms.

Bates's Aqua Camphorata.—Sulphate of copper is the base of this preparation, which was strongly recommended by Mr. Ware. The following was his recipe:—R. Cupri Sulph. Boli Gallic, a. a. gr. xv. Camphor gr. iv. solve. in aq. fervent. f℥iv. diluеque cum aquæ frigidæ oiv ut fiat Collyrium.

Lisbon Diet Drink.—Decoctum Lusitanicum. —R. Sarsap. concis. Rad. Chinæ, aa. ℥j.—Nucum Jugland. Cortice Siccatarum, No. xx. Antimonii Sulphureti ℥ij. Lapidis Pumicis pulverisat.—Aquæ distillat. lib. x.—The powdered antimony and pumice stone are to be tied in separate pieces of rag, and boiled along with the other ingredients. The use of the pumice stone is merely mechanical, to divide the antimony.

Emplastrum Ammoniaci, L.—Ammoniacum, reduced to a suitable consistence by distilled vinegar. It adheres to the skin without irritating it, and without being attended with any unpleasant smell. There is a peculiar disease of the knee, to which servant maids, who scour floors upon their knees, are liable, and for which this plaster is a specific. It is particularly eligible in cases of delicate women with irritable skins. A person of the name of Sterry, in the Borough, prepares a plaster of this description, which is sought after with great avidity.

Vesicatory Silk has been prepared as a substitute for the common blistering plaster. The following is the formula of Cadet de Gassicourt; Tincture of Cantharides, q. s., evaporate, and when in a state of sufficient concentration, spread it hot upon strained silk; it will be necessary then to spread two or three layers one upon another.

Guisbert's Epispastic Silk.—Mezereon bark oz. 24, Water 1,500 parts; boil, strain, and add Pulverized Cantharides, Myrrh, Euphorbium aa 24 parts; boil, strain through a double linen cloth, and evaporate until the liquor is of sufficient density to allow it to be spread upon waxed silk.

Baynton's Adhesive Plaster. (Strapping.)—Differs only from this preparation in containing less resin, six drachms only being added to one pound of the litharge plaster. This excellent plaster is sold ready spread on calico.

EXTRACTS FROM FOREIGN JOURNALS.

Experimental Researches upon the Formation of Arterial and Venous Cicatrices.

M. Amussat gives the following as his conclusions on this subject:—

1st. The frequency of aneurisms after wounds of arteries in the human subject had banished all hope of obtaining arterial *cicatrices*, and it had become a principle that wounds of arteries could not be firmly cicatrised. 2nd. His experiments upon living animals and some facts observed in man, prove the possibility of obtaining durable arterial *cicatrices*. They fully confirm the views of J. L. Petit and the theory which he had deduced simply from facts observed in the human subject. 3rd. Arterial *cicatrices* are never formed by the immediate reunion of the lips of the wounded vessel; these are always accomplished by the interposition of a clot of fibrine which adheres to the edge of the opening, becomes hardened, is organised and takes all the characters of the parietes of the artery with which it is identified. 4th. The results of general practice, in wounds of arteries in man, prove that much has been left undone in the way of obtaining solid arterial *cicatrices*. 5th. In general, too much haste is made in obliterating the wounded vessel, doubtless because great fear is entertained of wounds of arteries with the foreknowledge of inevitable aneurism. 6th. To obtain solid and durable arterial *cicatrices*, we must endeavour to maintain the clot in position, lower the action of the heart and keep the part in the most perfect immobility, in a word act as in fractures of the bones, that is to say, fulfil all the conditions necessary for obtaining perfect consolidation.

On the subject of venous cicatrices, he sums up in the following terms:—

1st. The cicatrices of venous wounds are formed in the same way as those in arteries, that is to say by a clot of fibrine, which closes up the wound and eventually becomes organised and united around the orifice, so as to form a species of *ampulla*. 2nd. The venous *ampulla* which exists after a wound, is merely the united cicatrix distended by the feeble impulse of the venous blood. 3rd. This *ampulla* is not an hernia of the internal membrane, as is generally believed, or as the experiment of inflating a vein would lead one to think. 4th. His experiments as well as observation on the human subject prove that venous *cicatrices* may take place in man, as well as in animals. 5th. The consequence to be derived from this fact, is the necessity of sustaining perfect compression for two or three days or even longer after the wound of a vein.

Dr. STEVEN'S THEORY OF VITALITY.

(To the Editor of the "Medical Times.")

Sir,—In a number of your periodical for Oct. 1st, 1842, there is an article giving an account of a new theory of the cause of vital phenomena (supposed to be by Dr. Stevens) in which it appears to me that the conclusions arrived at are not such as are necessarily deduced from the experiments made. Dr. Stevens has found that, after removing the brain and spinal cord from a living animal, respiration, circulation, assimilation, &c., still continue for a short time to proceed as before, and hence concludes that the brain and spinal cord are not the continents of the principles of vital action, and fixes on the solar ganglion as the seat of life, and further decides that mind or mental power has no effect, or very little in sustaining vitality, and that something else has, which he calls the VITAL AGENT OR LIFE. Now, I would ask, what difference does it make whether we say, at once, that an animal lives by means we do not comprehend, or say, with the appearance of great knowledge, that a VITAL AGENT produces vitality—that LIFE causes life. Are we after this lucid explanation, any more in the light than before? Do we know any better how animals live? I trow not. Dr. Stevens takes an animal, deprives it of its brain and spinal cord, and it lives afterwards, at the utmost seven hours. This proves that life does not merely consist in respiration, circulation, assimilation, secretion, absorption, &c., for these continue after the removal of the brain, and yet the animal dies; the creature not only requires to digest food, breathe, &c., but requires to obtain and masticate at first.

The experiments in my mind seem to shew that the brain is *most* necessary to life, and the short *apparently* vital existence, after its removal, may be most truly compared to the stoppage of a steam engine by extinguishing the fire, or letting off the steam, without injuring any of the machinery; the motive power is lost, but the machine still proceeds on its course stopping by almost imperceptible degrees, but by breaking any of the cranks, pistons, wheels, or other apparatus more immediately connected with the motion, the stoppage is more instantaneous, yet every one allows the fire or steam at least to be the real motive power. So with an animal, vital action does not cease so immediately on the removal of the brain, as on the removal of the heart, lungs, &c., which are, nevertheless, not the principal agents in vitality. But this illustration may be carried further. The experimenter says, mind is not the origin of life. No doubt he will say, that the motion of a steam engine is independent of mental power—but what would it be without mind? Should we have any steam engines at all, are they not outbirths of the inventive powers of the mind of man? And are not the improvements in them consequent on superior mental powers? Is not the mind of man continually aiding them in their course and keeping them under controul? Take for a time the direction of mind away and collisions, explosions, and death will follow. Just so with animals and all nature, they are outbirths of the mind of the Creator, who is continually acting, in creating, protecting, and guiding them, and as he has given to man a capability of improvement, and faculties approaching *nearer* to the divinity, so he leaves him, *in a measure*, to his own guidance, and gives him a species of controul over inferior nature; but as instinctive creatures, possess no mental faculty of their own, they are immediately under the guidance of their Creator, who directs them in the way suited to their state and character, and each in his peculiar kind is perfect; his instinct, i.e., the direction of the Allwise leading him to do that only for which his conformation suits him, and the opinion of an old writer is much to the point, where he says "*Deus est anima brutorum.*" Another point, Dr. Stevens touches on, is Somnambulism, and he says, that in this state the *mind is asleep*, the body and the *vital agent* active. The fact, I think, will be found to be that the *body* is asleep, and the mind fully *awake*. Thus a person asleep, gets up, dresses himself, and goes to write, and though a board be placed between his eyes and hand, he still writes as correctly as before. Does not this shew that the eye of the body transmits no impression to the mind, being asleep, but that the mind in its intense activity actually raises the dormant body, and causes it to perform its functions almost as if awake. I was told a day or two since of a person in the habit of sleep-walking; my informant who saw him in this state, knelt before him, and the somnambulist fell over his prostrate body and awoke. Here had there been no fresh object in the way, the sleeper would have continued his course, having in his mind the impression of the positions of the articles in the room, but

this fresh obstacle was not made known to his mind by the sleeping outward senses, and consequently not avoided, the sudden jerk roused him and the objects were distinctly perceived. Their not recollecting, on awaking, the circumstances occurring when asleep, arises from the fact, that the remembrance of actions is caused by the impressions made on the mind through the senses, which cannot be the case when the senses sleep; the ideas directing the somnambulist being those formed whilst awake.

A SUBSCRIBER.

MAXIMS IN MIDWIFERY.

By Edward Elton, M R C S.

OF THE PELVIS, ITS ARTICULATIONS AND THEIR DISEASES.

I.

The bones of the adult pelvis are four in number—the two ossa innominata, the sacrum, and the os coccygis. The latter of these presents the greatest interest to the obstetrician, from its cartilaginous and osseous portions possessing a minor degree of flexibility when pressed upon by the passage of the fœtal head.

II.

The ligaments of the pelvis are the obturator and sacro-ischiatic, but they are of little importance in connection with active parturition. The obturator ligament has an aperture transmitting the vein, artery, and nerve of that name—the latter is sometimes injured and compressed during the passage of the fœtal head through the pelvis. Preternatural rigidity of these structures is an occasional cause of lingering and retarded labour.

III.

Anchylosis of the sacro-coccygeal articulation is a very rare affection, but rigidity of this structure, in women who marry late in life, may occur, offering a considerable impediment to the expulsion of the head, by contracting the pelvic outlet, and forming another cause of lingering labour. Sitting, sedentary persons as milliners are very liable to this affection. Disruption of this joint, from forcible and violent pressure of the vertex is spoken of by Denman; inflammation may occur from similar causes, and suppuration of these parts sometimes happens in scrofulous subjects.

IV.

The articulation of the symphysis pubis is liable to inflammation, and quickly becomes the "subject of suppurative action, attended with high constitutional excitement and no small danger." This affection is of a very distressing character, and very difficult of cure, commonly confining the patient to the bed or the sofa for many months. It is to be treated in the most active anti-phlogistic manner, especially if it occur (which it is very apt to do) in scrofulous women, with blue eyes, fair complexion, flaxen hair, and attenuated skin. Leeches, blisters, issues, and setons, may be employed according to the active or chronic character of the disease. Avoid debility, and subdue the complaint as quickly as possible, is a maxim of mighty truth in every department of obstetric medicine.

V.

Relaxation of the symphysis pubis may occur independent of pregnancy, but it most frequently happens in connection with it. A painful state of uneasiness, which gradually increases until every position becomes one of great suffering, invariably developes itself during the progress and presence of this affection in the absence of parturition. But when that period supervenes, the woman will tell you that "her bones are in motion." Dr. Blundell states that he has "heard them move;" and that, upon making an ordinary examination, "the motion may be distinctly felt." After parturition, the joint recovers its lost powers in many cases, but its abnormal relaxation may "recur in an increased degree, with each succeeding gestation." In treating this peculiar and painful affection, the constitutional remedies indicated are, bitters, tonics, and alteratives,—whilst the local ones consist in plunging the hips into very cold water (a plan first recommended by Denman), a well-contrived, unyielding bandage, to bring the relaxed parts into closer contact, and keeping the extremities of the bones bearing upon each other, by a slight though firm pressure, whilst the patient should be kept at perfect rest, in the recumbent position.

VI.

The sacro-iliac synchondrosis is equally liable, with the symphysis pubis, to relaxation of its cartilaginous and ligamentous textures. Great pain in the back, and total incapacity of standing without firm, external support, are the symptoms mentioned by Sir C. Clarke, which "will enable you with facility to detect the disease in most instances." Blundell quizzically recommends medical men to remember that *women* are liable to this affection. Time has been known to cure this species of relaxation, but a strong, broad, bandage-belt would undoubtedly be of more service in this case, than in the one alluded to in the last maxim, from the affected articulation affording a broader surface for pressure.

OF THE PELVIS CONSIDERED OBSTETRICALLY.

VII

The standard pelvis of a woman has been divided into the true and false pelvis; and the former of these has been sub-divided into its superior part, or "brim," its inferior part, or "outlet,"—whilst the intervening space has received the name of the "cavity of the pelvis." The brim, whose osseous portion is chiefly formed by the ilium, is elliptical in shape, its regular oval being broken by the promontory of the sacrum—its average width between the sacrum and pubis is four inches—its average dimension, from side to side, is five inches—its oblique dimension, which stretches between the acetabulum on one side, and the sacro-iliac synchondrosis on the other, is $5\frac{1}{4}$ inches; these are nice points, but of great importance to remember. The "outlet," into which the ischium and pubis both enter, is more square than the brim, and its relative diametrical dimensions, as above described average four inches in either direction. But the diameter of this inferior portion may be elongated about one inch by the flexibility of the os coccygis, alluded to in my first maxim. It must be borne in mind, therefore, that, whereas at the "brim" the long measure is from side to side, and the short measure from before backwards—at the "outlet" the very reverse of this is the fact, the greatest dimensions there being from before backward, whilst the lesser one is from side to side.

VIII.

The cavity of the pelvis is of various depths,—in front it may be shallow, behind it may be deeper. This fact should be borne in mind in making an examination. "The greatest depth is from the sacral promontory to the tip of the coccyx, and should be from five inches and a half to six inches; at the side, from the lowest point of the tuber ischii to the brim, three inches and a half; and behind the symphysis pubis, one and a half."* Of the arch of the pubis it may be observed, that it is at the point of this arch that you will always find the orifice of the female urethra in the absence of active parturition. You will find this arch to vary very much, being of a wider space in some women than in others;—so important is this, that it may be truly observed that the wider the pubic arch, the wiser will be the child. It is of the greatest importance that every student should be correctly acquainted with the normal incurvature of the pelvis. Let him always, therefore, remember that the axis, or central line of the "brim," is downward and backward, whilst that of the "outlet" is downward and forward;—how very important and how very easy it is to recollect these "small matters," on which the lives of hundreds placed in our hands may depend.

IX.

It would be a most fortunate thing if every child-bearing woman possessed a standard pelvis of the size and diameter already alluded to—but, alas! this is not always the case. The pelvic shape and cavity may be distorted from their normal shape, and contracted in volume and capacity, by the presence of rachitis in youth, or malacosteon in adult age, in each of which the osseous system is found to be defective in solidity and strength, from the earthy matter entering into its formation being deficient in quantity, and the animal matter being in excess. This deformity may be partial, when either the brim, the cavity, or the outlet alone, are affected—or it may be general, when all these parts partake, more or less, of the deformity. "If the vicious formation be confined to the brim, the diminution in size is almost always produced by the promontory of the sacrum jutting too far forwards, and by this means contracting the conjugate diameter; if to the cavity, by the sacrum being too straight, so that the bone does not possess its due curvature; if to the outlet, by the tuberosities of the ischia approaching too near each other, or by the spinous processes of the same bones being too long, and directed too much inwards; or, again, by the joints of the coccyx having become anchylosed, and thus lost their mobility. Of these irregularities—the most frequent is that met with at the brim—the most rare, an undue straightness of the sacrum."*

X.

This contraction of the pelvis may be elliptical at the brim when the sacral promontory approaches to the symphysis pubis, and the diameter from before backwards becomes diminished, whilst that from side to side is increased; or it may occur at the outlet, when the symphysis pubis may approximate to the lower portion of the sacrum and coccyx, rendering the passage of the fœtal head utterly impracticable. But this distortion may be angular at the brim by the sacral promontory and acetabula being pressed in upon the axis of the pelvis—or at the outlet by the approach of the tuberosities of the ischia and the incurvature of the sacrum and coccyx.

XI.

The elliptical distortion is generally supposed to be caused by rachitis, whilst the angular has been considered to arise most frequently from malacosteon.

XII.

In delivering women who unfortunately labour under pelvic deformity, it may be laid down—1. That a living child may be brought into the world through a pelvis which has a clear available space of three inches in the conjugate by four in the lateral diameter.—2. That unless there be a space at the brim of

* Ramsbotham's Obstetric Medicine and Surgery.

* Ramsbotham's Obstetric Medicine and Surgery.

one inch and three-eighths in the conjugate by three and a half at the iliac, or one inch and a half in the conjugate by three in the iliac, it would be useless to attempt delivery by the natural passages, but it is very rare to find the lateral diameter at the brim less than three inches.

XIII.

The obstetric treatment of a woman in labour, who has a contracted pelvis, is one at which the stoutest heart may well stand appalled. In such cases, Nature has fearfully departed from her course of wise and adaptive conformation, and art and science must step in to save the life of the sufferer. If there exist not an adequate extent of space as before alluded to, embryotomy must be had recourse to, or the more dangerous performance of the Cæsarean section—an operation whose very contemplation is dreadful, and which (with three exceptions only) has hitherto proved fatal to the mother in this country.

XIV.

The following maxim may be relied upon as correctly diagnosticating such fearful cases.—"Whatever may be the deformity of the spine, if the legs are straight, the pelvis will be found well-shaped, but if the legs are crooked the pelvis is deformed. If women walk with their toes much turned out, they have a narrow pelvis, the acetabula being nearer to each other than in a well-formed pelvis and the symphysis pubis being very sharp; such women suffer much in labour."*

GENTILITY-MONGERING.

(*From Blackwood's Magazine for March.*)

There is another class of gentility-mongers more to be pitied than the last; those, namely, who are endeavouring to "make a connection," as the phrase is, by which they may gain advancement in their professions, and are continually on the look-out for introductions to persons of quality, their hangers-on and dependents. There is too much of this sort of thing among medical men in London, the family nature of whose profession renders connection, private partiality, and personal favour, more essential to them than to others. The lawyer, for example, need not be a gentility-monger, he has only to get round attorneys, for the opportunity to show what he can do: when he can do this, in which a little toadying, "*on the sly*," is necessary—all the rest is easy. The court and the public are his judges; his powers are at once appreciable; his talent can be calculated, like the money in his pocket; he can now go on straight forward, without valuing the individual preference or aversion of any body. But a profession where men make way through the whisperings of women, and an inexhaustible variety of *sotto voce* contrivances, must needs have a tendency to create a subserviency of spirit and of manner, which naturally directs itself into gentility-mongering: where realities, such as medical experience, reading, and skill, are remotely, or not at all, appreciable, we must take up with appearances; and of all appearances, the appearance of proximity to people of fashion is the most taking and seductive to people *not* of fashion. It is for this reason that a rising physician, if he happen to have a lord upon his sick or visiting list, never has done telling his plebeian patients the particulars of his noble case, which they swallow like almond milk, finding it an excellent *placebo*. As it is the interest of a gentility-monger, and his constant practice, to be attached to a fashionable physician, in order that he may be enabled continually to talk of what Sir Henry thinks of this, and how Sir Henry objects to that, and the opinion of Sir Henry upon t'other, so it is the business of the struggling doctor to be a gentility-monger, with the better chance of becoming one day or the other a fashionable physician. Acting on this principle, the poor man must necessarily have a house in a professional neighbourhood fashionable or exclusive; he must hire a carriage by the mouth, and be for ever stepping in and out of it, at his own door, keeping it purposely bespattered with mud to show the extent of his visiting acquaintance: he must give dinners to people "who may be useful," and be continually on the look-out for those lucky accidents which have made the fortunes, and, as a matter of course, the merit, of so many professional men.—He becomes a Fellow of the Royal Society, which gives him the chance of conversing with a lord, and the right of entering a lord's (the president's) house, which is turned into a sandwich-shop four times a-year for his reception; this, being the nearest approach he makes to acquaintance with great personages, he values with the importance it deserves.—His servants, with famine legibly written on their brows, are assiduous and civil; his wife, though half-starved, is very genteel, and at her dinner parties burns candle-ends from the palace.—If you pay her a morning visit, you will have some such conversation as follows.—"Pray Mr.——, is there any news to-day?"—"Great distress, I understand throughout the country.' "Indeed—the old story, shocking—very.—Pray have you heard the delightful news? The Princess-Royal has actually cut a tooth!"—"Indeed?"—"Yes I can assure you; and the sweet little royal love of a martyr has born it like a hero."—"Positively?"—"Positively, I assure you; Doctor Tryiton has just returned from a consultation with his friend Sir Henry, upon a particularly difficult case—Lord Scruffskin—case of elephantiasis I think they call it, and tells me that Sir Henry has arrived express from Windsor with the news."—"Indeed!"—"Do you think, Mr. ——, there will be a general illumination?"—"Really, madam I cannot say."—"There ought to be [with emphasis.] You must know, Mr. —— Dr. Tryiton has forwarded to a high quarter a beautifully bound copy of his work on ulcerated sore throat: he says there is a great analogy between ulcers of the throat and den—den—den—something, I don't know what—teething, in short. If nothing comes of it, Dr. Tryiton, thank Heaven, can do without it; but you know Mr——, it may, on a future occasion, be *useful to our family*."

* Dr. Macintosh's unpublished lectures in Midwifery quoted in Blundell's Principles and Practice of Obstetric Midwifery.

ADVERTISEMENTS.

THE MEDICAL TIMES.

A Journal of English and Foreign Medicine and Medical Affairs.

No. 183. Vol. VII. LONDON, SATURDAY, MARCH 25, 1843. PRICE FOURPENCE. Stamped Edition 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance), are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Summary.—*Various determinations given to the middle region of the brain, (Gall, Cuvier, Tiedemann, Treviranus, &c.)—Application of the principle of connexions as well as of the facts elicited by organogeny, in the determination of the elements of the brain in the four classes of vertebrata, and of the os quadratum of birds—Aid given by this principle to oology—Determination of the umbilical vesicle (Sœmmering, Wrisberg), and of the allantoid (M. Dutrochet), by the principle of connexions.*

We have stated in our preceding remarks that the chain of analogies, as exhibited in man and the mammifera was broken in birds. How was it that this interruption took place? Evidently, in consequence of the new forms presented by the middle region of their brain. To reduce these forms to those of the mammifera which serve as the type, the method so successfully adopted by Geoffroy Saint Hilaire presented itself; namely—to seek in the brain of the fœtus of the mammifera an organ corresponding in form to that of the middle portion of the brain in birds; such appeared to me at first the most likely means of reaching the solution of this problem. In execution, however, I was arrested by a difficulty which, for some time, seemed insurmountable. The human embryo at no period of its existence reproduces in the brain a form at all resembling that of the middle region of this organ in full-grown birds. This form is entirely peculiar and characteristic of this latter class. Discouraged by failure, I was about to renounce my efforts, when the idea occurred to me of comparing together the embryos of the two classes. In fact, if we consider on the one hand that this middle region is one of the most complex and most perfectly organized parts of the brain in birds; and, on the other hand, if we regard the atrophy of these parts (or of those which, according to Gall and Cuvier, we may consider as their *analogues*) in the mammifera and man, we shall find that there could be but little comparison between the two. For though the *tubercula quadrigemina* in the embryos of the mammifera are constituted by two vesicular lobes as those of birds, their situation and structure are so different, that the dissimilitudes greatly surpass the analogies; in the embryos of the mammifera, the lobes form a very marked projection upon the upper surface of the brain, and are, in fact, its most prominent part; in birds they are invisible upon this surface, and in their place we find a quadrilateral layer. In the full-grown bird, these lobes are contracted upon the sides, and form, at the base of the brain, the projection, which, in the mammifera, is found at the opposite surface. We see, then, that the two terms of comparison were formed from the opposite surfaces of the brain in the two classes.—Lastly, the embryonic lobes of the mammifera are in contact; those of birds, on the contrary, are greatly distant one from another, though united together by the commissura magna, formed by alternate striæ of white and grey matter.

If, in spite of such dissimilitudes, some anatomists (as Gall, Cuvier, Tiedemann), have drawn together parts so different, the heterogeneous characters which they presented gave rise to doubts, and so led to new theories. Thus, after the work of M. Tiedemann, M. Treviranus revived the views of Haller and Malacarne, which he modified in a very ingenious manner, thinking to have discovered the tubercula quadrigemina of this class in a small swelling situated over the sides of the aqueduct of Sylvius, and upon the transverse layer which serves as a covering to this aqueduct. If M. Tiedeman could cite in favour of his opinion the cavity of the lobes in the human embryo and the opening between this cavity and the aqueduct of Sylvius, M. Treviranus could allege in favour of his views the fixed position of the parts which he compares in the two classes.—Moreover, he found in the adult mammifera solid tubercles, like those of birds. His hypothesis was the more attractive, inasmuch as he had not only discovered the four tubercles of the mammifera, but also found in the middle lobes of birds the analogues of the corpora geniculata of the upper class. M. Rolando again regards the middle part of the brain in birds as corresponding to the optic thalami of the mammifera; while M. de Blainville, in a work published in 1821, assimilates this region to the cerebral hemispheres of the upper class.

We thus perceive that in this short space of time, four distinct theories were advanced on this subject:—1st. That of Gall, Cuvier, Arsaki, and Tiedemann, who assimilated this part to the tubercula quadrigemina.—2. That of M. Treviranus, who thought to have discovered in it the four tubercles, as also the corpora geniculata.—3. That of M. Rolando, who compared it, as Willis and Vicq-d'Azyr had done, to the optic thalamus.—and 4. That of M. de Blainville, who considered it as analogous to the cerebral hemispheres. If anything positive could be deduced from these different opinions, it evidently was that this middle region of the brain in birds was not accurately determined; and this common accord of anatomists, in directing their whole efforts towards this region, attested that all were of opinion that here lay the source of their incertitude upon this part of comparative anatomy, and that here also we ought to seek the key which might dissipate those doubts. Now, whenever a difficulty of this nature presents itself in the sciences, we should, according to the precept of Bacon, erase from our minds all that has been said or done upon the subject, and then proceed in our researches upon new facts and new observations. We shall then find, as this illustrious philosopher has said, that facts speak more strongly than words.

In fact, it required, in this state of anatomy, a determination which, effacing all the dissimilitudes of which we have spoken, and restoring the middle lobes of the brain in birds to that position from which they have been displaced, should assign to them the same limits which they occupy in man, the mammifera, reptiles, and fishes; a determination which, to this unity of position, should join unity of form, of structure, and which, to complete the application of all the rigorous laws of anatomy, should likewise join to them unity of relation or connexion. Then should we be enabled to tell not only what functions this part possesses, but likewise what it does not possess. Now, such a result we can hope to obtain only by the pursuit of comparative embryogeny.

A. *Unity of Position.*—I will preface my remarks by saying, that I have assigned the common name of *optic lobes* to this part, in all classes, by reason of its constant connexion with the optic nerve. On tracing the formation of these lobes, we find them situated upon the superior surface of the brain in the bird on the third, fourth, fifth, sixth, seventh, and eighth days of incubation. They then make upon this surface the same projection as the lobes of the tubercula quadrigemina in the human embryo at the second month; in the sheep and calf, at the fifth and sixth week; in the tadpole, or young frog, from the tenth to the twelfth day of formation; and in fishes, throughout all the conditions of their permanent organisation.

B. *Unity of form and of structure.*—At the above period of incubation in birds, the optic lobes are of an oval figure, somewhat depressed inwards, similar to the tubercula quadrigemina in the human embryo as well as in that of the calf, of the sheep, of the fish, &c. Their interior is hollow, and filled by a liquid in all classes. In all, the walls are formed of a thin layer, at first separated from its fellow, but soon afterwards becoming intimately united.

C. *Unity of connexion.*—These lobes in all classes cover over the aqueduct of Sylvius. In birds, as in all other classes, we constantly find at the posterior part of these lobes, the insertion of the fourth pair of nerves; in front and below, that of the optic nerves; in front and above, the pineal gland and its peduncli; while anteriorly, their cavity opens into the third ventricle, and posteriorly into the fourth. If we could, at will, arrest the forms of the brain in all classes at this period, we should see how simple would be the comparative anatomy of this part—or rather, we should find nothing but a system of analogies throughout organised beings. But if, quitting embryonic life, we suddenly come to the perfect animal, a very different picture presents itself to our notice. A total change takes place in the optic lobes of birds; the insect is not more different from its larva, the butterfly from its chrysalis, the frog from its tadpole, than the optic lobe of the adult bird is from the same organ in the embryonic bird. A complete metamorphosis takes place, in which every thing becomes changed, excepting the connexion. In fact, in the semi-circle, accomplished by each optic lobe in its rotation around the cerebral peduncle, the fourth pair of nerves, the optic nerve, the pineal gland and its peduncli, remain invariably in the same place, evidences, as it were, of their primitive analogy in birds, as well as of their permanent analogy in reptiles and fishes.

Now, this middle region of the brain being known and determined in all classes, the knowledge of all the other parts is necessarily derived from it; this is, as we have already said, the key to this so varied organ in the series of the vertebrata. Thus, behind the optic lobes, we find the cerebellum: an organ impossible to be mistaken, whether it be reduced to its smallest dimensions, as in reptiles, or carried to its maximum of development, as in the mammifera and man; or, lastly, whether we find it in its fixed forms, as in birds, or in the variable forms which it presents in fishes. So also with the cerebral lobes which, though not less variable in their forms than the cerebellum, cannot for an instant be mistaken in any class. Again, the pair of lobes placed on the fore-part of the cerebral hemispheres always represent the olfactory lobes, whether they equal in size the cerebral lobes, as in certain fishes, or are almost totally absent, as in nearly all birds and some mammifera; whether finally they are placed upon the same line as the cerebral lobes, whether they are concealed at their lower part, or project far beyond them, as in many reptiles. Such are some of the numerous diversities brought to a state of unity. No one, then, at the present day can doubt that the brain of vertebrated animals may be brought to an uniform structure, and that the laws of its variations may be determined.

The rigorous determination of the organic elements is, then, the basis of comparative anatomy, and organogeny one of the most positive means of arriving at this result. This determination becomes especially difficult in the apparatus of the life of relation, when, in their dismemberment, the parts composing them change in design or use, and become differently associated to produce new functions. Function then ceasing to direct the anatomist, it became indispensable to have recourse to other characters drawn from the organs themselves while undergoing these transformations. Among these anatomical characters, that of connexions deserves especial attention. We have just seen its application in the determination of the elements of the brain; and another instance will be found when studying the bony apparatus placed upon the sides and base of the cranium, and which are so diversified in the series of animals.

What combinations must have been attempted before discovering that the little bones of the ear are transformed, in fishes, into bony processes, assisting to form the respiratory apparatus! What concord in the results brought about by anatomy and by pathology to show us that the facial nerve is a nerve of respiration! It seemed a still more difficult matter to explain the os quadratum in birds: it was necessary, in fact, first to discover the parts which enter into its composition, and to deduce the individuality of these parts from the same necessity of use which they have in the mammifera and man. The frame of the tympanum forms a ring at the entrance of the external auditory canal. Now, the whole ring is formed of two pieces at least, as we have already said. Such I have always found to be the case in the young embryos of the mammifera and man. These two small bones, which have been named by Geoffroy Saint-Hilaire, the tympanal and the serrial, are always distinct in early age. Now, to this bony process we afterwards find added a third, applied against the base of the petrous portion of the temporal bone, and of which the object, in man, is to complete the carotid canal: this is the cotyleal of M. Geoffroy. By its body, this bone partitions off the entrance of the carotid into the the cranium, and, by its extremity, it aids in forming the cavity designed for the articulation of the inferior maxillary bone. The internal carotid being carried in man to its highest point of development, the body of the cotyleal is enlarged in the same proportion, its articular extremity, being, at the same time, atrophied. But in proportion as we descend from man, the internal carotid being diminished in size, the carotid canal itself is lessened, and consequently the body of the cotyleal is more and more reduced; but what the body of the bone loses in volume is gained by its extremity, which, embracing the base of the tympanal and the serrial, forms in the genus felis, the external auditory concha, named the caisse, or drum, by M. Cuvier. This drum is thus composed of the tympanal, the serrial and the cotyleal bones; on a level with them we find the stylhial, devoted to the functions of the hyoid bone. Now, in birds, the stylhial becoming united with the other three bones, a moveable bone having four surfaces is formed: this is the os quadratum, a kind of regulator to the movements of the maxillæ in this class. It thus results from the variations of functions in these different bones, that the only character to which they are subjected, is that that of connexion; and this connexion may be also remarked in reptiles, and especially in fishes, in which classes these parts remain entirely separated in the young embryo.

The principle of connexions is, in animal organogeny, a guide equally sure and fertile in its results as that of insertions in vegetable organogeny. The one corresponds to the other, and both are in a particular manner applicable to phytogeny and zoogeny, especially the latter, by explaining the earlier developments; for the organisms being primitively isolated, we may conceive that their association must take place in a fixed and predetermined order, so as to accomplish their formations. Now, the connexions are the bonds by which these necessary relations are established, and these bonds frequently become the distinctive signs of the organisms, and the bases of the comparisons which are drawn between the different classes of animals. So far we are guided by zootomy, without the aid of comparative anatomy.—This latter science can, in fact, only commence when the determination of analogous organisms has been already accomplished in the animal series.

Ovology was very early cultivated. Hippocrates, Aristotle, Galen, &c. studied with zeal the adventitious coverings of the embryo; Malpighi, Graaf, Needham, and their contemporaries pursued his branch with equal perseverance. Ovology advanced under their guidance, but not comparative ovology: comparative ovology is principally of recent date, and its rapid progress, together with its great certitude, have fully demonstrated the power of the principle of determinations, of which this science is but an application. We know that the ovology of birds serves as the term of relation to comparative ovology; we know also the important part which the vitellus plays in this class, both by reason of its size and of its connection with the intestine, by the vitello-intestinal pedicle. This organism, carried in them to its maximum of development, entirely eluded the notice of observers in man, on account of its extreme minuteness. Albinus originally perceived an isolated vesicle in the fœtal membranes. Sœmmering, who also observed it, was the first to indicate its relations with the intestines; and Wrisberg described in the young embryo the vitello-intestinal pedicle, so as to leave no doubt of its analogy with the vitellus of birds. It is by this determination, established at the two extreme points of its existence, that science has been guided, and hence the progress made in the study and comparison of this organ throughout the animal kingdom. The determination of the allantoid was, however, a more difficult matter. In birds this membrane had been mistaken, by reason of the differences, irreconcileable in appearance, which separate it from that of the ruminantia, in which class, like the vitellus in birds, it is carried to its maximum of size. Now, what is the connexion of this organism in the ruminantia? It is a double bladder, constricted in the middle. One of these bladders occupies the pelvis of the embryo; the other is lodged in its membranes. The constriction is formed by a hollow pedicle uniting them together. Now, this is exactly a repetition of the connections of the umbilical vesicle with the intestine. It was this connection which M. Dutrochet took as his basis when he named this membrane the ovo-urinary bladder; and this denomination, recalling its principal anatomical attribute, has become the guide which has directed anatomists in this formerly so confused, but now so accurate, part of comparative ovology. This result has been brought about by a rigorous mode of determination alone. So also was it upon the connexions of the ovum with the membrana decidua that Hunter based his description of this membrane.

These results, however remarkable, are, perhaps, less striking than those which have recently established the comparative anatomy of the proliferous vesicle. The anatomists of the 17th century were perfectly aware of the existence of vesicles in the ovary of the mammifera as well as in that of the human race. Unfortunately these vesicles were compared to the ovum of birds, and this error of determination destroyed the application of this discovery for more than an age. Graaf, however, who first pointed out the ovarian follicles, stated that they became ova only in the uterus; but his explanations on this subject were extremely confused. Haller and his school imagined the Graafian vesicles to be filled with a fluid which, at the moment of impregnation, escaped into the Fallopian tubes. Hayston endeavoured to prove this position, while Cruiskamp on the other hand, laboured to refute it by numerous and precise experiments. Still, after volumes written on this subject, the question was abandoned by reason of the failure of the modes of determination then adopted, to bring the facts which it embraced within the domain of comparative anatomy. But on reconsidering these facts, according to their true *signification*, as so happily expounded by the German anatomists, we shall see exhibited an exact knowledge of the Graafian vesicle, as well as of the ovule enclosed in its interior, the discovery of the proliferous vesicle, and its conversion into the blastodermic membrane, as the effect of impregnation. Comparative anatomy will thus succeed to zootomy; for these parts once accurately determined in a class, their application will immediately take place in all others. Placed by this order of researches at the commencement of animality, we shall pass without interruption or gap from the vertebrata to the invertebrata, and appreciate with their just value the modifications which all these parts undergo in the different scales of the animal series. To ovology will succeed comparative ovology, and this, in its turn, becoming confounded with ovogeny, is a new proof that comparative anatomy and organogeny are often one and the same thing. Such is precisely the case, and this affords an explanation of the rapid progress of ovogeny. Facts were not wanting to the anatomists of the seventeenth and eighteenth centuries to enable them to found comparative ovogeny. Why, then, was it not founded? Evidently because there was a something wanting to these facts to enable them to be compared one with another, and thus to exhibit the bonds which ought to unite them together. However numerous they might have been, their affinity was not perceived, because they remained undetermined. This determination has more recently been accomplished by means of a precise principle, and comparative ovology, as well as ovogeny, have progressed rapidly towards their degree of perfection.

We shall shortly see, that the same kind of indetermination has also arrested the progress of general embryogeny. The same cause holds, as it were, apart the organisms of invertebrated animals. Their zootomy so advanced, so rich in some particulars, is almost barren in what regards comparative anatomy. The one half of the animal kingdom is foreign to the other. Let us then attempt to draw them together by fixing the determination of that among the organic systems which, in the branch of the invertebrata, rules and governs all others—the nervous system; while, at the same time, we endeavour to render intelligible those anomalies which this branch presents when compared with that of the vertebrata.

SHORT APHORISMS ON THE TREATMENT OF UTERINE HÆMORRHAGE.

By CHARLES CLAY, Member of the Royal College of Physicians, London, &c. &c., Lecturer on Medical Jurisprudence, Manchester.

In the following brief observations it is my wish to give (intended chiefly for junior practitioners) an Epitome of the nature and treatment of Uterine Hæmorrhage, founded on practical experience. There is no point of obstetric duty that calls for greater display of energy and presence of mind, and none more trying, under many circumstances, than this; and it is so frequently occurring in every practice, that it soon convinces a tyro in the profession of its great importance, and that he should be well prepared with the general views entertained on such an important question, in order that he may meet the most extreme case on any emergency, with that judgment and determination which often ensure success, and increase the confidence of those placed under his management. The subject of uterine hæmorrhage has been much better understood of late years than formerly, and there are many excellent writers who have taken up this subject alone, extensively, and with that judgment its importance demands; many of them, however, are too lengthy for practical purposes, or to be easily borne in mind by the junior part of the profession, who must depend (for a time, in a great measure) on the experience of others. Such is the epitome of general practice I propose to give, shewing every feature under which such occurrences may exist, and in so concise a manner as to be brought almost within the immediate glance of those for whom these observations are intended.

The term, *Uterine Hæmorrhage*, is applied strictly to a flow of blood, per vaginam, from the inner surface of the uterus (with the exception of what is termed internal hæmorrhage, where the blood, instead of passing out of the vagina, collects

within the uterine cavity), attended by particular symptoms and appearances, which may be considered as either accidental or unavoidable.

General Causes of Uterine Hæmorrhage.—One of the principal causes of hæmorrhage, *before childbirth*, is the separation of the ovum from the internal surface of the uterus, wholly, or in part. *After childbirth*, the cause rests on the partial or entire absence of contractile force, in the uterus itself. The placenta, receiving its supply of blood directly from the internal surface of the uterus (to which it is adherent for that purpose), it follows, as a matter of course, if the whole, or any part of it, should be prematurely separated from its attachments, hæmorrhage must unavoidably occur, because the uterine cavity is not in a condition to obliterate the mouths of the vessels by contraction; in consequence of which, the blood flows into the cavity, distends it, excites uterine pain, dilates less or more the os uteri, and finally escapes from the vagina. Premature separations of the placenta may generally be traced to falls, blows, passions, fits, violent muscular exertions, &c. After delivery, the principal cause is, a want of power to contract in the uterus itself; thus, the mouths of the blood vessels, which contraction would otherwise obliterate, remain undimished in size; hæmorrhage is therefore the consequence, whenever any interruption arises to this beautiful provision of nature.

Character of Hæmorrhage.—Hæmorrhage varies in its character. Sometimes of very trifling extent; at others, in quantity almost incredible: sometimes of a thin consistence, filtering away almost insensibly, whilst, at others, in large, coagulated masses, the vessels rapidly emptying themselves, producing syncope, which sometimes gives a slight check to flooding, but is immediately resumed when the patient recovers. The quantity of blood lost is often surprising, without any serious injury to the female. I have had many cases which recovered without one bad symptom, after the loss of a fearful discharge of blood, and such cases have often impressed my mind with the fact, that pregnant females will bear far more extensive depletion than at any other time of life. That more blood in proportion exists in the pregnant female, there can be little doubt, and less on the supposition that more is required before childbirth for fœtal circulation, and after childbirth for the secretion of milk—borne out by the fact of severe cases of floodings being much longer before the secretion of milk appears, and in some very extreme cases it does not appear at all.

Progress of Hæmorrhage.—If the hæmorrhage be slight, and has not continued long, the prognosis may be favorable, but if it dribbles constantly away, and has continued long, the prognosis must be a guarded one. Indeed, in all cases of hæmorrhage, it is well to be very guarded at least, in prognosticating too positively, for many cases have sunk after the most effectual assistance, and when the discharge has been but trifling, and many others have got well, after a loss that, at the moment, appeared next to impossible. The time it has continued is of great importance to be considered. If the flooding is rapid, and large in quantity, the worst is to be feared, and prepared for. The external appearance of the female assists much in forming prognostics. I have known little, delicate, thin women, bear large depletion by hæmorrhage, much better than the more robust and plethoric, and it is such that are generally more liable to it. I have also observed that hæmorrhage occurs more frequently in the middle and higher classes than in the lower orders of society.

Symptoms of the Milder Species of Hæmorrhage.—These are better understood when seen than described; pallid countenance, languor, nausea, small quick pulse, profuse perspiration, chilliness, syncope, with more or less discharge of blood.

Of the Severe Species.—The symptoms are syncope, alternating with rapid and extensive floodings, often in large coagulated masses. Sometimes, continued syncope, languor, vomiting, dim eyes, rapid small pulse, cramps, cold clammy sweats, convulsive motion of the depressor anguli oris, tinnitus aurium, &c. &c.

Cause of Hæmorrhage during the First Stage of Labour.—As already stated, this is owing to an entire or partial separation of the placenta from the inner uterine surface. One of the worst species of hæmorrhage is that arising from *the misplacement of the placental mass*; its usual attachment is to the sides, or fundus, but occasionally it is found adherent over the os uteri. In this case it is not necessary to produce hæmorrhage, *that either a partial or entire separation from the uterine surface should take place.* It is caused by uterine action (prematurely or otherwise) dilating the os uteri, (which, however slight) tears the vessels of the placental mass asunder, producing a fresh gush of blood at every pain. It would perhaps be more strictly correct to distinguish these cases from the rest by the term *placental hæmorrhage*; as uterine hæmorrhage can only be properly applied *to those cases where the hæmorrhage is directly from the vessels on the inner surface of the uterus.* During the first stage *of first labours* there is a discharge of blood, often to a considerable extent, but which is not to be taken for uterine hæmorrhage (as I have known two instances where young men of little experience did so consider it), as it is quite independent of hæmorrhage, and unaccompanied with any of its symptoms. This is often the case with females who commence having children much later in life than usual.

What is to be done on Hæmorrhage occurring during the First Stage of Labour.—The first step is to ascertain the cause, and this can only be effected by an examination per vaginam; and having once introduced the hand for that purpose, it should never be withdrawn until the case is perfectly understood. The placenta will be found attached either over the os uteri, or higher within the uterus; if the former, the hæmorrhage will be placental, from the torn vessels by the dilating of the os uteri by uterine action; this case is easily detected by the soft cushion presented at the uterine orifice to the touch of the finger, and the peculiar gushes of blood at every pain, with the inability to define the presenting portion of the child beyond the cushion. But if the hæmorrhage proceeds from a partial, or complete, premature separation of the placenta from the sides, or fundus of the uterus, these characteristics are absent (with the exception of the flow of blood), and the examination (per vaginam) presents no unnatural deviations to the touch, but from the existence of hæmorrhage the conclusion to be drawn is, that the placenta is situated in the higher portions of the walls, or fundus of the uterus, and wholly, or in part separated from its inner surface.

Treatment of Hæmorrhage when the Placenta is in the higher portions of the Uterus.—This is either palliative or radical. *The Palliative* consists in the admission of a free circulation of air, cold drinks, light clothing, quiet, anodyne draughts, &c. &c., provided sufficient caution is exercised, that the palliative treatment does not occupy too much time, and the patient's chance of life be thereby sacrificed.

Radical Treatment.—Should the palliative means fail in controlling the symptoms, the patient still progressing for the worse, the flooding considerable, treatment of a more determined character must be substituted. The greatest error is likely to arise from carrying the palliative means too far. The radical treatment consists, 1st, in not losing sight of a continuance of the palliative means as to outward circumstances. 2ndly, Dilating the os uteri. 3rdly, Friction over the uterine region, and 4thly, rupturing the membranes and completing the delivery as expeditiously as possible. *With respect to the first position*, in addition to the palliative means already given, cold applications to the uterine region should invariably be applied, to induce uterine contraction, together with horizontal position, or rather the head low, and the hips raised; acidulated drinks are recommended by some, they are not, however, of much service, and only tend to disorder the stomach.

Bleeding has been frequently resorted to; for my own part I never practised it, and should not certainly advise others to do what I consider unsupported by proof as to its efficacy; enough of blood is generally already lost per vaginam, indeed too the lancet cannot be reprobated in terms too strongly in such cases.

Second Position, Dilatation of the Os Uteri.—When this step becomes necessary, it should be effected carefully, gradually, but constantly, and not at intervals as practised by some, under the idea of resting the patient; the object in view when deemed justifiable must be accomplished, and provided no undue severity be used. I cannot do better than recommend steady perseverance until the full amount of dilatation required is produced.

Third Position, Friction over the Uterine Region.—This species of manipulation tends to suppress the hæmorrhage, and assists materially in exciting uterine action, by which the dilatation of the os uteri is more easily accomplished. Simple, however, as this means may appear, the manner of applying friction properly is but little understood. It is not by the friction of the hand upon the parietes abdominis, but by grasping the integuments with the hand and rubbing them upon the uterine tumour beneath.

Fourth Position, Rupture of the Membranes and Completion of the Delivery.—However objectionable this may at first appear, there is no doubt but it is the most valuable and certain means at command for the suppression of hæmorrhage from the uterus. One of the principal arguments against rupturing the membranes is, the difficulty of turning the child. I admit it adds to the difficulties in cases where there is no hæmorrhage, and turning is necessary, or where there is unusual delay in turning after the membranes are ruptured. But where hæmorrhage has previously existed, the same relaxation is present as is produced by venesection in cases of rigidity of the os uteri, in tedious labour. Thus rupturing the membranes in a case of hæmorrhage, is not only proper, but in such cases there are less difficulties to encounter than is generally supposed, in the attempts to turn the child, from the relaxed state of the parts concerned. After rupturing the membranes, no time should be lost in introducing the hand steadily, and the child be delivered as speedily as can be effected, as well as the placenta. When the uterus is clear of its contents it ought to contract and the hæmorrhage ought to cease. The practitioner would ill discharge his duty if (in extracting the placenta he found the uterus not disposed to contract) he withdrew his hand until convinced the uterus had contracted. It is often necessary for the accoucheur to employ his other hand in friction over the uterine region, by which, as well as with the hand introduced, he may judge when the uterus is contracted sufficiently *to be left safely*. A broad bandage should now be applied, the pressure of which should be particularly over the uterus, and if not sufficient without, a thick pad of linen (one or two napkins doubled into four) must be placed over the uterine region under the bandages.

(To be continued.)

Placental Souffle.—There are some cases where this sound is indistinct, or where it cannot be heard at all, though the patient be placed upon her back, with the knees drawn up, nothing covering the abdomen but the shift, no noise in the apartment to interfere with the auscultation, and the instrument be employed in the most proper manner. In some cases the uterine sound could not be heard, when the fœtus could be felt distinctly kicking against the end of the stethoscope. It is necessary, also, to be aware that this sound may be heard in the abdomen of some women who have ovarian cysts and tumours of the uterus, and who are not pregnant. Dr. Montgomery relates a case of large fibrous tumour of the uterus, in which this sound was distinctly heard; and another in which the spleen was supposed to be enlarged, and in which this sound was audible. Dr. Hope has recorded cases of ovarian cysts in which the placental souffle was clearly heard, in the second edition of his work on the diseases of

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

By C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN—We now proceed to the subject of the physical signs of the diseases of the chest and the respiratory organs, and the way in which these become indications of the condition of the organs of respiration. I have given a general outline of the mode of this investigation, and I have now to give by way of comparison, a very short view of the general symptoms, with reference to the relations of direct physical causes to the vital functions. Some of these vital functions we have considered in detail under the head of general pathology. What we are now going to consider belongs to the special pathology of diseases of the organs of respiration.

The first and most important disease connected with the respiratory function is that called dyspnœa, or difficult breathing. It is here applied particularly to obvious difficulty in the performance of the function of breathing felt by the patient, or else obvious in the effects of disease in imperfect respiration on the system generally. As for instance, the patient has a feeling of dyspnœa, or oppression, or some other disturbance in the system in reference to the chest; or else it may not manifest itself in that way, but, in some instances, the disorder is shewn in some other functions of the body: sometimes in a lividity of the face, and a general distension of the veins, or sometimes in a general disorder of the cerebral functions, through which functions the proper act of respiration is interfered with. You have here a table constructed so as to give you some idea of the uncertainty of these symptoms:—

PROXIMATE CAUSES OF DYSPNŒA, OR DIFFICULT BREATHING.

1.—BY IMPEDING THE ACCESS OF PURE AIR TO THE LUNGS.

(a) *Mechanical.*
Rigidity of parts of the respiratory machine . . . Rickets distortion; Ossification of the cartilages; [illegible] of the pleura.
Pressure of ditto . . . Tumour, or dropsy of the abdomen.
Obstruction of the air tubes . . . Effusion in, swelling of, tumour, pressing on, the air tubes; spasm of the glottis, [illegible] the trachea.
Compression of the lungs . . . Effusions, or tumours in the pleural sac: Pleurisy, Hydrothorax, Pneumothorax, Aneurism, &c.
Alterations of the tissues of the lungs . . . Engorgement; Effusion: Œdema, Hepatization, Tubercles, &c.; Altered texture: Emphysema, Dilated bronchi, Vomicæ, &c.

(b) *Mechanical.*
Deficiency of oxygen in the air . . . Mephitic gases [illegible].

(c) *Vital.*
Paralysed parts moved in respiration . . . Pleurisy, pleuritic [illegible].
Paralysis of muscles of ditto . . . [illegible] the [illegible]; Paralysis of the bronchial [illegible]; [illegible].
Weakness of ditto . . . [illegible] fever, &c.
Spasm of ditto . . . [illegible] spasmodic asthma, &c.

2.—BY [illegible] OF BLOOD.

(a) *Mechanical.*
Obstruction to the passage of the blood . . . [illegible].

(b) [illegible]
[illegible] . . . [illegible].
Deficiency of red particles . . . Anæmia.

3.—BY THE VARIOUS RELATIONS OF [illegible].
[illegible] . . . Hysteria, [illegible] fever, [illegible]; Coma, [illegible].
Defective [illegible] . . . [illegible].

You see from this diagram what a vast number of different diseases, not only of the lungs themselves, but of other parts of the body, may result from the disorder of dyspnœa. You see that dyspnœa is thus very indefinite in its indications; that it may arise, not only from all those causes affecting the respiratory apparatus, in all sorts of diseases of the lungs—not only internal diseases of the lungs, —for weakness, for instance, will produce it, by affecting the motions of the chest, or paralysis of the muscles, or spasm from nervous causes. You see it may not only arise from causes affecting specially the organs of respiration, but also from circumstances affecting the circulation, by which a feeling of dyspnœa may be produced without any disorder of the function of respiration, such as an obstruction in the passage of the blood. So likewise we find—and it is a curious fact—that it will sometimes arise from certain conditions of the blood. The feeling of dyspnœa in its most distinctive form is dependent on the condition of the blood, or the blood being in a state not sufficiently purified by the air; and sometimes, it appears, that this condition of the blood may take place totally independent of any disease of the organs of respiration. For example, there may be such a thing as an excessively venous state of the blood. It is this which is exhibited where the blood is circulated with greater force from the heart under the influence of violent exertion. There is here a hurried and disturbed respiration without any disorder of the respiratory organs. The too great liquidity, and a deficiency of the red particles in chlorosis, will produce dyspnœa. Then, again, nervous respiration will be another mode of announcing the existence of dyspnœa; accordingly in hysterical affections, more particularly, people will feel a want of breath more than usually; so that if there is any want of breath, if the quantity of air supplied is not sufficient, then the action of the respiratory organs will be affected, so that the patient is nearly suffocated. This arises from intense sensibility of the nerves of respiration, and there is apparent disorder of the breathing and a feeling of dyspnœa. Sometimes under the influence of this disorder the breath becomes oppressed, and there is a heaving and very slow action without the patient feeling it at all. This is perceived in fevers and affections of the brain, and in nervous symptoms generally. Sometimes chemical causes have the effect in persons of contracted breadth of chest, of causing destruction of the respiratory function altogether, by a deficiency of oxygen. This arises sometimes from heated rooms, and may be more generally the case than we have been in the habit of considering. The breathing is diminished as a natural consequence of the deficiency of oxygen.

Now, although dyspnœa may be so very varied as a symptom, it is by no means a representative of the seriousness of diseases of the chest, as even it may be present when there is no disease of the chest; yet, if it is present, in connection with other signs, it is an important indication, and very often it is a measure of the inroad of disease on other organs. The real value, therefore, of a knowledge of the existence of dyspnœa is this, that having made out by physical signs what disease there is occupying the respiratory organs, the dyspnœa becomes a sign of the amount of disease, or of its increase or diminution. Dyspnœa alone, without a diagnosis of the nature of the disease, is very deficient. It may tell us very much with regard to the other symptoms.

The most intense dyspnœa is that induced by sudden causes, such as spasmodic action, or a swelling of the glottis, or sudden effusion in the bronchial tubes. Under these circumstances a convulsive kind of breathing takes place,—the feeling is overwhelming, and there is an expression in the countenance of great anxiety, almost amounting to despair: whilst the patient is struggling for breath, the eyes become protruded, the nostrils distended, and the posture constrained, as if every muscle and every limb of the body were placed in the best possible attitude for taking in breath, to supply the want of the respiratory organs. Under these circumstances, it is remarkable how the pulse will vary: sometimes it beats very hard and strong, and at other times very weak and irregular, varying with the amount of extra blood, but not at any interval of time. The organs of respiration will be seen working in an irregular manner, and also disturbing the circulation,—not only indirectly, by altering the quality of the blood, and by not altering and arterializing it in the proper way—but likewise mechanically, in the obstruction to the passage of the blood through the lungs. Then another thing important to be noticed is, that the muscles of respiration themselves, when violently exercised, tend to disturb the heart's action in a great degree; and sometimes there will be a strong palpitation, and at other times a weak one. This is the case when dyspnœa proceeds, as it very frequently does, from milder causes. Now, on the other hand, where the dyspnœa is more gradual, the feeling of want of breath is much more acute. The sensibility is, under some circumstances, gradually blunted by the circulation of imperfectly arterialized blood. This I shall have to notice under the head of Asphyxia. Under these circumstances, the dyspnœa is no measure of the amount to which the breathing may be disordered; so, a fatal and insidious disease may go on to destroy the organs of respiration, and cause death, without the patient feeling to a great extent the symptoms of dyspnœa. Even in a degree short of this, a permanent affection, such as that arising from emphysema of the lungs, habituates the system to the imperfect oxidation of the blood. Many persons, with this imperfect action of the lungs, are scarcely conscious of it. Their breathing is always laboured; and if the blood were transferred to any other person, it would be sufficient to induce suffocation; but being habituated to it, they do not feel it. In these cases, persons have a large flow of blood sent over their countenances, which would indicate the approach of death in other persons. The veins, too, are distended in a similar way, particularly those about the neck, and before their entrance into the thorax; and this arises from other causes, not only from the difficulty in the passage of the blood *through* the lungs, but also the difficulty in the passage of the blood *into* the chest. Thus, you have difficulty of breathing, particularly when the expiration is prolonged, as it is in Emphysema. The pressure on the lungs is greater here than it is under other circumstances, and the return of the blood to the chest is impeded; hence you see persons suffering under a great degree of emphysema, with the veins of the neck greatly distended. In fact we see, in this very condition, an illustration of what takes place in dying animals. There is an enlargement of the veins, which admits the accumulation of venous blood during the suspension of the respiratory [illegible]. This is one reason why some animals can remain so long without air. Persons labouring under this disorder may actually be said to be lowered in the scale of creation, like cold-blooded animals; living in a state of degradation, which would have been fatal if it had come on suddenly.

With regard to the treatment of the symptoms of dyspnœa, it is impossible to assimilate practical matters with each step of our pathology, and you can easily understand that it is not easy to prescribe for dyspnœa occurring as a symptom in the various conditions in which it is seen in the diagram I have given. The great object is, when dyspnœa is present, to find out the cause, and prescribe for it in a great degree; but where we cannot readily remove the cause, as in a case of obstruction of the air tubes by a tumour pressing on them, the object is to remove the symptoms for the time. Now, we cannot supply the deficiency of blood, but we may diminish the want of breath, or the want of supply of oxygen or air to the blood. This want of breath is proportioned to the want of oxygen in the system: oxygen is more required where there is more exercise [illegible]. Oxygen is always wanted to keep up the heat of the system, consequently, if a person takes cold, he will feel the want of oxygen still more; this becomes a certain indication,—when a person is struggling for want of breath, and has not the means of supplying it, to keep the surface of the body as warm as possible. Then there are the functions of nutrition and assimilation, and the conversion of the food into nourishing [illegible]. These, we know, depend on the activity of the respiratory process, and these processes cannot go on effectually unless the respiration is complete. We may lower it in some degree—may paralyse it—by the influence of narcotics chiefly. [illegible] will, in some degree, remove the feeling of dyspnœa, and it is quite obvious, that in all cases in which these remedies have this effect, they have it not merely by relaxing the spasm, or diminishing the sensibility, but that they, in some degree, lower the system, producing a state in which the respiration is not required to be so active. Accordingly, if we find these symptoms of difficult breathing quite permanent and not to be removed, sometimes narcotics, such as [illegible] ether, and belladonna, will be applied with advantage. Again, the question arises, is it possible to supply the defective respiration by other [illegible]

nasmuch as very little air is taken into the lungs, wing to the cause of dyspnœa, is it possible to ender this air more pure? I think it not improbable that some means will be found out by and bye, , which this difficulty in breathing will be much decreased; some such means as Dr. Payerne makes use f in the diving bell. At any rate there is one mode which the quantity of oxygen may be increased, nd that is by taking care that the air that is sent the lungs may be as cool as possible. Patients ften call out for cold air, and for the windows to e opened, and the relief given in this way is very ecided; under dyspnœa, you will perceive, it beomes a great object to have the air as cold as posible, because it contains more oxygen and less rbonic acid than warm air does. As to the posbility of supplying oxygen in any way after the ngs have abstracted all that they can, this is a uestion which experience hardly enables us to nswer. It has been recommended to apply oxyenated water, but I think that though this may, some stages of dyspnœa, be productive of some lief, the amount of oxygen conveyed in that way very trifling. It is still quite open to experience, d it is a question whether, by such a method, lorate of potash and other matters, held in sotion, may not be smuggled in. I must advert to e fact, that besides oxygenating the blood, there a simultaneous process required, that of decaronising the blood. It is highly probable that the ver assists in this decarbonising process, and sists in drawing off the carbon from the body; d I have seen, in some cases of dyspnœa, very eat relief derived from a great and sudden disarge of bile, and this, sometimes, under the inence of mercury, which may act in some degree purifying the blood. A feeling of want of eath has been adduced as a test of the want of tivity in the lungs, and it has been said to be proced by a want of power in the chest and the orns of respiration. This may be ascertained by termining how long a person, after taking a full eath, can go without taking another breath; this most effectually done by counting, one, two, ree, and so on, and in a healthy person it may carried on for three quarters of a minute, and a diseased person, not for more than twenty seнds. This depends upon the amount of inspiraon that can be taken by the actual capacity of the spiratory organs.

The next symptom to be adverted to is cough, hich becomes an indication of disease of the spiratory organs only so far as it is connected th the healthy or unhealthy condition of those gans. It may sometimes arise independently of y disease of the respiratory organs. Cough nsists of one or more abrupt and forcible exrations, accompanied by a contraction of the ottis, the trachea, and other tubes. In fact, ugh is intended to effect the process of expectoion, and the discharge of foreign matters acmulated in the air tubes. The proximate cause cough, that which causes the movements of the ugh, is irritation of parts of the air tubes, re particularly the glottis and the trachea. The ttis is the chief seat of sensibility, and it is the itation of that which causes cough. It may be d to be dependent on sensibility, and it must be erred to a class of reflex functions depending on tation, of which the mind is not always conus. A cough may arise from irritation of, or pression on, the incident nerves, without the sitive nerves being conscious of being affected it. Many experiments have been tried to shew t the glottis is the chief seat of irritation proing cough. Scratching the trachea has not n sufficient to produce cough, but immediately glottis was touched a cough ensued. Somees a violent cough will be produced by inflamion of the air tubes, and foreign bodies moving ut from one part to a more sensitive part, cause tation, and a fit of coughing comes on from that se. The same thing takes place in phthysis. It ell known that lying in a particular position cause a sense of tickling, so that the patient not lie in that position without a fit of coughing ing on. It is obvious that the sputa rolling one part to another will fall on a sensitive , so as to excite an act of coughing. The same g takes place in the early stages of bronchitis. Cough is excited in the natural mode by an irritant, causing increased sensibility, particularly in the upper parts of the air tubes. Sometimes the cough arises from an irritation more distant, such as inflammation of the diaphragm on the upper surface. If you ask a patient what is the cause of the cough, he will point to the trachea as the seat of the irritation; but it is reflected from the diaphragm, which is the seat of the irritation, to the spinal marrow: the action is altogether a reflex one. Diseases and foreign matters in the stomach sometimes cause cough.

Now cough, though often connected with diseases of the respiratory organs, sometimes may be produced by diseases of other organs, and are referable to the excito-motor function connected with those organs. But, in spite of all this, it is very important to study cough as a symptom, not only as helping us in some degree to discover the nature of the disease, but because it is an exceedingly troublesome symptom, and one that requires to be relieved in many cases before we can find out what the disease is; and when the disease is found out we sometimes cannot remove it. For this reason it is useful to discover some of the varieties of cough, and to study them. We may analyse a cough, just to understand what the nature of a cough is, although we cannot follow that analysis in the treatment. It arises often from a person swallowing something irritating which goes the wrong way. If it is a weak substance the irritation is slight, but if it is something stronger the irritation is greater. Again, it may vary according to the sensibility of the feeling of irritation. By the term sensibility I wish to include also that function which is impressed sometimes without any feeling—the function of the incident nerves transmitted to the spinal marrow. This reflex action varies in different individuals. It may vary according to the irritability of the muscles excited, and according to the violence of the motions of respiration. You remember that there are two sets of muscles concerned in the act of coughing; not only the external muscles of respiration, but also the muscles of the glottis and the air tubes, the closure of which is necessary to the performance of the act. When the glottis is not closed, and the act of coughing is violent, there is a tendency to vomit instead of to cough; the pressure in that case goes on to the stomach. Cough also depends on the state of the bronchial membrane and its secretion. The most common coughs we have are the hacking coughs, which are slight coughs, in which the different causes we have been mentioning are concerned. In the early stage of bronchitis it is very slight; when the bronchitis goes on, the cough is increased, for in that case the irritation becomes constant from the presence of tubercles in the upper part of the lung, causing an increased sensibility, and the cough is then brought on by exertion, or by heat, which sometimes increases the vascularity of the vessels, and the nervous properties of the parts. Even odours sometimes excite cough. This hacking cough, without any other serious causes than those I have described, is chiefly to be treated by mild diaphoretics. Excessive irritability and mobility of the muscles concerned in coughing may be stated to be another cause of cough varying according to the irritability of the muscles excited. Now this gives rise to what is called convulsive cough, where the muscles of respiration are easily thrown into very violent action. This kind of cough is associated with nervous temperaments, or occurs in persons who exhibit a tendency to convulsive disease. Hooping-cough is of a similar kind, but it is something more. This is to be treated chiefly by remedies which act on the reflex function in operating on the muscles affected by the excito-motor function, such as narcotis, stramonium, and hydrocyanic acid;—sometimes nervous tonics, such as oxide of zinc and carbonate of iron. These are more useful in case of disease of the nervous system connected with the respiratory organs, than merely of the respiratory organs themselves. There is excessive irritability of the bronchial tubes and the glottis: but sometimes the irritation more particularly affects the glottis, or other tubes, during forcible inspiration, and causes the sonorous or back draught, or the hooping-cough—and this occurs chiefly, but not exclusively, in the convulsive cough of children: under these circumstances, the first remedy is more particularly a narcotic, stramonium or belladonna. The affection, here, is not only one of the external muscles, but there is spasm in the bronchial muscles, and those of the glottis, during inspiration, so that they do not relax at the time of the inspiration, and there is violent expiration accompanying, and difficulty in the passage of the air. Then there is the hooping or shrieking cough, not unfrequent in hysterical females; it is one of a very remarkable character, more alarming than serious. This depends on the spasmodic contraction of the glottis during expiration, so that the glottis is kept in a state of vociferous contraction; in such a state, the air passing through it produces a noise—in fact, a voice; indeed, the act of coughing is accompanied by a hooping or a shriek, and in many cases this is exceedingly under the control of the individual, if she choose to exercise her power. The remedies, here, are anti-spasmodic, such as turpentine and assafœtida, and other medicines of that nature. There is another state of the air-tubes, that of extreme relaxation, so that they do not contract; and the cough in these cases is a sort of halloa, with a great difficulty in expectoration. It causes chronic laryngeal diseases, sometimes, in nervous and hysterical subjects, and it occurs with a sort of paralysis of the muscles of the glottis. In nervous and hysterical persons, the best way of remedying the cough is, by particular means, to stimulate the muscles concerned in the affection. Electricity will sometimes cure a severe cough, when there is no particular irritation. Turpentine, in small doses, is particularly useful in this variety of cough.

The character of the bronchial secretion modifies the cough in a very signal way; thus, for instance, we find a dry cough from a want of expectoration, and a moist cough from an excess of expectoration. The cough, being dry, depends on the deficiency of the expectoration, and usually on an inflammatory state of the bronchial tubes, and this may be opposed to the loose or fat cough, called so by the French. Now, these different varieties of cough may become the subject of special treatment; and, therefore, may be treated in various ways, according to the irritation, or the state of the membrane.

One word more, on the subject of cough connected with expectoration. This arises sometimes from bile, as well as from a diseased state of the organs. Expectoration may be evidenced as a morbid act of respiration, or in connection with the matter expectorated. Now, the act of expectoration arises from various sources. The respiratory organs are naturally adapted for expectoration to take place. The trachea and the air-tubes, ramified, may be represented as a cone, the base of which is in the periphery of the lung, and the apex of which is at the glottis, and the division of the tubes are just of that description which favours the occurrence of the cough. The air is flowing upwards as well as downwards, and is very likely to promote the passage of the expectorated matter upwards.

Hippuric Acid in Urine.—To detect the free hippuric acid after the administration of either benzoic or cinnamic acid, it is merely requisite to inspissate a portion of the urine by means of a steam bath, to boil the resulting extract with alcohol *in vacuo*, and allow a little of the clear supernatant liquid to evaporate spontaneously upon a slip of glass. In the course of some hours, characteristic crystals of hippuric acid, namely, quadrangular prisms, with dihedral summits, may be distinguished with the microscope. This agrees with the recent researches of Pelouze, who has shewn that urea may be present along with lactic, or hippuric acid, without entering into chemical combination with either of them; thus, demonstrating the fallacy of all the theories based upon the supposition of the existence of lactate, or hippurate of urea.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

At a meeting of this Society, held March 14th, 1843, Edward Stanley, Esq., F.R.S., President, in the chair, the following papers were read:—

Some Account of an Hysterical Affection of the Vocal Apparatus—by Oscar M. P. Clayton, Esq.

The author prefaced the details of his paper, by drawing attention to the too frequent generalization of the treatment of hysterical affections, which he supposes chiefly to arise from hysterical disease being confounded with diseases occurring in an hysterical diathesis.

The cases, 16 in number, occurred in two groups—the first beginning in February, 1841, accompanied by well-marked progressive symptoms—the second in October last, in which the symptoms were clearly hysterical, and imitative from the first. They occurred in a charitable institution for the maintenance of female children, and those attacked were from 11 to 14 years of age. In February, 1841, seven of the children were attacked as follows:—with a short hacking cough, almost constant; much pain and distress in breathing; no expectoration; pulse quick, hot skin, tongue white, bowels costive. After two or three weeks, during which time these symptoms withstood all remedies applied, the cough changed to sounds varying in the different patients; in some, resembling the double action of a large saw, in another, a shrill screaming expiration, followed a quick, catching, inspiratory effort; in another, the sound was like that produced by blowing into a small, metallic tube—in fact, it is difficult to conceive the dissonance and constancy of these sounds.

Besides these, one girl, aged 14, became affected with symptoms exactly resembling those of laryngitis, and requiring the usual means for their removal, but, after a week or two, the noise above alluded to supervened. In the commencement, sinapisms, blisters, expectorants, and nauseants were tried in various forms; and, subsequently, sedatives, alone, and conjoined with anti-spasmodics, without avail. When the anomalous sounds were established, a combination of hemlock, sulphate of iron, and quinine, was given, as well as full doses of sesqui-oxide of iron; these remedies, however, produced no effect, till the children were separated from one another, when, with the exception of two, who were sent home, the patients slowly recovered. The two who were removed speedily recovered, although all required the long-continued exhibition of mineral tonics, to remove the very considerable debility that remained.

In the second group, commencing in October last, the double sounds—the inspiratory and expiratory—succeeded almost immediately on the hacking cough, and there were some catarrhal symptoms; on the whole, the hysterical character was well marked. A considerable number were now attacked, many of those who had formerly laboured under the same symptoms. Their form became alarming to the neighbourhood. No remedial means—including turpentine, spiritus ammoniæ succinatus, anti-spasmodics, tonics (mineral and vegetable), combined with the regular use of the shower-bath—being, after long continuance, found of any use, the author determined to try the effect of mental influence; and following the example of the celebrated Böerhave, he assembled the children, and informed them that he should, with a red-hot instrument, bore the throats of all who were not well by the following morning. Their fright urged them to escape from the school on the next day, when they ran to their respective homes, and on being collected at the school on the day after, were all found to be well. Two of the elder girls did not escape, and in them the symptoms persisted; and in the others they returned in little more than a week. All other means failing, their throats were blistered with a spatula, heated in boiling water, and covered with a silk handkerchief. This, with some, succeeded—in two others, secluded from the rest, the affection gradually wore out; but two were at last sent to their homes, where, removed from their noisy companions, they soon recovered.

Dr. Mayo observed, that imagination was affected very much by disease; but, as far as the application of it was concerned, it was of little use without some stimulus. Cold effusion he thought efficacious in some such cases as those stated in the paper just read. He thought the better word would be, *sympathy*, and not imagination.

Case of Erectile Tissue in the Popliteal Space, and its Removal—by Robert Liston, Esq., F.R.S., Surgeon to University College Hospital.

The patient was a stout, healthy-looking lad, 10 years of age. He had a tumour on the right ham, of an oval shape, about 3½ inches in its long diameter, unattached to the skin, and unattended with pain. It had a doughy, elastic feel, giving a sensation, when the limb was extended, almost exactly resembling fluctuation, produced by deeply seated matter. When the limb was flaccid, this sensation was less perceptible, and it had more the feel of an elastic, solid tumour, which was moveable, and could be distinctly raised from the bone. The tumour first attracted attention when the patient was about two years of age. In the course of a year it had increased in size, so as to be nearly the size of a turkey's egg. Being punctured at this time, with a grooved needle, no fluid escaped. It slowly increased, without occasioning pain or inconvenience; and, three years ago, a surgeon passed a seton through it, which was withdrawn in a few days, when a discharge had been established. No benefit was gained by this proceeding, or by other means adopted to reduce its size. The operation for its removal was performed on Jan. 6th. An exploring puncture, with a bistoury, was first made into the centre of the tumour; this was followed by a profuse discharge of blood, and the swelling somewhat diminished in size. Its surface was next exposed, by dividing the skin and fascia, and it was soon observed that it had the aspect of a fatty tumour, and was evidently much less in its dimensions than before the commencement of the operation. As the operation was proceeded with, the tumour continued to decrease in size. It was found that the substance of which it was composed was covered by the fibres of the semi-membranosus muscle, and to extirpate it, it was necessary to cut into the muscle. In the course of the operation the tumour had to be followed deeply into the popliteal space, and had to be dissected off from the nerve, and a good deal of blood was lost: only one vessel required ligature. The wound healed favourably, and the boy was able to walk about the ward on the tenth day from the operation. On making a section of the tumour, it was found to consist of a mass about the size of a hen's egg, of most perfect erectile tissue. On a microscopic examination, an appearance was visible like that of the musculi pectinati of the heart; the columns of the reticulated structure being covered with a smooth membrane, resembling that lining the inner surface of veins. A preparation of the tumour was exhibited.

The author adds some observations on the circumstances which were peculiar in this case, directing the attention especially to the difficulties occasioned in the operation, by the tumour being covered on all sides by muscular fibres, and by the diminution which occurred in its size as he proceeded. He closes his remarks by offering the opinion that the tumour was developed in the substance of the muscle with which it was connected. Another case is appended, where the author removed a tumour of a different construction, from the side of the neck; and where he was of opinion that the morbid substance originated in the interior of the sterno-cleido mastoideus muscle.

A drawing of this tumour was shewn.

Mr. Lawrence thought this case was rightly stated, by the author of the paper, to be a rare instance of erectile tissue in the substance of the muscle. He recollected a similar tumour in the deltoid muscle, in a child three years of age. He saw the child after repeated efforts had been made to get rid of the tumour, and he recommended the removal of it. He divided the integuments, expecting [t]o expose the tumour and easily detach it from t[he] muscles; but, when he came to it, it appeared [to] be really a part of the deltoid muscle itself, and [he] could find no termination of it; and on procee[d]ing further, he found the excision of the musc[le] necessary to remove the tumour, which present[ed] a congeries of vascular ramifications. He, how[ever] took it out, and when he had done so the[re] was little to be seen: there was a large quanti[ty] of blood, and nothing else to be observed but [a] mass of enlarged vessels, which, under the ski[n] formed a considerable swelling, but, when expose[d] became reduced to a very small bulk. Nothi[ng] further, remarkable, occurred in this case. T[he] edges of the wound made were brought togeth[er] uniting very well, and the cicatrix was perfect[ly] sound—and the child had continued well up to t[he] present time. He then went on to observe that [he] had met with something of a similar character [in] the course of an operation where he undertook [to] remove a large tumour from the ham of a patie[nt] 40 or 50 years of age. This tumour arose fr[om] the patient sitting on some iron fastening on [a] coach for a considerable time, during a lo[ng] journey. The tumour when he (Mr. Lawrenc[e]) saw it had grown to a considerable size—leec[hes] and lotions, and other things, having failed to r[e]move it; and it was deeply seated in the ha[m], tolerably loose, and moveable. He decided th[at] there was no remedy but an operation to effect [its] extirpation; and, as it was deeply seated, a co[n]siderable excision was required. On making t[he] incision, he failed to discover the boundaries [of] the tumour, which presented a congeries of vei[ns] from which the blood flowed in immense quanti[ties]. Having failed in getting at the boundaries of t[he] tumour, he saw no other course to be adopted [but] that of closing the wound; and he intimated [his] fears that the patient would not recover from t[he] effects of the operation, as he was apprehe[n]sive that an oozing would take place from t[he] wound, which he did not expect would clo[se] effectually. The patient, however, did recov[er], although he had been brought to a very low sta[te] from the extreme loss of blood that had tak[en] place. All alarm subsided, but the wound w[as] not quite healed: an opening took place in [the] part, and ultimately a much larger tumor [oc]curred in the same place, filling up the ham h[igh] up the thigh, and extending downwards to the l[eg], and all the inconveniences of the first tumour [re]curred. In this state of things, he expressed [his] assent to an operation; the tumour, he thoug[ht], must necessarily be fatal if it remained, [but] if it could be removed it might save his li[fe]. The first attempt, however, was very discouragi[ng]. The patient, however, decided upon submitting [to] the operation, and it was performed. He (M[r.] Lawrance) undertook the operation with gr[eat] anxiety: the swelling was very large, and [he] doubted the possibility of cutting it away; ho[w]ever, as the patient had placed his life in his han[ds], he determined to do the best he could. He fou[nd] it necessary to make a very large incision high [up] the thigh, and down into the calf of the leg, [in] spite of which, he found it almost impossible [to] arrive at the boundaries of the swelling. Af[ter] cutting away a considerable portion of the swelli[ng] he at last removed it. Contrary to his expec[ta]tions, the patient recovered, and lived for thr[ee] years afterwards, and might be considered as p[er]fectly cured. The patient died at last from so[me] internal disease.

Mr. Liston mentioned the case of a tumour i[n]volving the popliteal nerve, in which three inch[es] of the nerve was removed, the patient recoveri[ng] with merely the loss of power in the extremities.

Mr. C. Hawkins related a case of a tumo[ur] in the same position, in the removal of which, [he] divided the vein, to which the tumour w[as] attached. The vein was tied, and the tumour r[e]moved without any more trouble: the patient s[uf]fered considerably at the time, but ultimate[ly] recovered.

Mr. Bransby Cooper mentioned the case of [a] tumour operated upon by Mr. Green at [St.] Thomas's Hospital. It was about the size of [a] pullet's egg, and was deeply decussated with t[he] muscle. A large incision was made—the skin a[nd]

fascia were cut through, and the tumour considerably diminished, but it was not removed. The edges of the incision were brought together, and in six years afterwards the tumour remained in *statu quo*. With these tumors that were thoroughly of erectile tissue, communicating with the popliteal nerve, however difficult it might be to remove them entirely, it was yet worthy of consideration, whether some means could not be adopted to reduce them so much in size as to hope for a favorable change.

The discussion was adjourned to the next meeting.

SIR JAMES CLARK ON MEDICAL REFORM.

The worthy baronet has favoured us with a copy of his second letter to Sir James Graham. We shall this week content ourselves with giving a few of the more important passages.

Our first extract will be on *Medical Education*—the matter principally dwelt upon in this letter. After shewing its importance, its necessity, the comparative want of it long exhibited, *peculiarly* by our own country—the writer thus perspicuously exhibits the absolute and relative positions occupied by the general practitioner, the surgeon, and physician, deducing from it a powerful argument for the necessity of interference.

Medical practitioners of all classes are now much better acquainted with the structure and functions of the living body in a state of health, and with the causes and nature of those changes which constitute disease; and they are also possessed of more resources in the treatment of disease, than were their predecessors at the commencement of the present century. The rate of improvement has not, however, been equal in the three classes of medical practitioners. The apothecaries, who had most to learn, have made greater advances in this respect than the physicians and surgeons; generally speaking, they may indeed be said to have risen from a state of comparative ignorance and inferiority, to emulate the latter in professional acquirements and to share with them the confidence of the public.

As a natural consequence of this state of things, a material change has taken place in the duties and relative position of the apothecary and of the other two classes. From being the humble individual whose duty it was implicitly to follow the directions of the physicians, and compound the drugs which he prescribed, the apothecary has gradually risen to be the ordinary medical attendant of the great bulk of the population; and, for the most part, he is now only required to summon the physician to his aid in cases of difficulty or danger. Such, at the present day, is the position of the apothecary, or, as is he now more appropriately styled, the general practitioner. The expectant mother during her pregnancy is under his direction; he conducts her through the often critical period of parturition, and her offspring from the moment of birth is his accustomed charge. Can a medical man have more important or more responsible duties confided to him? Ought any man to be intrusted with such duties who has not brought a well-instructed and disciplined mind to the study of a profession involving such vital interests? And it is the duty of the legislature to take care that no man shall be licensed to undertake these duties without having adduced proofs of being qualified to perform them? These are questions which admit of being answered in one way only. Upon the skill and judgment of the general practitioners depends mainly the health of the community; because they are, as we have seen, the ordinary attendants of the great body of the people, and the diseases of almost all ranks come under their care at their onset—the period be it observed, when disease is much more under the controul of efficient medical treatment than at any other: upon judicious management during the first few days—it may be hours—of an acute disease—depends very often the result of the case.

The relation of the apothecary to the surgeon has been no less altered; and, as a consequence of this, the character of the surgeon's practice has undergone a remarkable change.

Not many years have elapsed (some surgeons now living have, no doubt, witnessed the change) since surgeons of hospitals, and those who have been styled pure surgeons, were alone intrusted with the treatment of surgical diseases, and with the performance of all operations of any consequence. Patients with local disorders requiring operations were brought from great distances to London and other large towns where operating surgeons were only to be found. At present, on the contrary, general practitioners in the smaller towns, and even in villages over the whole country are frequently called on to perform the most important operations in surgery, in cases where the patient must lose his life were immediate assistance not procured. A considerable part of the practice of the surgeons, as well as of the physicians, has thus fallen into the hands of the general practitioner; and the result has been, that the surgeons finding themselves deprived of a large share of what they were accustomed to consider their legitimate right, now undertake the treatment of purely medical as well as surgical diseases; differing in their practice from the general practitioners only in not attending to midwifery, and not supplying their patients with medicines.

From this exposition of the relative position and functions of the three different classes of medical practitioners, it will, I think, be admitted,—First, that the duties of the general practitioner are not the least onerous or important; and, secondly, that the professional duties of the three classes being essentially the same, so ought to be their medical education—up, at least, to that point which is considered sufficient to qualify for general practice.

He now disposes of the objections to the requirement of a good preliminary education, on the quality and quantity of which Sir James thus discourseth:—

It is self-evident that the preliminary instruction of the medical student ought to comprehend at least those branches of literature and science which are absolutely necessary to enable him to understand his professional studies. For this object he requires a certain amount of classical knowledge, in order to read professional books and understand professional terms; he must be familiar with the common rules of arithmetic, and he ought to know something of geometry, to enable him to make the most common calculations or measurements; with the principles of physics or natural philosophy he must be acquainted, to understand some of the most important functions of the living body, and the operation of the various natural agents with which we are constantly surrounded, and which exert an unceasing influence in the preservation of health and the production of disease. In like manner the principles of chemistry are necessary to prepare him for comprehending the more complicated processes of that vital chemistry which is continually in action in the living body. Chemistry has hitherto been considered, but improperly, a part of the medical curriculum. It is no more a branch of medicine than is physics. The student should be well instructed in the principles of both, before he commences his strictly professional studies. In the course of these he will have occasion to resume the study of chemistry in its higher departments—its application to physiology, to pathology, and to therapeutics; but to enable him to do so, a knowledge of the principles of chemistry ought to form part of his elementary education.

The elements of botany should also form part of his preliminary instruction, and more especially the structure and functions of plants, as a preparation for entering on the study of the more complicated anatomy and physiology of animal life. Nor ought he to be ignorant of the other branches of natural history, of meteorology, zoology, and geology. Without some acquaintance with these sciences he could not understand or investigate some of the common causes of disease, or draw up the simplest medico-topographical account of any situation in which he might be placed; he would scarcely be qualified to perform the duties of a medical officer to a poor-law union. In addition to an acquaintance with these branches of natural knowledge, which I deem indispensable, he ought to know something of the Philosophy of Mind, to guide him in reasoning correctly, and exercising his judgment on the subjects and objects presented to his observation during the study and practice of his profession.

Such are the branches of knowledge with which every youth ought to be acquainted previously to his commencing the study of Medicine. Without such preliminary instruction, and the mental discipline which it implies—and which, be it observed, forms an important item in the list—I do not hesitate to affirm that the student can never thoroughly understand medicine as a science or practise it as an art, with satisfaction either to himself, or full benefit to the public. Respecting the amount of acquirements to be exacted in each of the subjects enumerated, there is, no doubt, room for difference of opinion; but I regard the amount as of less consequence, in the first instance. Let the minimum fixed be very moderate, and the natural emulation of students and schools, and the daily increasing facilities for the acquisition of such knowledge will be the means of soon raising the standard of that minimum. It is hardly necessary to observe, that, however, small may be the amount of knowledge required, is ought to be sound as far as it goese not a smattering of the different subjects, but a knowledge of principles, upon which a superstructure may subsequently be reared.

On the present want of education, he says:

In proof of the almost total disregard of preliminary education, the following statement, recently made in a public lecture by Mr. Guthrie, will be admitted as unquestionable evidence:—"I regret to say," observes that gentleman, "that among the students who entered the profession some years back, and are only *now* presenting themselves for examination under the regulations of 1836, there are many who cannot spell very common words in their native language."* Mr. Guthrie has been long on the Council of the Royal College of Surgeons, and, is, therefore, well acquainted with the acquirements of the candidates for the College diploma. What these were before 1836, Mr. Guthrie does not inform us; but such, it seems, is the deplorable state of ignorance of a portion of those permitted at the present day to pass the Royal College of Surgeons of London! Are men so educated worthy of being intrusted with the important duties attaching to the ordinary medical attendants of the community? Is it surprising that quackery and quacks should thrive, when such is the education of the regular practitioner? Natural talents and good sense may compensate, in some measure, for a defective education, and enable men to become good practitioners in a profession where so much depends upon the sagacity and powers of observation of the individual; but it is surely hazarding too much to permit men so ignorant as those described by Mr. Guthrie to undertake the responsible duties of a surgeon. Such a state of things ought not to exist in a civilised country, and would not have existed at the present day, had the institutions intrusted with the regulation of medical education done their duty.

On a grade of medical men, with inferior education, we have the following remaks:—

If, in an evil hour for the character of the medical profession and the progress of medical science in this country, it should be decided to keep a subordinate class of practitioners, required only to have a slender education, and to pass a slight examination—the amount of their education to be regulated, or at least tested, by the very bodies whose object seems to be to keep them in their present degraded position—I hope that a better educated class of general practitioners may also be recognised, and that some encouragement may be held out to induce medical students to prefer the

* Clinical lecture delivered in Westminster Hospital, Oct. 15, 1842.—See *Medical Times*, Oct. 22, 1842.

latter. Let their qualifications be such as to entitle them fairly to the degree of Bachelors of Medicine, and give them the right of becoming members of the corporate body or bodies of the profession, and at no distant period the former class will, I trust, disappear.

But I cannot believe, Sir, after you have been made acquainted with the responsible duties of the general practitioner, that you will recommend, or the legislature sanction, a scheme fraught with such injurious consequences to the profession, and such injustice to the public.

I can easily believe that you are not a little perplexed by the different opinions which you may receive on the education and position of the general practitioner; but there is one test by which you may safely try those opinions, namely, the *minimum* education and the character of the man to whose care you would willingly trust your own family in a serious illness, when you could not call in the aid of the physician.

TO CORRESPONDENTS.

We shall next week give another extra Number, 72 quarto columns, for 4d.! It will be the first of our new volume, and will give the first Lecture of a Course by Professor BRANDE, *of Her Majesty's Mint, F.R.S., L. and E., &c. &c., on the all engrossing subject,* ORGANIC CHEMISTRY.

A Friend.—*The London deaths by typhus in the week ending March* 11 *were* 55, *in the preceding week* 51. *The weekly average during the last five years has been only* 37. *Scarlatina is about the yearly average.*

A. B.—*The election of members of the council is in no particular, deserving notice, changed by the new charter to the Pharmaceutical Society.*

A Constant Reader.—*The omission was the printer's.*

Quack Assassination.—*The following atrocious case is extracted from the Coroner's minutes of evidence, kindly sent to us by Mr. Prankerd, surgeon of Langport, Somerset, a gentleman who deserves our highest thanks for the assistance he has before this, rendered us in unkennelling the unholy brood of men destroyers. Barzillard Card laboured under some taint apparently of syphilitic, or less probably scorbutic disease, which now shewed itself, after an intermission of three years on his thighs and scrotum. A quack doctor, named* Corner, *was consulted, and gave the poor fellow a lotion composed of arsenic and water, in the proportion,* Corner *says, of half an ounce to two quarts, with an order to drink a decoction, made of dock roots, and middle bark of elm. The lotion was applied to the parts abraded by the disease, the poison was taken into the system, and the usual symptoms in such a case followed, viz. restlessness, acute pain, fainting fit, retching, violent vomitings, swellings, fever, delirium, death. When Mr. Tomkins, surgeon, saw the deceased just before his death, the following were the symptoms. "On visiting the deceased I found him in bed, and in a dying state, his thighs swollen, the left particularly so, the scrotum, the abdomen, the face and head were also much swollen. I understood, from some of the family, deceased had been constantly vomiting and purging for some hours. His tongue was very nearly black, and I also understood he had experienced difficulty in swallowing. He was delirious, and incapable of answering any questions wholly, except when roused, his eyes were suffused, and I could not distinguish any pulse at the wrist." The jury found that it was from deceased's* improper *use of the lotion that his death took place! The wretch that did the mischief is therefore at liberty.*

A Constant Reader *sends us eight queries in reference to the quis quid, quomodo, quando, &c., of Dr. Willis, which we have neither the power nor certainly the inclination to answer. As a matter of courtesy, we have ordered a copy of them to be forwarded to the worthy Doctor; and on his views as to the expediency of a notice, our correspondent must depend for an answer.*

Mr. P. O'Brien.—*We have received the note, and forward the journal. The rule with London journals is to be paid in advance.*

Mr. Rudkin *writes to us in confirmation of Dr. Trusen's opinion on Croton oil in remedying hoarseness. He has, however, now a patient, who laboured under laryngeal and tracheal inflammation, on whom the oil was inefficient, and whom he succeeded in relieving by a lotion made of*

applied to the tonsils and posterior part of the pharynx with a camel-hair pencil, night and morning.

A.—*Mr. Wakley is as silent as the poisoned man, on the subject of the inquest. We should be glad to see him publish the true minutes of the evidence.*

We are obliged to decline the communications of J. A.—Argus—Philo-Mercator—A Constant Reader, Bath—A Constant Reader, Finsbury—M. N. H.—Physicus—M. D., Edinburgh. *Others are under consideration.*

THE MEDICAL TIMES.

SATURDAY, MARCH 25, 1843.

Proximorum non incuriosi, longinqua sectamur.

THE medical profession in France is dependent for its present form and government principally on the law of the 19th Ventose, an XI. (10th March, 1803), the law of the 21st Germinal, an XI., with incidental enactments occurring since in laws or ordinances, having generally a wider operation.

The first great maxim in French medical legislation is, that no man shall practice medicine, surgery, or pharmacy, unless he can shew a strict legal title. The divisions we remarked in Germany, exist in less extent, and in greater uniformity, in France. We have Doctors (1) both of Surgery and Medicine—(2) of either—(3) Officiérs de Santé. Mr. Lee, in his useful and elegantly written work on Foreign Medical Institutions, has given so good a summary of the education and standing of these different grades, that we cannot do better than submit it in lieu of as many remarks of our own.

There are in France three Facultés de Medecine, viz. at Paris, Strasbourg, and Montpellier; the two latter being much inferior, as schools, to the former, so that many of those who have there taken their degree, are not satisfied unless they likewise possess a Paris diploma. At most of the large provincial towns there are also secondary schools for medicine, where lectures on the various branches of the science are delivered, as preparatory to those which the students resident in these towns have subsequently to follow when they come to pursue their studies in the metropolis, or at either of the other Faculties. An inferior grade of practitioners, termed officiers de santé, who are restricted to practise in the smaller towns and villages, attend for the most part the courses of instruction at the secondary schools; and after having lived for six years with a Docteur en Chirurgie, or attended hospital practice during five years, they are eligible to undergo the examinations which authorize them to exercise their profession, viz. an examination on anatomy; one on the elements of medicine, and one on surgery and on pharmacy. The whole expense attending these examinations does not exceed two hundred francs. Officiers de santé are prohibited the performance of important operations. No persons, with the above exception, are allowed to practise in France unless they possess a diploma of a doctor of medicine, or doctor of surgery, from one of the faculties.* Candidates for the diploma are required to have studied four years, during which period they have to take out an inscription every three months for attendance on the lectures and hospitals. Members of foreign colleges and universities may, however, present themselves for examination after two years study in Paris. The scholar year begins on the first of November, and terminates on the thirty-first of August. The expense of the course of study required for making a degree does not exceed a thousand francs, (£40).

The following is the prescribed order of study.

First half year—Anatomy, Physiology, Chemistry. Second—Medical Physics, Hygiene, Medical Natural History. Third—Anatomy, Physiology, Operative Surgery. Fourth—Hygiene, Medical Pathology, Pharmacy. Fifth—Operative Surgery, Medical and Surgical Pathology. Sixth—Clinical Medicine, Clinical Surgery, Materia Medica. Seventh—Clinical Medicine, Clinical Surgery, Medical Pathology. Eighth—Medical Jurisprudence, Therapeutics, Obstetricity.

The examinations for the diploma are made publicly, and are five in number. The first takes place after the fourth inscription has been taken out; the second, after the twelfth inscription; the other three take place at the termination of the course of study. An examination lasts two hours; four candidates being questioned at a time by three examiners. Each examiner receives a salary of six thousand francs per annum. The examination fees are likewise divided amongst them—these amount to one hundred and fifty francs for each candidate.

The subjects of the first examination are, Natural History, Physics, Medical Chemistry, Pharmacology. Of the second, Anatomy and Physiology. Third—General Pathology, Medical and Surgical Pathology. Fourth, Medical Jurisprudence, Hygiene, Materia Medica and Therapeutics. Fifth, Clinical Medicine and Surgery, Operative Surgery, and Obstetricity.

For the anatomical examination, the candidate is required to dissect and prepare a part of the body which is indicated to him on the same morning, and to answer the questions proposed to him relative to the preparation. Candidates have also to write and defend a thesis on some points of medicine or surgery. The clinical examinations take place in the clinical hospital at the bedside of patients.

As minor points, it may be added to Mr. Lee's statement, that "the clinical examinations" refer to external or internal lesions, accordingly as the candidate seeks a surgical or medical diploma,—that all medical men, with diplomas received before 1803, are not interfered with in their former privileges by subsequent legislation,—that the *Government* can, by law, empower foreign Surgeons or Physicians, "Graduates of a University," to practice in France,—that the Officiérs de Santé are exempted, both from hospital practice, during the five years, or from attendance on Surgeons' or Physicians' practice six years, on passing three consecutive years at one of the Schools of Medicine,—that they are examined in the chief town of their department, by a jury composed of two resident Doctors, and a President chosen by Government from one of the State Schools of Medicine,—and that they cannot practice out of their own departments.

REGISTRATION.—The Doctor or Officiér is bound, within a month of settling in practice, to present his diploma to the Government officers (the one a *legal*, the other a *state* employé) at the town where he establishes himself: two lists are thence made up once a year by the Commissaries and Prefects—and presented, the one to the "Minister of Justice," the other to the "Minister of the Interior."

* English medical men in France are, however, allowed to practise among their own countrymen.

Persons acting illegally as Doctors, may be fined a thousand francs, and five hundred if falsely pretending to be Officiérs de Santé. An unlicensed midwife subjects herself to a fine of a hundred francs.

In another number we may make known the French law in regard to patent or quack medicines.

Nam deteriores omnes simus licentia.
TERENCE.

We extract the following observations on the autopsy of the late Richard Carlile, from the last number of our able contemporary, the *Carlow Sentinel*:—

The moralist and the Christian cannot entertain any other but feelings of abhorrence and disgust at the fearful prevalence among humanity-mongers and modern philosophers of that morbid sympathy for great criminals whose hands have been either uplifted against the law of the land or against the commands of the Almighty. Hence the lock of hair of such a cut-throat as Courvoiser, is eagerly sought for as a precious relic by some sentimental young lady. There are not a few who now admire the "manly consistency" and the "fortitude" of a miserable "atheist;" and some popularity-hunting anatomical lecturer in London, named Grainger, delivered something between a funeral oration and a lecture "to a crowded audience" over the mortal remains of this "*victim to prejudice!!*" whose opinions are oracularly said to be "deliberately formed," and his "convictions sincere," from such peculiar conformation of the system, and a long dissertation follows on the cerebral development to prove the dogmatical assumptions of the learned lecturer. These exhibitions inflict deep injury on the public morals, without contributing much to the advancement of medical science; and it is to be hoped that such influential and respectable journals as the London *Medical Times* will exert itself to prevent the delivery of those funeral orations over the bodies of such enemies of social order, civilization, and Christianity as the notorious Richard Carlile.

Though, by the special request of the authorities of St. Thomas's Hospital, we were made the channel of publication for Dr. T. Williams's able paper on the physical conformation of the person, so strongly censured by *The Sentinel* we forbore at the time expressing any opinion of our own, as to the conduct of either the donors or recipients of the singular bequest. Our reason was, that, apart from whatever utility science might extract from an anatomical examination of the corpse—*as a corpse*—there was nothing in the death of the individual, or in his character generally, that required, especially from a medical journalist, a moment's public notice. In Mr. Carlile's uncleanly, unwholesome, public displays against not more the religion than the *good taste* of the country—we never saw anything but the characteristics of a semi-madman: and the fact announced by Dr. T. Williams, that the distinct remains of prior disease were found in the substance of his brain—disease evidently, from the statement, of no recent origin—this fact goes far to justify the charity which would consider him to have wanted, at times, a satisfactory controul over his actions. So truly low, therefore, in the world of intellectuality, so much below anything but our fraternal pity as a public character, we cannot—if, thus called on, we may express as brief an opinion as the case warrants—but hold that the bequest of his body was not one of those events which would justify its being anxiously made the means of inviting the greatest possible amount of notoriety to the institution receiving it. While no prudishness on the one hand, blinds us to the meddling absurdity of the well-meaning governors, who thought it necessary to announce, publicly, that the cutting up of the body by their employé, Mr. Grainger, was not to be considered as their assent to their unfortunate legacy's former religious tenets —we must yet feel that no reason can be suggested why Mr. Grainger's promissory note for the autopsy should have been carefully made known to the entire public press; and the whole world, which had hitherto thought Mr. Carlile a very insignificant personage, have been startled by the announcement of the coming *post-mortem* examination as an event of at least regal importance. We wish we could impress scientific men more strongly with the truth, that true science shrinks from vulgar contamination, and if she courts *light*, certainly does not court it through *notoriety*.

EXTRACTS FROM FOREIGN JOURNALS.

(For the Medical Times.)

French.—*Observations on some Diseases peculiar to the Membrana Decidua. By M. Devilliers.*—The following are the conclusions at which M. D. has arrived on this interesting subject:—

The state of congestion, and of inflammation of the uterus, may be propagated to the *membrana decidua* and there determine the effects of inflammation, sanguineous engorgement, effusion of blood, and the formation of matter. The deciduous membrane may not only take part in the various congestions attacking the uterus, but it may also become the seat of diseased conditions, the ordinary result of inflammation. Moderate congestion taking place in a part or the whole of the *membrana decidua* is not always immediately hurtful to the existence of the ovum. It may be merely temporary, and disappear of its own accord, or under the influence of a prompt and vigorous treatment. Sanguineous effusion into the *membrana decidua* is a much more frequent disease, and this frequency seems to depend on the slight resistance presented by the parietes of the adventitious vessels. If the effusion be considerable, it may occupy not only the substance of this membrane and its cavity, but also rupture the other membranes and penetrate into their interior. Hypertrophy of a part of the membranes, which takes place after the death of the fœtus, and which gives rise to the mass denominated a *mole*, may also be considered as a product of disease of the deciduous membrane. Congestion and effusion of the deciduous membrane are most frequent during the early weeks of gestation, a fact which is explained by the close connection which it has, at this period, with the uterus. Finally, diseases of the *membrana decidua* are more common causes of abortion than is generally supposed. We have but carefully to examine the ova, expelled during the early weeks, to be convinced that, very frequently, the chief alterations are effected in this adventitious membrane.

Diabetes Mellitus successfully treated by Animal Regimen and Glutinous Bread.—M. Bonnefous relates the case of a patient affected with this disease, who came under his four months after its first appearance. He then voided daily two pailfuls and a half of urine, containing seventy *grammes* of sugar in 1,000 of the water. He was for two months subjected to the following treatment; a flannel covering was applied next the skin; as much animal food as he could take; and, after a short time, the common bread was substituted by that prepared with gluten, which was given *ad libitum*; some Bordeaux wine was also daily administered. The quantity of urine gradually diminished. The sugar completely disappeared from this liquid, and, in three months and a half, the patient left the hospital, apparently cured.

On Eczema and the Cutaneous Eruptions accompanying Teething.—M. Trousseau treats these obstinate affections, when spread over the body, with great success by means of mercurial baths. The following is the formula which he usually adopts for children; corrosive sublimate, sal ammoniac, of each from two to five *grammes* (half a drachm to a drachm and a half) to be mixed in a sufficient quantity of water to form a bath. In the adult he employs fifteen *grammes* of each. These baths, which exert so beneficial an influence in the treatment of all cutaneous diseases, especially in eczema and the chronic forms of impetigo, produce none of the bad effects attending mercurial absorption, and this, although the baths be administered daily, for one or two months. For the tooth-rash, which most usually shows itself under the form of chronic eczema, ointments made with red precipitate or calomel, in the proportion of one part to ten or fifteen of lard, produce a rapid improvement in the local state, and generally a perfect cure. In that form of milk-blotch attacking the face and hairy scalp, and which usually shows itself in pustules and impetiginous ulcerations, poultices should be applied to remove the crusts, and the hair should be cropped quite close, before applying the mercurial ointment, which must be continued as long as the disease shows itself.

M. Trousseau is, however, far from advocating the immediate cure of all chronic cutaneous affections, or even of all acute diseases of the skin occurring in children or robust individuals. The milk-blotch, for instance, in children often succeeds to a general indisposition, of which it seems to be the cause; it is characterized, either by an erythematous eruption, by eczema, or by impetiginous pustules. We must then, if not favour the original eruption, at least do nothing to check it; but as soon as the fever ceases, or the disease assumes a chronic form, we need no longer hesitate to attack an affection so liable to extend over the surrounding parts. When the cure is nearly complete, he generally applies a blister to the arm, and exhibits an occasional dose of purgative medicine.

Gangrene of the Vaginal Mucous Membrane caused by the administration of Ergot of Rye.—Case.—A female, about 40 years of age, affected with cancer of the neck of the uterus, which had destroyed a large part of this organ, being reduced to the last stage of marasmus by a sero-purulent and sanguineous discharge, was ordered the employment of catechu, combined with ergot of rye, the latter in the dose of one scruple to half a drachm in the twenty-four hours, and injections of carrot-juice, to which was added a little alum. Having used about three drachms of the ergot, she was seized with violent vomitings, and the whole vaginal mucous membrane was discovered to be in a state of gangrene. On holding apart the labia, this membrane was found of a dark slate colour, emitting the characteristic odour. In the course of eight or ten days it separated; but when the patient was getting the better of

this attack, the hæmorrhage recurred as before and proved fatal.—*Gaz. Med.*

M. Amussat in a paper on the *prolonged and graduated taxis, or the reduction of strangulated hernia by the united means of the surgeon and of one or more assistants*, deduces the following conclusions:—1st. The ordinary taxis is insufficient; in many cases, it requires a more sustained and greater force than that of a single operator, because the resistance to be overcome is too great, and the powers of the surgeon are too soon exhausted. 2nd. To act effectually when the operator alone is insufficient, we must associate the aid of one or more assistants, as in luxations, fractures &c, so as to prolong and graduate the taxis suitably and present some chances of success. 3rd. The process which he prefers consists (having first placed the patient upon some resistant body) in embracing the tumour, circumscribing it lengthwise instead of flattening it, and compressing its base perpendicularly to the ring, with two, four, or six hands at the same time. 4th. The results obtained by this proceeding, he states, to be very satisfactory; and he considers them of sufficient weight to induce a change in the established practice, that is to say, that instead of operating speedily as generally advised, we ought to prolong the employment of the taxis in the above method; a plan which he thinks will be attended with great success. 5th. That to be enabled to treat these diseases properly, we must study the surgical and pathological anatomy of the parts, and make ourselves in every way acquainted with the subject.

Artificial formation of a new Urethra.—M. Ricord presented lately to the Academy of Medicine a patient on whom he had performed the above operation, in consequence of the urethral canal having been completely destroyed by a phagedenic chancre, throughout the whole extent of its spongy region. The greater part of the skin of the penis had also been destroyed, and two-thirds of the circumference of the corpora cavernosa, as well as the longitudinal groove marking the course of the urethra, were covered with a thin tissue of cicatrix. The urine escaped below from an opening situated in a deep fold of the skin of the scrotum. To remedy this condition, M. Ricord suggested the formation of a new canal between the corpora cavernosa and the cicatrized tissue surrounding them. For this purpose, he employed a trocar-shaped instrument, somewhat flattened, and terminating in a lancet point. The instrument was first introduced by the meatus urinarius, and towards the middle of the glandular region its point penetrated into the cellular tissue surrounding the corpora cavernosa. In this progress, M. Ricord divided the external fold, until meeting with the gorget previously introduced into the opening through which the urine escaped. The artificial canal thus commencing at the centre of the glandular region was made to rejoin the portion of the urethra corresponding to the scrotum, at the distance of one *centimeter* and a half beyond its external opening. After this operation, which gave no great pain to the patient, a silver canula was introduced in the place of the perforating instrument, and two hours afterwards the urine escaped freely by this new passage. Compresses dipped in cold water were the only dressings applied to the wound. Very little swelling or inflammatory action occurred. The canula was replaced on the fifth day by a gum-elastic catheter, and since the 27th January, the day of the operation, the size of the catheters has been gradually increased so as to give this new canal a suitable diameter.

GERMAN.—*Cæsarean Section, with Recovery of Mother and Child.* By Dr. Ringeno, of Overath.—A woman, aged 30, of small but strong frame, and apparently regularly formed, had been already delivered three times by "perforation." Labour commenced this time on the 12th of August; the waters came away the same evening, pains very weak. In spite of the admonitions of the midwife to call in an accoucheur, the woman, by the advice of a neighbour, endeavoured to expel the child naturally by forcing down with the pains. On the 14th Dr. Klein, of Siegburg, was with the woman at ten o'clock, and, after vain efforts with the forceps, declared that help could only be expected from the cæsarean section. The woman, however, continued to bear down; at mid-day the pains were violent, and she suffered much. Dr. Klein was again present about the next mid-day. She would not hear of the operation. To mitigate the violent pain, Dr Klein gave some doses of tinc. opii., but without relief. According to the woman's account, the violent pains had continued for twenty-four hours; when I arrived about four o'clock P. M. she suffered frightful pains, she screamed for help, and wrung her hands unceasingly. At length, whilst I tried to examine the abdomen with the hand laid flat, her voice suddenly failed, and she could only whisper. The uterus was firmly contracted round the child's body; on touching the left half of the abdomen she appeared to suffer great pain.—*Internal Examination*:—First position of the occiput, the head partly pressed down into the upper aperture of the pelvis, immoveable, even during the pains; the promontorium not to be reached. The woman had not for many hours felt the motion of the child, yet, by means of the stethoscope, the heart beats of the child were clearly perceived; less clearly the placenta-bruit. The strength of the woman was pretty good. I agreed with Dr. Klein, as to the necessity of the cæsarean section, and, with the consent of the woman, performed it in the direction of the linea alba, while Dr. Klein with his hands defended the bowels from accidents, without meeting with any greater impediment than a part of the edge of the placenta falling in the direction of the wound, which was quickly cut through upon the finger. The right arm instantly projected into the wound; I, however, held it back, and not without some trouble extricated with the right hand the fast fixed head of the child, when the whole body immediately followed. The funis was twice wound round the child's neck (a strongly formed female); after taking it away and sprinkling it with cold water, it cried aloud, and moved itself in a living manner. The funis was tied, and the placenta, with the membranes, taken away through the wound. Duration of the operation and the application of bandages, one quarter of an hour. Little hæmorrhage; little pain. The woman was as well as before the operation, the pain of which was not to be compared with the overpowering labour pains, while the section produced only the feel of a light burning. August 16. The abdomen much swollen, painful to the touch; the windings of the inflated colon could be clearly followed by the finger; loud borborygmi, scarcely a trace of fever. By the use of a suppositorium very much flatus passed away, and the entire disappearance of pain. Henceforward all the functions regular, without the least disturbance. Elect. lenitiv. was only once given, on account of costiveness. She suckled her child herself, and her recovery proceeded so rapidly that after four weeks she was able to perform light house-work; after the first four days she sewed some articles she was in want of for the child,—for she had calculated only on having a dead child; some days later she was able to milk her cow and perform other usual labours. At this time she is in good health.

REVIEWS.

A Treatise on the Enlarged Tonsil and Elongated Uvula, in connection with defects of Voice, Speech, and Hearing, &c. &c. By James Yearsley, M.R.C.S. London, 1842.

WE must confess that we came to the examination of the book before us with no great predilection in favour of its author, yet it is but justice to state that the work is not without cleverness, and that it even displays some little novelty of practice. The effects of enlargement of the tonsils and uvula, are truly described in clear and forcible language, and were there not a too frequent and obvious aiming at popular effect, we think the treatise before us would have been of more benefit to the profession than it is ever likely to be. The author has made some just remarks on the *effects* of morbid condition of the throat on the organ of hearing, and glanced at the treatment of tonsilar and uvular enlargements. In the topical and constitutional treatment of these affections there is nothing new. The excision of the enlarged tonsil is also effected in the usual way if we except the modified form of the knife which cannot but be useful. In excising the *uvula*, the author reprobates the practice of removing only a *part* of that body, and justly recommends its *total* removal. This we consider the most important practical enunciation in the book and merits commendation. For obstructions of the nose the author recommends the use of an elastic probe or bougie, and for the removal of mucus from the orifice of the Eustachian tube, as well as for washing and cleansing ulcerations of the throat, an apparatus is recommended consisting of an elastic bag for holding the fluid to be injected and an elastic tube to convey the fluid along the floor of the nostril to the seat of the ailment. We have no doubt that both instruments will occasionally be found useful, but how the elastic probe can act beneficially in dilating *congenital contractions* of the nostril we are at a loss to discover. When the contraction arises from a thickening of the mucous membrane of the passages, dilating instruments will undoubtedly prove useful, but what effect can the introduction of such instruments have upon the bone? Obviously none, and in congenital contraction, the bone is always at fault. We place, therefore, no reliance *whatever* on the following announcement.

"There are cases, however, in which the nostrils and nasal canals are congenitally of small size, where the elastic probe, or any instrument capable of gradually dilating them, will be very beneficial. Of this kind was the case of a nobleman whose nares were so small that the passage of the Eustachian catheter, in Paris, by Deleau, (a very experienced operator,) occasioned much pain, but the careful performance of the same operation in this country, by means of a catheter of small size, which I had made expressly, afforded his lordship considerable relief, as far as the nasal obstruction from which he suffered was concerned."

On Gravel, Calculus, and Gout &c. By H. Bence Jones, M.A., Cantab, &c. &c.

THE failure, for the most part of endeavours, to unravel the proximate causes of disease, and the utter inability of forming satisfactory theories for the action of some of our most valuable remedies, are causes which have tended not a little to humble the pride of the philosopher, and to teach him how limited are his powers of investigation when employed to unravel the secrets of all-mystic life. Of all theories, none are so difficult to establish, or to disprove, as

those connected with medicine, hence the wild doctrines which ever and anon disfigure this beautiful science. Perhaps no set of men have proposed doctrines so wild, so devoid of all the elements necessary to ensure truth, and undertaken in such a spirit of unbecoming arrogance as the chemical pathologists. It will not be forgotten for some little time how cinchona bark was presumed to contain gelatine, because it happened to precipitate infusion of gall nuts, and how gelatine was forthwith introduced as a substitute for cinchona bark, and how many and wonderful were the cures which this gelatine effected in ague! After considering this, and some other parallel cases, it cannot be wondered at that "*chemical practitioners*" are treated with much distrust. Be it so, the circumstance is fortunate for them, and for the world; the chemists have a character to restore, and will restore it.

Of all diseases to which man is heir, those of gout, and calculus, are most strictly chemical, and may be supposed to be capable of alleviation in proportion as the circumstances which regulate their development are more clearly understood. It has long been known that an excess of uric acid in the system was an universal concomitant, and, therefore, the probable cause of gout, and the alkaline treatment of this disease has been vindicated in chemical principles. In no disease has the necessity for dietic measures been more obvious than in gout, although the regulation of this, hitherto, has been a matter of empiricism. From the immense strides which organic chemistry has lately made, we are now in a position to learn by reference to symbols what ingesta are most calculated to produce this uric acid, and the contrary, what measures are most likely to effect its decomposition. All this the author has most elaborately explained. Although he merely professes to elucidate the theories of his friend, and chemical instructor, Liebig, yet the treatise bears evidence of his own thorough knowledge of the subject. Perhaps to the medical public, the book would have been more useful had it been less profusely supplied with formulæ, the general tendency of which is to the effect that insoluble uric aeid is converted by a full quantity of oxygen into carbonic acid, aod urea, by a smaller quantity into oxalic acid and urea, that consequently our object should be to promote oxydation.

Gout, belonging as it does to the uric acid diathesis, occupies a large portion of the author's attention, the oxalic and phosphatic diatheses are also treated of. The presence of the former is also shown to depend upon the action of oxygen in uric acid. "In the oxalic acid diathesis, the oxydising process in the body is carried on a step further than it is when the uric acid diathesis exists, but it is still stopped short of the extent to which it is carried in the state of health."

It is in the oxalic acid diathesis that chemistry throws its greatest light, and prompts us to a mode of successful practice. Now, it is known, that oxalic acid results from the uric, and, therefore, the treatment in both cases should be the same. This has not, hitherto, been the case, for the presumed source of oxalic acid was thought to be decomposing sugar, a substance on which, therefore, an interdict was laid.

Chemistry does not suggest any new treatment in the phosphatic diathesis, but illustrates very satisfactorily the process by which such depositions occur. The two sources of phosphoric acid in the blood, are 1st. from the food, 2nd. from the oxydation of the phosphorus in the tissues. A portion of this phosphoric acid, in combination with lime, and magnesia, finds its way into the urine, where the phosphates are held in solution by free acids always present in healthy urine, when, from any cause, however, those acids are neutralized, or absent, a phosphatic deposition occurs.

The portion of the treatise on calculus is a condensed abstract, and professes to be no more. The whole book is written in a spirit of true philosophy, and we cordially recommend it.

THE PHRENOLOGICAL SOCIETY.

At a meeting of the members of the London Phrenological Society, on Monday evening, Dr. Elliotson, the president of that body, delivered to an audience, consisting principally of ladies, an address on "the plea of insanity." He commenced by referring to the universal disappointment, particularly manifested by the female sex, that M'Naughten, the assassin of Mr. Drummond, was not hanged for the horrible deed he committed. Calm thought, however, impressed us with the conviction that, if he had been hanged, it would have been a deed of cruelty, for M'Naughten being insane, of which there could not be a doubt, was not an accountable being. What was meant by "an insane person?" A person in his senses appreciated, and was expected to act according to, motives, but even here great allowances were to be made. The usages of the nation, to which he belonged, were to be taken into account; the morality, the received code of morality of that nation, presenting good or bad motives, might, or might not, relieve a man of the responsibility of a criminal act. Now, what was meant by saying that an individual was mad? The reply, which he, (Dr. Elliotson) gave, was either that he could not appreciate circumstances, or was completely under a delusion, mistaking things completely without any fault of education, not through accidental habits. This was the view of insanity given by Gall, who considered insanity to be of two kinds, where there was a delusion, such as frequently occurred in states of hypochondriasis, and where persons did things which were wrongfi l in spite of themselves. There were instances of persons who committed murders and robberies, without any motive, but from the force of some irresistible delusion; other persons who fancied they were called upon to do certain things, and that they were to be raised to some high situation; and that they were kings and emperors; and, even, in some cases, to believe that they were the Almighty. In all these cases some feeling or faculty of the mind was diseased. It was important to know that there might be cases of this description without any delusion. Persons acting under delusions, or impulses, knew that these impulses were wrong, and it was often incorrect to say, that a maniac did not know the consequences of certain actions, that they were wrong in law and punishable. There were many cases of persons who had committed murder, and had, beforehand, "hoped, to God, they should not do it," and entreated their friends to bind them down, and restrain them from doing what they felt they would, otherwise, be irresistibly impelled to do. These facts were important to be noticed at the present time, because persons were said to be punishable if they knew that they were doing wrong; nay, that they were acting in opposition to the law. It was an unquestionable a et that many insane persons knew they were doing wrong, but were unable to resist the impulse. He could only account for this apparent anomaly by supposing that there was an exceedingly rapid alternating action of the brain. It was not, he said, true to say, that if a maniac *knew* he had done wrong, or purposed doing wrong, that it was a circumstance rendering him deserving of punishment; he might know all the time that he was doing wrong, and yet be unable to resist it. It often happened that madmen were favoured with talent, and extreme sagacity, on many points. Sometimes it was said that a person could not commit crime from inadequate motives, but it was quite impossible in many cases to discover any motive whatever for the crime of a madmen; the impulse in such a case appeared to come on inevitably, unexpectedly and to overwhelm him. There could be no doubt about ascribing a crime so committed to insanity, many circumstances, blows, and other injuries, producing nervous disturbance, might lead people otherwise sane, to commit insane acts, and, therefore, he could not subscribe to the opinion that if madmen were capable of knowing what they were doing they ought to be punished like sane people. Now the fact was well known that madmen were capable of being influenced by motives as well as other people, and this principle was acted upon in madhouses by a system of encouragements and deprivations. But insane people were only accessible to these influences within a certain range. The conclusion derived from the fact of madmen being thus influenced within confinement, was that they were equally accessible to the influence of the fear of punishment out of confinement, and while there were so many mad people about, the question arose what punishment should be established for their crimes. He thought the same rules should be followed as were adopted in lunatic asylums, where everything was conducted without cruelty, and upon the most benevolent principles. As no madman would be tortured under confinement, so no madman out of confinement should be subjected to corporal punishment. Society had a right to protect itself from the crimes of madmen, and it ought to do it by holding out the same punishments that operated in lunatic asylums. As to the question of hanging, insanity was of such various degrees that it was hardly possible to say whether a person was a lunatic or not. He was opposed to capital punishments in any case, and he conceived there was now a means of getting rid of the difficulty raised of late as to the wisdom of capital punishments, in admitting the plea of insanity, and punishing, sane as well as insane criminals, with confinement tor life. Society in all cases of crime had only the right, with respect to the criminal, which a mother had with regard to her child, that of punishing it by way of correction and example. All our actions were the result of our internal frame, acted on by external circumstances, and, therefore, if an individual under the influence of some morbid disease committed a crime, it was wrong to think ill of him although it was proper to condemn his actions; therefore, punishment ought not to be inflicted with the object of giving the individual pain, but of applying motives to that individual and others to avoid that which was criminal and wrong. The punishment he would substitute for capital punishment would be confinement for life in a lunatic asylum without reserve; it would be hard upon the individual if he ever came to his senses, but society had a right to protect itself by holding out this punishment to others, and also of protecting itself in the event of such an individual turning mad again. Madmen should not only know that if they commit crime they will be confined, but that that confinement will be a real calamity to them. If these principles were acted upon, justice would be done to society, madmen would be considered madmen, and society would be secure.

SOME REMARKS ON MEDICAL LEGISLATION.

By Dr. LICHLENSTADT, in the 'Berlin Medical Gazette.'

We find almost everywhere various grades of medical men, but in this divisional arrangement there is great imperfection. Certainly, every medical man cannot be equally skilled in every branch of his art. If, therefore, in large towns the practice of one branch has for a long time been allowed to medical men, as operative surgeons, accoucheurs, &c., yet every medical man should be familiar with all these branches, and be able to employ them, if he should happen to stand alone and a sudden necessity should arise for such treatment. We cannot allow the separate exercise of any branch if it be not founded upon general medical principles, except in subordinate branches, as dental surgery. A similar exception might be made on good grounds with respect to midwifery. Can physicians allow that those who, on account of imperfect knowledge and principles, have only a circumscribed permission to practise, and who are distinguished by ambiguous names, as—surgeons, country physicians, licentiates, officiers de santé, &c., half doctors, in fact, agree with a pure medical constitution? They are, perhaps, useful in their circles, but they certainly have overstepped their limits. A just government will not take from individuals what has been granted; but it ought not to allow any more opportunities for the formation of half doctors. Russia has long since done what is right in this respect. The striking divisions into physicians, staff physicians, medico-chirurgi, and doctores medicinæ et chirurgiæ have there no influence on practice; for every one of these can follow medicine in its entire compass. Subordinate to all these is the assistant, called feldscheer, who is allowed to act only by their direction. In France the old ridiculous separation of physician and surgeon still obtains, and in the army stands out in fuller prominence. That the medical staff of the army has long been formed peculiarly, and that a less complete plan of instruction subsists for its medical men, is a great defect. Two kinds of physicians, military and civil, of different education and heterogeneous pretensions, have hence arisen, and have encountered each other's practice in fierce hostility. The military physician should have a due position and sufficient remuneration. In those countries where the army is composed of all grades, its medical men ought not to be a separate caste from other physicians. It is to be hoped that the time is not distant, when in all civilized countries the existence of different degrees of education and different modes of examination, in and out of the army, will be only known as a matter of history.

Whether the physician should pursue his studies according to a rigorous plan, or be allowed a free option in the matter, is a difficult question. If we determine for free University studies generally, so must we allow them also to the physician: on the contrary, if all other studies are bound to an entirely fixed course, so must the physician be subject to the same rules. In this, however, the following points ought to be observed.

1st. Young men who possess a University education can alone be permitted an entirely free course of studies. The unriper, the intended physician in knowledge and age, so much the more dangerous is freedom.

2nd. Free studies are suitable only in an Universitas Literarum, where all human knowledge is taught, and where a general zeal is excited for knowledge.

3rd. Moderate capacities will learn much more by prescribed regulations, than by a more free option; these are not worthy of freedom.

4th. With regard to the expression "free studies," unlimited discretion must not be understood; but the absence of compulsion to any determinate period, or to abide by the regular instruction of any determinate teacher; but a moderate compulsion to the physician arises from the peculiarities of his studies. During many other studies, nearly everything may be learned from books, and often without prejudice. The medical student is little benefitted by private study. Few departments of medicine are at present propounded in so abstract a manner, that the student can give a preference to a printed book, unless he is attracted through the beauty or peculiarity of the subject. A further constraint may lie in this,—that every teacher might have a right not to admit any student who is not properly prepared. Before physic, chemistry and botany are studied, no one ought to be allowed to attend any medical lecture. The French regulations to receive the students immediately after the first year of study into the hospital, as "*externes*," must produce a neglect of the preparatory province, and a premature predilection for practice. The great compulsion will be exercised by the *final examination*. Half yearly, and even yearly examinations, are incompatible with free studies, and generally lead to a superficial science, of which at the termination of his academic life the student possesses little more, unless compelled by a final examination in every department. There ought to be an examen philosophicum held, as a trial of initiatory studies (physics, chemistry, natural history, anatomy, and physiology,) after two years; and an examen practicum, which should proceed upon that which is peculiarly *medical*. It ought also to be permitted to the student, if he would choose, to have the first mentioned examination some short time before the second; and it should also be well known to him that at the end of his University life, and before he enters into his chosen calling, he will be subjected to "*an every sided*" examination—an examination that by free study ought to be much more severe than by a constrained course. The misuse of freedom, would thus only be feared in light-minded men.

FOREIGN LIBRARY OF MEDICINE, SURGERY, AND THE COLLATERAL SCIENCES.

[Exclusively compiled for the "Medical Times," from French, Italian, and other Continental Periodicals.]

Andral, G., *Essai d' hematologie pathologique*, 8vo. 4s.——Petit, A., *Memoire sur le traitement de l'alienation mentale*, 8vo. 3s.——Piorry, J. A., *Traite de medicine pratique et de pathologie intrinsique ou medicale, professé a la faculte de medecine de Paris en* 1843. *Tome* 3, *Livns.* 1 & 2. 8vo. 8s.——Gerdy, *Resume des principales recherches d' anatomie, de physiologie, de chirurgie*, 8vo.——Amussat, J. PERISCOPE OF THE WEEK.

Caloric and Thermo-Electricity.—Dr. Knorr, Professor at the University of Kasan, has lately made a discovery which may lead to important results in the study of the nature of caloric and thermo-electricity. He has discovered a method of copying, by means of heat, on silver, copper, and steel plates, not prepared as in the daguerreotype and other existing systems. Some of these thermographs were taken in from eight to fifteen seconds; others, by another process, in from five to ten minutes.

Improved State of Health of the British Navy.—Dr. Wilson in his recently published reports, says—the causes of the improved health of British seamen consist in an almost entire change in the constitution of the service, especially in the following important particulars:—abundance of nutritious food, and of wholesome palatable water; personal and general cleanliness, and comfortable clothing; ventilation, reduced allowance of spirits, and afternoon meal of tea; small monthly payment of money, partly in addition to wages, since the year 1825; regulations and restrictions respecting punishments; provision for mental improvement and recreation; better built ships, with greater capacity between decks; and, it may be added, without reflecting generally on the spirit and practice of former times, at least in so far as the executive was concerned, more judicious and humane treatment generally of seamen.

Bilin.—Bilin forms the chief part of fresh gall, at the expense of which the acids peculiar to gall take their origin, perhaps whilst still in the body of the animal, and certainly very quickly after having been removed. Bilin is a perfectly amorphous body in the pure state, hard, transparent, and colourless, although it is sometimes obtained, in experiments for its preparation, of a yellowish, sometimes of a perfectly yellow colour, produced by colouring matters which cannot be entirely separated. In order to obtain it colourless it is best to employ old gall, as the colouring matters contained therein are already destroyed; but in that case it is difficult to separate it from a salt of soda, which obstinately adheres to it. It is perfectly neutral, of a bitter taste like gall, and afterwards leaves a somewhat sweetish taste, resembling that of Spanish liquorice, or rather that of the bitter sweet substance in the abrus precatorius; this slightly sweetish sensation is chiefly felt afterwards in the throat. It has not any odour; if dissolved in water, and then evaporated by heat, it evolves a smell like boiled glue. It does not deliquesce in the air, but in dry air is soon covered with numerous fine fissures, in consequence of which it loses its transparency. In this state it contains a quantity of water, which it yields up at a temperature of + 140, = 284 deg. F., becoming at the same time a semi-fluid mass, which is inflated by numerous bubbles, and which can be easily ground to a colourless powder: this absorbs gradually the lost water from the air—thus becoming coherent, and forming a transparent shining mass as before. It dissolves in water in all proportions, forming with it either a thick extract, like mass, or a solution at pleasure, which when diluted does not deposit any sediment. It dissolves also in alcohol, either pure or containing water in any proportion; by either, however, it is so very slightly acted upon, that it may be considered as insoluble therein, if the experiment be undertaken with the requisite care.—It is not precipitated by concentrated or diluted acids, not even by tannic acid; but by the strongest acids, with simple radical, sulphuric, phosphoric, nitric and hydrochloric acids, its composition is gradually altered if exposed to the influence of heat,

This occurs to the extent that bilifellinic and bilicholinic acids are deposited from the liquor. Nitric acid produces the same effect; it afterwards destroys the different products, and by evaporating the solution to dryness in the water bath, a porous, clear, swollen mass remains, which easily dissolves in water, leaving behind a brown, resinous, and not bitter substance, which is not acid, and dissolves in boiling water.

Singular Case.—The *Medicinische Zeitung* mentions a case of hydrocele in a man, aged 50. He would not submit to the operation, but he himself repeatedly pushed a pin into the tumour, in consequence of which it gradually disappeared. The writer of the case, Dr. Peters, opines that the pin produced chronic inflammation of the lining of the sac, and thereby reabsorption of the fluid.

A Third Mamma.—There is a woman in Remagen, writes Dr. Oberstadt in a German paper, who has a third mamma, about three fingers' breadth below the left breast; it measures about three inches in diameter, and is provided with its proper nipple, and a peculiar areola. When the woman reached her last month of pregnancy, milk flowed abundantly from it, which continued for about a month after her confinement and then gradually ceased.

The Quantity of Carbonic Acid Gas Exhaled in Respiration.—Messrs. Andral and Gavarret draw the following conclusions from a series of experiments instituted by them, to discover the quantity of carbonic acid gas exhaled from the lungs in man:—1st. The quantity of carbonic acid gas, exhaled in a given time, varies according to the age, sex, and constitution. 2nd. In man, as well as in woman, the quantity is modified according to the age, independently of the weight of the individuals experimented on. 3rd. At all the periods of life, between the age of eight years and extreme old age, man and woman are distinguished by, the difference in the quantity of carbonic acid gas exhaled by their lungs in a given time. All things being otherwise equal, man always gives forth a much more considerable quantity than woman. This difference is especially marked between the ages of sixteen and forty, at which periods man furnishes nearly twice the quantity of carbonic acid gas from the lungs that a woman does. 4th. In man the quantity of carbonic acid gas is constantly increasing from the eighth year to the thirtieth —the increase becoming suddenly very great at the period of puberty; from the thirtieth year the exhalation of carbonic acid gas begins to decrease, the diminution becoming more marked as age advances, so that at the extreme point of life the exhalation of this gas may not be greater than it was at the tenth year. 5th. In woman the exhalation of this gas increases according to the same laws as in man during infancy; but at the period of puberty, at the same time that menstruation appears, this exhalation, contrary to that which happens in man, is suddenly arrested in its increase, and remains stationary (nearly as the amount which it exhaled was in infancy) as long as the menstrual function is duly performed, when it ceases, the exhalation of the gas from the lungs is increased in a remarkable manner, after which it decreases, as in man, in proportion as the woman advances towards extreme old age. 6th. During pregnancy, the exhalation of the gas for the time equals the quantity given forth by woman in which menstruation has ceased. And 7th. in both sexes, and at all ages the quantity of the gas exhaled is greater when the constitution is strong, and the muscular system well developed.

Precautions for Chemical Tests.—Mr. R. Howard submitted to the last meeting of the Pharmaceutical Society a paper on this subject, and after showing that disulphate of quina may be adulterated with sulphate of cinchonine and *many* soluble vegetable substances and defy detection by any one of the usual tests suggested the following as approaching perfection. Put one hundred grains in a Florence flask, with five ounces of distilled water, and heat it over a spirit lamp; when it boils, notice whether complete solution is effected by this quantity of water; if so, your specimen is too soluble, and probably contains either some soluble adulteration, or some impurity, which renders the disulphate itself more soluble. Add two ounces more water (taking care to manage the flame of the lamp so as to avoid loss by evaporation): this quantity *boiling briskly* ought to dissolve the one hundred grains—if more is needed sulphate of lime may be suspected (and recognized by the test of spirit of wine). Now, let it crystallize in the flask, and when quite cold, filter out the crystals, washing out the flask with some of the filtered liquor, to avoid using more water. Put the filter with the crystals upon blotting paper folded many times, to absorb the mother liquor; let them dry in the air till they are quite dry to the touch, but not effloresced. In this state they ought to weigh about ninety grains, the mother liquor and unavoidable waste even of so simple a process, accounting for the rest. If the mother liquor be evaporated to one ounce, a second crop of about six grains may be obtained. The remaining mother liquor ought not, when evaporated to dryness, to yield more than two grains; any soluble impurity will, of course, increase the quantity of residuum. It will be well to try some which you have recrystallized, as a standard experiment, as the results depend in some degree upon the skill of the operator.

Mineral Acids in Dropsy.—Dr. Trusen, of Posen, has found mineral acids of universal benefit in dropsy not dependent on disease of the respiratory organs, or extensive disorganisation of the liver. The principal medicines of this class he employed, were the acid-elixir of Haller and phosphoric acid. The former is useful in dropsies of an adynamic character, those consequent on intermittent fevers, and others due to checks of the perspirations or other secretions. The phosphoric acid is suitable in cases of dropsy owing to an altered condition of the blood, those supervening after diarrhœa, dysentery, chlorosis, &c. The above medicaments, of themselves, generally, insure a free action of the bowels; in some obstinate cases, alcoholic vapour-baths are used to produce a sudorific effect. M. Trusen remarks, that the extensive tumefaction of the scrotum, which presents so marked a tendency to terminate in gangrene, yields, under the use of detergent lotions of vinegar, muriate of ammonia, and water.

Pulmonary Tubercles.—M. E. Boudet, after hundreds of autopsies of all kinds, thinks that between the age of 1 day and 2 years, tubercles exist in the lungs and bronchial glands in 1 of 57 subjects From 2 to 15 years three times in four (33 in 45.) From 15 to 76 years six times in seven (in one hundred and sixteen of one hundred and thirty-five subjects.) During this period of life, six out of seven, i. e., present recent or old tubercles, and their presence may be considered the rule, their absence the exception. The favourable modifications of tubercles of the lungs are 1. *Sequestration.*—The tubercular matter, without being obviously changed in its nature, is isolated from the surrounding parts by means of a mucous, or a fibrous, or a fibro-cartilaginous membrane. 2. *Induration*, i.e., the tubercle is of a dry friable consistence, or it becomes tenacious and dense, though fatty to the touch, or it becomes calcareous. 3. They become *black pulmonary matter.* 4. Are *absorbed.* 5. They are *eliminated* by the bronchiæ. These transformations which sometimes co-exist in the same individual, may be effected during any of the periods of the evolution of tubercles. In one hundred and ninety-seven promiscuous cases, M. Boudet found in ten a cavity completely cicatrised, without any recent tubercle. In eight cases the complete or incomplete cure of one or several morbid cavities coincided with the presence of recent tubercles. Pulmonary cavities cicatrise by the organization of an accidental mucous membrane, or by the formation of a fibro-cartilaginous envelope. Whether the cavities communicate or not with the bronchial tubes, they may remain open.

Iliac Disease.—A labouring man, forty-eight, robust, was attacked with a sudden and violent pain in the abdomen to the right of the umbilicus. The pain persisted, and for several days no evacuation of the bowels took place. Aperient medicines and lavements, now employed, were far from producing any benefit, and the patient soon took to his bed. Agitation and restlessness continual; the tongue furred; pulse small, though regular, abdomen inflated, particularly its gastric region, but painful only at the one point to the right of the navel. Frequent excrementitious eructations, and in twenty-four hours afterwards stercoral matters were vomited. The pain, anxiety, &c., continued to increase, while the pulse fell so as to become almost imperceptible. Dr. Schrobitz, of Gaudenz, first obliged the patient to take a warm bath, and then had him placed on his back, and raised his legs over the shoulders of a strong man. The latter, having grasped his ankles, the rest of the patient's body was supported by two other persons, so as to hang head downwards. The patient was then shaken briskly several times, while the practitioner kneaded the abdomen with both his hands. After about twenty-five minutes incessantly occupied with this kind of manipulation, the patient experienced all at once, in the chief seat of pain, a sensation of something having given way (*le sentiment d'unecessie qui se serait dechiree,*) when the pain immediately and wholly ceased. Warm baths and gentle aperients now insured complete recovery.

Marine Glue.—The new marine glue will be found an excellent cement for joining pieces of glass together, and especially in the making of cells for the reception of microscopic objects, mounted after the method of Mr. Goadby. The glue is prepared in the following manner: Take 4 gallons coal naphtha, in which 1 pound caoutchouc is to be dissolved, by maceration for several days; and with 1 pint of this solution, 2 pounds shellac are to be mixed by heat; and when the fusion is complete, the material is to be poured out on a cold slate, and moulded into convenient forms for use. When cold, it is hard as sealing wax, and is applied by heating the pieces of glass, which, when hot, and covered with the cement, should be pressed closely together.

Potatoe in Scurvy.—In an article published in the *Medical Gazette*, Dr. Baly states that he has found that the efficacy of the potatoe as an anti scorbutic, which was demonstrated by Sir Gilbert Blane, Mr. Smith, and M. Julia Fontanelle, is not essentially impaired by the boiling heat; and that, as ordinarily cooked, it is an admirable preservative against scurvy. He was induced to turn his attention to the subject by noticing that the soldiery confined in the Penitentiary, who had not any potatoes on their diet-table, where subject to scurvy, while the convicts, who were supplied freely with that esculent, escaped its ravages.

After some unimportant changes in their diet, which were without benefit, potatoes were ordered for them on Dr. Baly's suggestion, and soon afterwards the disease finally ceased.

THE URINE.—The peculiar value of the information afforded by an examination of the urine arises, in addition to the readiness there exists for detecting any change, from this fluid being a secreted excretion, and not being, like the alvine evacuations, an excretion made up in great part of the debris and effete portions of the ingesta, and therefore liable to have its indications masked by a series of causes which are nearly without action on the urine. The urine, in a physiological sense, must be regarded as arising from three sources, each of which, however, acts in preserving the equilibrium of the delicately adjusted balance of the several functions of the body. The effects of large aqueous potations in producing a copious discharge of pale urine, at once shews one source of the secretion, and points out one of the great functions of the kidneys, viz. the pumping off any excess of fluid which may enter the circulation. The peculiar character of the urine passed just after the digestion of a meal is complete, partaking often of the physical or chemical characters of some element of the food, indicates a second great function of the kidney, viz. the removing from the system those portions of the ingesta which have been absorbed whilst passing though the small intestines, and thus have entered the circulation, or of excreting from the circulating mass the—often noxious—results of mal-assimilation of the former. The fœtid urine voided after eating a meal of asparagus may be taken as an example; and of the latter, the abundant elimination of oxalic acid from the blood in many forms of irritative dyspepsia will serve as an illustration. The third and very important function performed by the kidney is its serving as an outlet, to evolve from the animal organism those elements of the disorganization of the tissues, which cannot serve any ulterior purpose in the economy, and which cannot be thown off by the skin or lungs. Every moment we live each atom of our frame is undergoing some change or other: the old matter is absorbed, and ultimately thrown off by the excretion, whilst an equivalent quantity of new matter is deposited to supply its place. The old matter absorbed is not thrown off as dead tissue, but its elements become re-arranged; a portion, especially its carbon, has to perform an important secondary office in the economy before it is got rid of, whilst its azotised elements are excreted by the kidney; and this constitutes a third variety of urine in health.

MEDICAL NEWS.

Mr. Cooper, the surgeon, has been elected coroner for Portsmouth, by a majority of eighteen over his competitor, Mr. Newlyn, a solicitor.

Mr. Isaac Flower, surgeon, abandoned the contest for the coronership for Wiltshire, in consequence of a notice from the Poor Law Commissioners that he could not be allowed to hold the county coronership and medical officership of a union at the same time.

A society for reprinting old and publishing new medical works has been formed. Mr. Burroughs, of George Street, Hanover Square, is the secretary.

Mr. Perry, of the Medico-Chirurgical Society, is the new inspector of prisons, vice Dr. Shortt deceased.

Mr. Bouilland has been re-elected a Member of the Chamber of Deputies.

Dr. Kingston has been elected surgeon to the Westminster Hospital by a majority of fourteen. Dr. Basham was strongly opposed by most of the medical officers of the Institution, who charge on him, we know not with what truth, a love of *eavesdropping* sycophancy to the committee.

Mr. Tucker, of Bridport, recently brought an action against the executors of a Mr. Chambers for monies due to him for medicines, surgical operations, and *attendances*. The last item was disputed as contrary to custom. The jury, under the judge's direction, decided that the surgeon might charge for attendances and gave the plaintiff a verdict.

Mr Meymott has been elected surgeon to Surrey County Gaol, Horsemonger Lane, after a hotly contested election by a casting vote of the sessions chairman. Mr. Harris was the other candidate.

FALSE NEWS.—An obscure weekly journal has been recently asserting that the College of Physicians has been admitting into its body, under false colours, a new kind of practitioners, who are marked in contra-distinction to the fellows and licentiates as "*members*." This is neither more nor less than arrant nonsense. The trifling truth on which the falsehood has been raised is, that the College authorities have found it convenient to shew increased liberality, in the admission of old general practitioners into the number of their *licentiates*.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of Gentlemen admitted Members on Friday, March 10, 1843:—

P. Walsh, G. W. Bagg, R. Lee, W. Mitchell, W. B. Francis, J. Arthur, J. Ness, J.O. Goodridge, T. J. Austin, and T. P. Smith.

Admitted, Friday, March 17th, 1843.—P. Hubbert, T. A. Warren, W. Williams, T. Hawkins, P. A. Boyle, J. B. Davis, J. Allan, J. R. Pope, J. T. Jenkins, J. S. Nott, J. H. Coveney.
